sediment by (Soxhlet) solvent extraction. This process can be expedited using an accelerated solvent extractor (ASE) at high temperature and pressure using small solvent volumes for a short duration (e.g., >100 °C, >1,000 psi, 20 min per sample). Organic extracts are typically evaporated under a N₂ stream and then rediluted (e.g., with toluene) and spiked with recovery standards. Each sample is vaporized and injected onto the head of the chromatographic column, which contains a stationary phase adsorbed onto the surface of an inert solid, for example chemically bonded to the inside of a fused silica tube. The sample is transported through the column in its vapor phase by the flow of an inert, gaseous mobile phase such as helium, separated into its components according to volatility under a temperature gradient program. The response of each component is precisely quantified in a detector such as an FID (flame ionization detector). For alkenones, the analytical procedure typically has a reproducibility of better than $\pm 0.005 U_{37}^{K'}$ units, corresponding to a temperature uncertainty of ± 0.2 °C.

High Pressure Liquid Chromatography (HPLC) was developed in the mid-1970s following a variety of older techniques for chemical separations, including open-column chromatography, paper chromatography and thin-layer chromatography, begun by Tswett (1905). HPLC quickly improved with the development of column packing materials and the additional convenience of on-line detectors. It is now routinely employed for the separation, identification and quantification of pigments and sterols. It utilizes a liquid mobile phase to separate the components of a mixture (dissolved in a solvent), which are forced to flow through a chromatographic column under high pressure. The mixture is resolved into its components in the column according to their interaction with the stationary phase (column packing material). As each component emerges from the column, it is carried in the mobile phase to a flow cell in which detection occurs. Typical detectors include fixed/variable wavelength and diode array UV/Visible, and fluorescence detectors. Each component is identified according to its characteristic emission spectrum response.

Summary

Geochemical proxy indicators for environmental reconstruction rely on both organic and inorganic sources. They may reveal the history of temperature, vegetation, wind, aridity, nutrients, ocean circulation, and plankton trophic structure. Analysis of organic matter involves both identification and quantification of its bulk and molecular composition. Complementary information is derived from inorganic proxies reliant upon biogenic/lithogenic and metal/Ca ratios in sediment and skeletal material. Geochemical proxy interpretations may be confounded by post-depositional diagenesis, especially in environments exposed to non-stable temperature, oxidation or biological activity. The lability of geochemical components typically renders them more susceptible to diagenesis. Abundance records are susceptible to systematic bias from preservation effects such as dissolution or water column depth. Ratio proxies may overcome such difficulties, but their link with the primary signal (such as paleoproduction, nutrients or temperature) is typically more tenuous and usually wholly empirical. Although ideally the interpretation of a proxy record relies upon the laws of thermodynamics, most paleoceanographic data are at least partly governed by poorly understood biological processes. Because further biological processes following the production of geochemical markers by organisms can create

additional biases in the sedimentary record, multiple proxy studies are favored to identify the primary signals of interest. A multi-proxy approach, such as combining analysis of alkenones and planktonic Mg/Ca for SST reconstruction, may compensate for post-depositional effects and improve the interpretation of paleoclimates and ancient environments.

GLACIAL ERRATICS

A glacial erratic is a glacially transported clast of non-local provenance. Some erratics are noteworthy because of their large size or exotic bedrock type. Erratics were pivotal to the development of the Ice Age theory, popularized by Louis Agassiz. They continue to be used to determine the limits and flow paths of past glaciers. Erratics have also been useful in mapping ore minerals.

Saussure was the first to use the term erratic (in 1779) for granite boulders overlying limestone in the western Alps (Flint, 1971). Like others, he believed they were transported by water. In 1787, Benard Friederich Kuhn was the first to interpret that they were carried by more extensive glaciers (Imbrie and Imbrie, 1979). James Hutton reached the same conclusion in 1795. Inhabitants of the Alps recognized that they were carried by past glaciers (e.g., Jean-Pierre Perraudin in 1815). Both Ignaz Venetz (from 1816–1829) and Jean de Charpentier (from 1829–1833) further developed this hypothesis after conversations with Perraudin. Jens Esmark in Norway (in 1824) and Reinhard Bernhardt (in 1832) in Germany both noted erratics and argued that they indicated glaciation of northern Europe. Jean de Charpentier introduced Louis Agassiz to erratics in 1836. In 1837, Agassiz presented an expanded version of Charpentier's ideas. Agassiz proposed that a great Ice Age had once gripped Europe. During the next 30 years, Agassiz championed the Ice Age. Upon landing in North America in 1848, Agassiz found erratics there also. Louis Agassiz is buried in Boston's Mount Auburn Cemetery and his grave is marked by an erratic of gray granite.

Glacial erratics are commonly found in till and on end moraines. They may also be found overlying bare bedrock. In alpine glaciers, large erratics can be carried on the surface of the ice onto which they fall during landslides. In ice sheets such as those that covered North America and Europe 20,000 years ago, erratics must have been eroded near their beds and then transported in the ice or on the ice surface. The exact processes by which the very largest erratics become incorporated and transported great distances is not completely understood, but erratic paths indicate that transport may occur in stages during more than one glaciation.

Erratics range in size from pebbles to megaliths of well over 100 tons. Many erratics have clearly traveled more than 500 km, but none appears to have traveled farther than 1,200 km (Flint, 1971). Erratics form boulder fans or erratic trains, which are fan-shaped distributions of boulders downstream from the outcrop of origin. Some of the most famous indicator erratics in northern Europe include the Rapakivi granites and copper of Finland, and the porphyries of Sweden. In North America, some of the most famous include the Alberta erratic trains, the Sioux Quartzite of South Dakota and Minnesota, and native copper from the Lake Superior region. Diamonds are found as erratics in glacial till of the western Great Lakes. A diamond-bearing kimberlite pipe in the Canadian Northwest Territory was discovered by tracking indicator minerals in erratics (Kjarsgaard and Levinson, 2002). In Finland, numerous studies have located ores by mapping and tracing erratic trains.

GLACIAL EUSTASY

Introduction

Glacioeustasy is defined as global sea-level changes resulting from terrestrial ice-volume changes. Sea level is defined as the distance of the sea surface relative to the center of the Earth, which closely coincides with the geoid – a surface of equal potential gravitational energy. A more accurate definition would take into consideration undulations due to continents or mountain ranges, or ocean currents. Two factors control sea level. The first is the volume of water in the ocean, which is largely dependent on glacial eustasy and to a lesser extent on the volume of water in terrestrial aquifers, as well as thermal

expansion and contraction of seawater. The second are changes in the shape and volume of the ocean basin, which is controlled by continental collision, spreading rates of mid-ocean ridges, and the formation of large oceanic igneous provinces. Of these mechanisms, only glacial-eustatic changes are both large (>10 m) and rapid (<<1 Myr).

As sea level either rises or falls eustatically, flooded portions of the crust experience water loading or unloading, so that observed fluctuations in water depth relative to the ocean floor (termed apparent sea-level (ASL) changes; Pekar et al., 2002a) exceed the original eustatic changes by a factor of ~ 1.48 (Kominz and Pekar, 2001). Changes in ASL are solely of eustatic origin, but they differ in amplitude because their reference frame is different. The concept of ASL change also differs from that of water-depth change at passive continental margins and other sedimentary basins, because water depth at such locations is influenced by sediment accumulation and by subsidence unrelated to changes in water loading (Pekar et al., 2003). The concept of relative sea-level change, as widely used in the stratigraphic literature, implicitly includes the effects of sediment loading (e.g., Posamentier et al., 1988). In the literature today, many of the sea-level estimates are not strictly eustatic, in that these estimates include water loading. For example, the sea-level changes observed at small islands in the ocean (e.g., Barbados; Fairbanks, 1989) are ASL changes because the crust that underlies such islands is regionally loaded by water. The ice-volume-related changes in sea level obtained from such locations for calibration against oxygen isotope records need to be multiplied by 0.68 to obtain eustatic changes (Pekar et al., 2003).

Today most of the Earth's ice is stored in the East Antarctica Ice Sheet (26 km³) with lesser volumes in the ice sheets of Greenland (2.7 km³) and West Antarctica (3 km³). Portions of the ice sheet that are below sea level do not contribute to sea-level rise given that they already displace ocean water, as in the example of the West Antarctic Ice Sheet, which mainly resides below sea level. The portion of the East and West Antarctic Ice Sheets above sea level contains the water equivalent of a ~ 66 m sea-level rise. The Greenland Ice Sheet lacks large floating ice shelves and contains the water equivalent of a ~ 7 m sea-level rise. Ice stored by mountain or alpine glaciers (0.2 km³) is minor in comparison and would be equivalent to less than a meter of eustatic change. If the total stored ice volume today were to melt, this would result in a eustatic rise equivalent to ~ 73 m. In contrast, as recent as 20 ka B.P., sea level was ~ 120 m lower than today because of large continental ice sheets in the Northern Hemisphere (e.g., Fairbanks, 1989).

Methods for estimating glacial eustasy

Within historical time scales (10^0 – 10^2 yr), tide gauges have provided estimates of local sea-level changes. Although these sea-level changes at any particular site contain a glacial-eustatic signal, they are also controlled by expansion of sea-surface waters due to global warming and by local crustal movement of the area. The latter is controlled by uplift or subsidence on tectonically active margins (e.g., California), subsidence due to sediment loading, thermal cooling of the crust, and uplift from isostatic adjustments after the retreat of an ice sheet. By examining tide gauges globally and removing local effects, the global mean sea-level rise is estimated to be 1 to 2 mm yr⁻¹ (e.g., Houghton et al., 2001). However, it is uncertain how much of this signal is due to the expansion of water as the oceans warm.

Measuring sea-level changes from Holocene and late Pleistocene records have been accomplished mainly by examining records from shoreline emergent reefs (e.g., Fairbanks and Matthews, 1978; Fairbanks, 1989; Chappell et al., 1996) and salt-water marshes (e.g., Scott and Medillio, 1978; Goodbred et al., 1998). In the case of emergent reefs, the species *Acropora palmata* was used as a sea-level indicator as this coral typically lives on reef crests in 5 m of water or less. Glacial-eustatic changes were estimated by making assumptions of uplift rates of the reef. Sea-level estimates based on salt marsh studies have used benthic foraminiferal and plant zonation to provide sea-level estimates for the Holocene with accuracy to ± 10 cm. Furthermore, modeling of the quantity of ice volume that existed during the Last Glacial Maximum (Peltier, 1998) has provided an additional means to constrain glacial-eustatic change.

For pre-Pliocene times, methods for constraining glacioeustasy have relied on stratigraphic records from passive margins and $\delta^{18}\text{O}$ records from both planktonic and benthic foraminiferal shells (called tests) obtained from deep-sea cores. Although stratigraphic records have been especially useful in constraining pre-Pliocene eustatic changes (e.g., Vail et al., 1977; Haq et al., 1987; Miller et al., 1998; Kominz and Pekar, 2001), a triad of processes controls these records: eustasy, sediment supply, and local tectonics. Evaluation of eustatic changes from stratigraphic records requires estimates of the effects of sediment compaction as well as subsidence due to flexural sediment loading of the margin and thermal contraction of the crust (e.g., Steckler and Watts, 1978; Steckler et al., 1999; Kominz and Pekar, 2001). Various methods have been used to estimate eustatic changes from continental margins. In 1977, the Exxon Production Research Company (EPR) demonstrated the relationship of the stratigraphic record to sea-level change by estimating sea level from calculations of sediment aggradation on passive margins using seismic reflection profiles and core material (Vail et al., 1977; Haq et al., 1987). Nevertheless, controversies have arisen over the specific methodologies used and the proprietary nature of the data (Christie-Blick, 1991; Christie-Blick and Driscoll, 1995). However, non-proprietary studies have verified both the number and timing of many of the sea-level changes identified in the EPR records (e.g., Eberli, 2000; Miller et al., 1996; Pekar and Miller, 1996; Miller et al., 1998), although the amplitudes appear to be overestimated by up to a factor of two for many of them (e.g., Miocene: Miller et al., 1997; Oligocene: Miller et al., 1985; Pekar et al., 2002a; Eocene: Browning et al., 1996; Pekar et al., 2005; Cretaceous: Miller et al., 1999).

Recent studies have modeled the effects of compaction, sediment loading, and crustal cooling in order to isolate a eustatic signal from stratigraphic records (i.e., backstripping). Kominz et al. (1996) provided constraints on Eocene through Miocene times using one-dimensional backstripping. These methods provided quantitative constraints on the subsidence due to compaction, but not on the rates of subsidence due to flexure loading and thermal contraction. More recently, Kominz and Pekar (2001), using two-dimensional flexural backstripping, have provided perhaps the best-constrained estimates of pre-Pliocene sea-level changes (between 34 and 23 Ma), which they attribute mainly to ice-volume changes in Antarctica.

In cases when flexural backstripping is not used, stratigraphers have relied on correlating sequence boundaries (e.g., water depth lowering) to other sites globally as well as to oxygen isotope increases (inferred glacioeustatic lowerings) in order to indicate a eustatic control (e.g., Browning et al., 1996; Pekar and Miller, 1996; Oleg et al., 1999). Oxygen isotopes obtained from

marine carbonates vary as a function of ice-volume changes, as well as the temperature and precipitation/evaporation history (i.e., salinity effect) of the seawater in which the carbonate formed. Thus, glacial-eustatic estimates derived from $\delta^{18}\text{O}$ records (e.g., Miller et al., 1985, 1991, 1998; Abreu and Anderson, 1998) require an evaluation of the temperature signal and the “salinity effect”. Studies using coupled Mg/Ca ratios and $\delta^{18}\text{O}$ measurements have begun to provide estimates of bottom-water temperature for the Quaternary (Martin et al., 2002), which have permitted evaluation of the $\delta^{18}\text{O}$ of the seawater and thus placed constraints on ice volume. This technique has been extended through most of the Cenozoic, with limited application in older records due to diagenesis affecting the original seawater value of the calcite (e.g., Lear et al., 2000; Martin et al., 2002; Billups et al., 2002). Although questions have been raised about possible oceanic Mg/Ca ratio changes through time (Billups and Schrag, 2003) and isotopic species offset, bottom-water temperature estimates have begun to allow the isotopic proxy for continental ice volume to be evaluated for these older times. Finally, direct evidence of ice sheet extent, such as ice rafted debris (IRD), has demonstrated the presence of continental ice sheets beginning no later than the base of the Oligocene (Breza and Wise, 1992). However, IRD provide evidence for existence of an ice sheet only when glaciers reach the coastline.

History of glacial eustasy

Holocene and Pleistocene glacial-eustatic changes

During the past 18,000 years, the collapse of large ice sheets in the Northern Hemisphere as well as ice volume reductions in Antarctica have resulted in a sea-level rise of about 120 m (e.g., Fairbanks, 1989). The decay of the ice sheets occurred in several steps, with two meltwater pulses occurring at ~ 12 ka and ~ 9.5 ka, and rates of sea-level rise ranging from 24 to 28 meters per 1,000 years (Fairbanks, 1989). With the final demise of the Northern Hemisphere ice sheet around 8 ka B.P., the rate of sea-level rise has slowed continuously since about 8 ka (Peltier, 1999), with the current eustatic rise due to ice melting estimated at ~ 1 mm yr^{-1} .

The late Pleistocene contains the largest glacial-eustatic changes of the past 200 Ma with a number of amplitudes >100 m. In $\delta^{18}\text{O}$ records, these glacial cycles have followed a sawtooth shape for the past 800 ka with a periodicity in phase with the eccentricity cycle (the “100-kyr cycle”) of Milankovitch (Shackleton and Opdyke, 1973). Beyond ~ 800 ka, $\delta^{18}\text{O}$ records indicate that the obliquity cycle (41-kyr cycle) dominated the record through the Pliocene, coupled with smaller glacial-eustatic amplitudes. Large scale Northern Hemisphere glaciation was initiated at approximately 2.4 Ma (Raymo et al., 1989), as evidenced by $\delta^{18}\text{O}$ excursions concomitant with the occurrence of IRD in the North Atlantic, providing unequivocal evidence for proximal continental ice sheets (Shackleton et al., 1984). Between 2.4 and 2.7 Ma, evidence for glacial-eustatic changes less than half those of the late Pleistocene are implied by $\delta^{18}\text{O}$ values (Raymo et al., 1989; Jansen et al., 1990; Raymo, 1994), which are thought to have originated from Antarctic and limited Northern Hemisphere ice growth. An early Pliocene warming has been suggested to have resulted in at least a partial collapse of the Antarctic Ice Sheet (Raymo et al., 1989; Hearty et al., 1999). Eustatic estimates also indicate that sea level was up to 40 m higher, supporting the notion of a significant deglaciation (Haq et al., 1987; Dowsett and Cronin, 1990). However, this is still controversial, with further studies required (Denton et al., 1984).

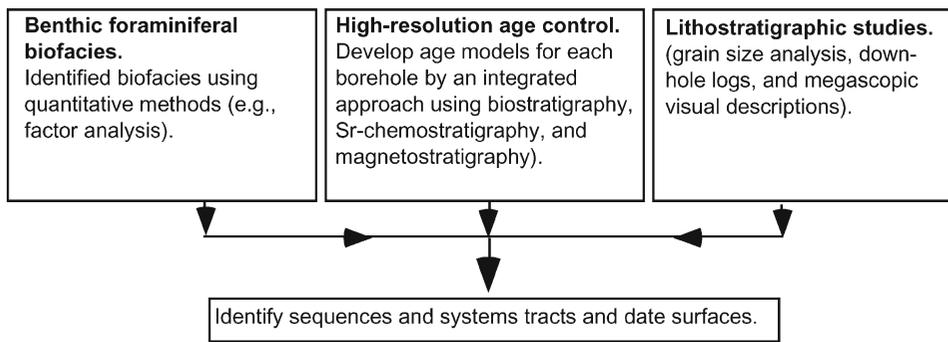

Pre-Pliocene glacial-eustatic changes

Unlike Pleistocene glacial-eustatic changes that were the result of both Northern and Southern Hemisphere ice sheets, pre-Pliocene glacial eustasy is mainly the result of ice-volume changes in Antarctica. Most of our understanding of glacial-eustatic changes for the Tertiary comes from the Ocean Drilling Program drilling of shallow marine strata (Bahamas, Eberli, 2000; Miller et al., 1996; Miller et al., 1998) and deep-sea $\delta^{18}\text{O}$ records (e.g., Miller et al., 1987; Miller et al., 1991; Zachos et al., 2001). Miller et al. (1991) noted that covariance between subtropical planktonic and benthic foraminiferal $\delta^{18}\text{O}$ records plus large $\delta^{18}\text{O}$ amplitudes ($<0.5\%$) with high $\delta^{18}\text{O}$ values ($<2\%$) in benthic $\delta^{18}\text{O}$ records from the Miocene and Oligocene implied the growth of ice sheets. Subsequent stratigraphic studies showed that sequence boundary development and $\delta^{18}\text{O}$ events correlate well, indicating a global mechanism (e.g., Eberli et al., 2000; Miller et al., 1996; Pekar and Miller, 1996; Miller et al., 1998). Furthermore, estimates of eustatic amplitudes used paired Mg/Ca ratios and $\delta^{18}\text{O}$ ratios to place constraints on ice-volume changes and thus glacial-eustatic changes for the past 50 Ma (Lear et al., 2000; Billups et al., 2002; Pekar et al., 2002b). Results from stratigraphic records (Miller et al., 1998) indicate that glacial-eustatic changes ranged up to perhaps 40 m ASL during the early Miocene (21–16 Ma). In contrast, using calibrated $\delta^{18}\text{O}$ records, estimates of ice volume ranged from 125% to $\sim 25\%$ of the present-day Antarctic Ice Sheet during glacial maxima and glacial minima, respectively (Pekar and DeConto, 2006).

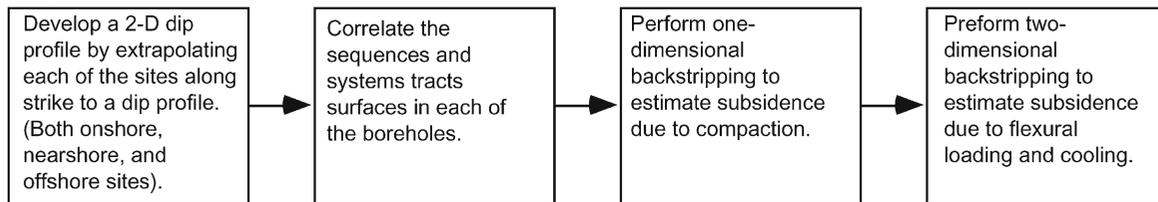

The Oligocene is considered the start of the Icehouse World of the Cenozoic (Miller et al., 1991) and contains perhaps the best estimates of sea level for a pre-Pliocene time. Kominz and Pekar (2001) and Pekar and Kominz (2001) estimated glacial-eustatic changes for the period between 23 and 34 Ma by combining two-dimensional flexural backstripping with two-dimensional paleoslope modeling of foraminiferal biofacies and lithofacies of the New Jersey Coastal Plain (Figure G16). Results indicate ASL amplitudes ranging from 20 ± 10 to 80 ± 20 m, with the largest sea-level change occurring during the earliest Oligocene (33.5 Ma). The size of this change implies that the Antarctic Ice Sheet was small or absent at the end of the Eocene, but grew rapidly (<100 kyr; Zachos et al., 1996) to nearly the present size of the East Antarctic Ice Sheet, or perhaps up to 30% larger (Kominz and Pekar, 2001; Lear et al., 2004; Coxall et al., 2005; Pekar and Christie-Blick, 2007) (Figure G17).

The late Oligocene Epoch has presented a climatic conundrum because of low $\delta^{18}\text{O}$ values from deep-sea records, which suggest bottom water warming, coupled with at least partial collapse of the Antarctic Ice Sheet. However, Antarctic drilling results (e.g., Cape Roberts Project), indicate that East Antarctica was heavily glaciated during the late Oligocene (Naish et al., 2001; Roberts et al., 2003). Additionally, high $\delta^{18}\text{O}$ values from Weddell Sea Sites 689 and 690 (2.9 and 3.3‰) are consistent with a fully-glaciated East Antarctic Continent (EAC) and cold bottom water temperatures (2.0–2.5 °C) (Pekar et al., 2005a). This paradox can be explained by spatial restriction of deep waters produced near the Antarctic Continent (proto-AABW), coupled with the presence of a large ice sheet covering most of East Antarctica. Bottom waters elsewhere may have been influenced by a combination of proto-AABW and warmer, more saline deep waters (Pekar et al., 2006). Glacial-eustatic estimates at higher frequency timescales during the Oligocene have been developed by calibrating amplitudes

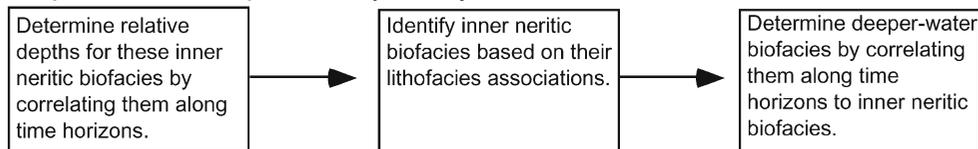

Step 1. Develop a sequence and chronostratigraphic framework by integrating:

Step 2. Reconstruct the original depositional stratal geometry of the margin.

Step 3. Determine paleobathymetry for each of the benthic foraminiferal biofacies.

Step 4. Determine the apparent sea-level and eustatic change.

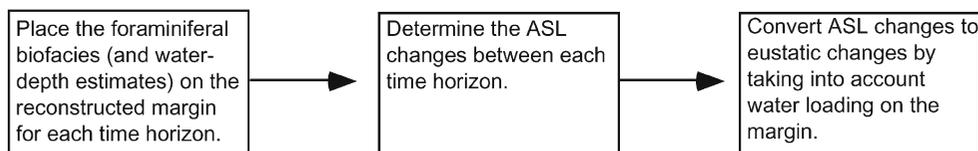

Figure G16 Flow chart showing method for determining paleobathymetric estimates for benthic foraminiferal biofacies, apparent sea-level, and eustatic changes using two-dimensional paleoslope modeling and two-dimensional flexural backstripping.

of $\delta^{18}\text{O}$ events (Oi-events, Miller et al., 1991; Pekar and Miller, 1996) to sea-level estimates (Pekar et al., 2002a) and then applying them to high-resolution $\delta^{18}\text{O}$ records (Pekar et al., 2006). At 100- to 400-kyr timescales (corresponding to orbital eccentricity cycles) glacial-eustatic changes ranged between 20 and 35 m, and at the 40-kyr timescales (obliquity cycle), 20–30 m eustatic changes were inferred.

Recent studies indicate that during the late middle to late Eocene (42–34 Ma) there were at least episodically significant ice sheets in Antarctica (Browning et al., 1996; Miller et al., 1998). Sequence boundaries, interpreted to represent sea-level changes and dated between 42–34 Ma, were correlated with $\delta^{18}\text{O}$ increases identified in deep-sea records, indicating a global causal mechanism, such as glacial eustasy (Browning et al., 1996; Miller et al., 1998).

The early to middle Eocene (55–42 Ma) has been dubbed the “doubt house” world. Although Browning et al. (1996)

determined that late Middle to late Eocene (<42 Ma) sequence boundaries in New Jersey were controlled by glacioeustasy, they concluded that it was unlikely that early to early-middle Eocene sequence boundaries were the result of ice-volume changes. Subsequently, Miller et al. (1998) concluded that there were hints of glacioeustasy operating during the early to early-middle Eocene. Pekar et al. (2005) identified seven sequence boundaries of late early to Middle Eocene age (51–42 Ma) in core material from ODP Leg 189 Site 1171 (South Tasman Rise). These sequence boundaries correlate well with deep-sea $\delta^{18}\text{O}$ increases and sequence boundaries identified from other margins. The synchronous nature of sequence boundary development from globally distal sites together with $\delta^{18}\text{O}$ increases suggests a global control. The only mechanism that can explain these significant and rapid changes is glacial eustasy, indicating that large ice sheets existed in this supposedly ice-free world. Modeling studies and atmospheric $p\text{CO}_2$

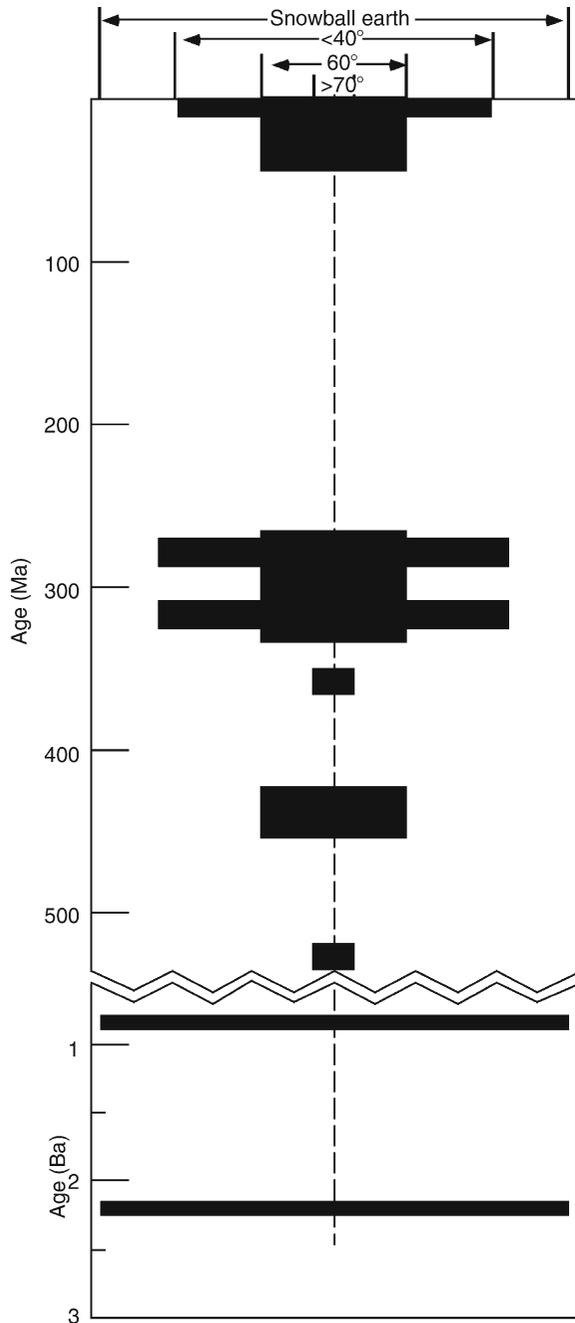

Figure G17 The paleolatitudinal distribution of glacial evidence during geological time (adapted from Crowley and Burke, 1998).

estimates show that the first time $p\text{CO}_2$ levels decreased below a threshold that could support the development of an Antarctic Ice Sheet occurred at ~ 51 Ma (Pearson and Palmer, 2000; DeConto and Pollard, 2003). Sea-level amplitudes estimated from $\delta^{18}\text{O}$ records ranged from ~ 20 m for the early Eocene (51–49 Ma) and ~ 25 m to ~ 45 m for the middle Eocene (48–42 Ma) (Pekar et al., 2005).

The glacial-eustatic record for the Paleocene remains cryptic. Oxygen isotope values during this time were relatively

low ($\sim 1.0\%$), although these values are similar to those of the middle Eocene. Additionally, stratigraphic studies have identified sequence boundaries that may be due to ice volume changes (Haq et al., 1987; Liu et al., 1997). Thus, it is reasonable to infer that small (< 25 m), ephemeral ice sheets may have existed during this time.

The Mesozoic era

The Mesozoic was a time of generally warm equable climates that extended to high latitudes, thus the existence of significant ice sheets was unlikely. Yet, rapid and large sea-level changes, recognized in stratigraphic records, present a conundrum in this supposedly ice-free world (Haq et al., 1987; Hallam, 1992). These greenhouse sequences can be explained as follows: (a) they are locally controlled (e.g., delta lobe switching, local tectonics); (b) they formed from low amplitude sea-level changes (sea-level changes of up to 10 m on a million-year timescale can be caused by a number of mechanisms such as thermal expansion or contraction of ocean water); (c) in as much as the mechanisms of large rapid sea-level changes are poorly understood, there could have been significant ice sheets during so-called greenhouse worlds (Miller et al., 2004).

Recent stratigraphic studies from a number of sites around the world (New Jersey: Miller et al., 2004; NW European sections: Hancock, 1993; and Russian sections: Sahagian et al., 1996) have lent credence to the idea that significant ice sheets existed at least intermittently during the Cretaceous, by identifying and dating large and rapid sea-level changes. The good correlation between the timing of these sea-level changes and increases observed in oxygen isotope records supports this hypothesis (Miller et al., 2004). The paradox of high-latitude warmth during the Cretaceous together with significant ice volume can be resolved if one assumes ephemeral, areally limited ice sheet development in Antarctica. The estimated size of ice sheets would have been restricted to the interior of the Antarctic Continent. Thus coastal waters around Antarctica could have remained relatively warm, while at the same time, ice sheets equivalent to ~ 10 – 40 m of sea-level change could have grown and decayed (Miller et al., 2004).

Evidence for extensive glacial-eustatic changes for the remainder of the Mesozoic era remains largely uncertain. This period of rising sea level during the fragmentation of the super-continent Pangaea was associated with generally warm and equable climates and was largely ice free. A number of studies suggest numerous rapid sea-level changes during the lower Cretaceous down through the base of the Triassic (Haq et al., 1987; Hallam, 1992). Nevertheless, it is uncertain whether these were due to tectono-eustasy or local changes in sedimentation or tectonics.

The Paleozoic era

Large-scale waxing and waning of ice sheets in the southern super-continent Gondwanaland occurred episodically throughout the Paleozoic (Figure G17). Glacial-eustatic changes during the late Paleozoic have been ascribed to at least three glacial periods in Gondwanaland (e.g., Isbell et al., 2003). The late Carboniferous and early Permian contain perhaps the best evidence for large (> 30 m) glacial-eustatic events. This includes glaciogenic sediments in Gondwanaland and transgressive/regressive cycles observed mainly in North America and Europe. Stratigraphic evidence indicates large eustatic amplitudes ranging from ~ 60 – 70 m (Moore, 1964; Adlis et al., 1988; Crowley and Baum,

1991) to ~100 m (Smith and Read, 2000; Heckel, 1994) and as high as 200 m (Soreghan and Giles, 1999; Ross and Ross, 1987). Cyclothem deposits (transgressive/regressive sedimentary packages) characterize Carboniferous to lower Permian strata in both North America and Europe and have been ascribed to glacial-eustatic changes. The deposits display a cyclicity between 44 and 412 kyr, which falls within the range of Milankovitch orbital cycles (Isbell et al., 2003; Imbrie, 1985). In contrast, smaller eustatic amplitudes have been suggested based on the aerial extent of Gondwanaland glaciogenic sediments of no more than 50 m (Isbell et al., 2003). Two other glacial events (late Devonian and late Mississippian to early Pennsylvanian) were probably smaller in extent and consequently resulted in smaller glacial-eustatic changes. Cyclothem and longer timescale sea-level changes have been correlated between stratigraphic sections in North America and Europe, indicating a global mechanism. The lower Paleozoic records contain evidence for glacial events in Gondwanaland and glacial-eustatic sea-level changes in the stratigraphic record. One of the largest Paleozoic glaciations occurred during a two million year span (437–435 Ma) in the late Ordovician, as northern Africa drifted over the South Pole (e.g., Berry et al., 1995). Glaciogenic sediments typical of large continental ice sheets have been identified in Saharan Africa and Saudi Arabia (e.g., Vaslet, 1990). Geological data suggest that southern ice sheets may have reached paleolatitudes near 50° S (Brenchley and Newell, 1984).

Snowball earth episodes in the proterozoic

The largest glacial events in Earth's history occurred during the early Proterozoic (~2.3 Ga) and Neo-Proterozoic (~0.7 Ga) when cold glacial conditions extended into the tropics. Ice-volume extent and subsequent glacial-eustatic amplitudes are uncertain during the Neo-Proterozoic, with estimates ranging from 160 m, inferred from stratigraphic records of an incised valley, to perhaps several times that of the Pleistocene glaciation (Hyde et al., 2000). A debate continues over the extent of the sea ice and whether the Earth did indeed become a true "snowball" or whether it remained a "slush ball", with the tropics remaining mainly ice-free (Hoffman et al., 1998; Christie-Blick et al., 1999). In both glacial periods, decreases in greenhouse gases are thought to have been a primary mechanism for the initiation of these colder periods. It has also been speculated that the Earth's tilt may have been higher (>54°) during these periods, which could have resulted in low latitude glaciation without the entire Earth experiencing glacial conditions (Jenkins, 2003).

GLACIAL GEOMORPHOLOGY

Glacial geomorphology is the scientific study of the processes, landscapes, and landforms produced by ice sheets, valley glaciers, and other ice masses on the surface of the Earth. These processes include understanding how ice masses move, and how glacial ice erodes, transports, and deposits sediment. Landscapes and landforms that developed as a result of glaciation are the dominant focus of this field since they carry distinctive features and forms related specifically to glacial processes. Likewise, glacial geomorphology encompasses the impacts of glaciation upon floral and faunal evolution, modification, and distribution; and includes study of those areas peripheral to glaciated terrains, where drainage pattern alteration, climate, vegetation, and soil conditions are all severely affected by glaciation. This field

includes studies of the causes of glaciation, the chronology of glaciation through geologic time (the retreat and advance of ice masses), glacial sediment stratigraphy, and the global impact of glaciations on oceans, climate, flora, fauna, and human society (Mickelson & Attig, 1999; Bennett & Glasser, 1996; Benn & Evans, 1998; Menzies, 2002). Closely allied to glacial geomorphology are studies into the physics of ice masses (glaciology), global climatology (paleoclimatology), and paleoenvironmental reconstructions (paleoecology). It is generally accepted that glacial geomorphology has become synonymous with glacial geology.

In every geological period, other than the Jurassic, there appears to have been at least one, if not several, global glaciations. Earth is a “glacial planet” where ice masses have covered at least 30–60% of the Earth’s surface (continents and ocean basins) approximately every 100,000–150,000 years over the past 800,000 years. Glacial sediments, both lithified and unlithified, are found on every continent, and the present oceanic basins of the Earth are covered by great thicknesses of glaciomarine sediments. At the maximum of the last Pleistocene glaciation, sea levels were at least 120 m below the present sea level, permitting temporary land bridges in the immediate postglacial period to appear between Siberia and Alaska, South Asia and the Indonesian Archipelago, and between continental Europe and the British Isles. Such land bridges acted as corridors through which flora, fauna, and humans colonized North America, northwestern Europe, and parts of Australasia.

The impact of glacial geomorphology upon human society is immense especially in the mid-latitudes and poleward in both North and South Hemispheres. Soils and construction engineering are, for example, affected by glacial sediments and glaciated terrains. Cities such as Boston, Massachusetts and Glasgow, Scotland have been built on drumlin fields such that urban planning and transportation systems must adapt to this “peculiar” hummocky topography. The siting of dams, the intricacies of groundwater pathways, and the location and discovery of minerals are tied to glaciations and problems in glaciated terrains. The impact of glaciation is enormous in the continental USA where at least 60% of the population live and work in areas once covered by the last glaciation (the Wisconsinan). Likewise, in Canada, a comparative figure would be closer to 99% of the Canadian population, and in Western Europe at least 50–60% of the population inhabit formerly glaciated terrain.

Extent of glaciation at present and in the past

Today approximately 10% of the Earth’s surface is covered by ice masses. The two largest ice masses are the Greenland, and the West and East Antarctic Ice Sheets. The remaining ice masses are various mountain valley, cirque, hanging, and piedmont glaciers, small ice caps and fields, and ice shelves attached to the fringes of the Antarctic and the Canadian Arctic Archipelago (Figure G18a). Present ice sheet thickness varies from around 2,500 m in central Greenland to over 4,600 m in Antarctica. Valley glaciers and smaller ice masses are considerably thinner. During the maximum extent of the last glaciation in North America, the thickness of the Laurentide Ice Sheet over Hudson Bay would have been similar to that of Antarctic today (Mickelson & Attig, 1999).

The extent of glaciation during the Pleistocene may have covered at least 30% of the continents. If the oceanic basins in the Arctic, north Pacific, north Atlantic, and Southern Oceans are included, then over 60% of the Earth’s surface would have been ice-bound (Figure G18b). Similar percentages of ice cover may have occurred in earlier geological times.

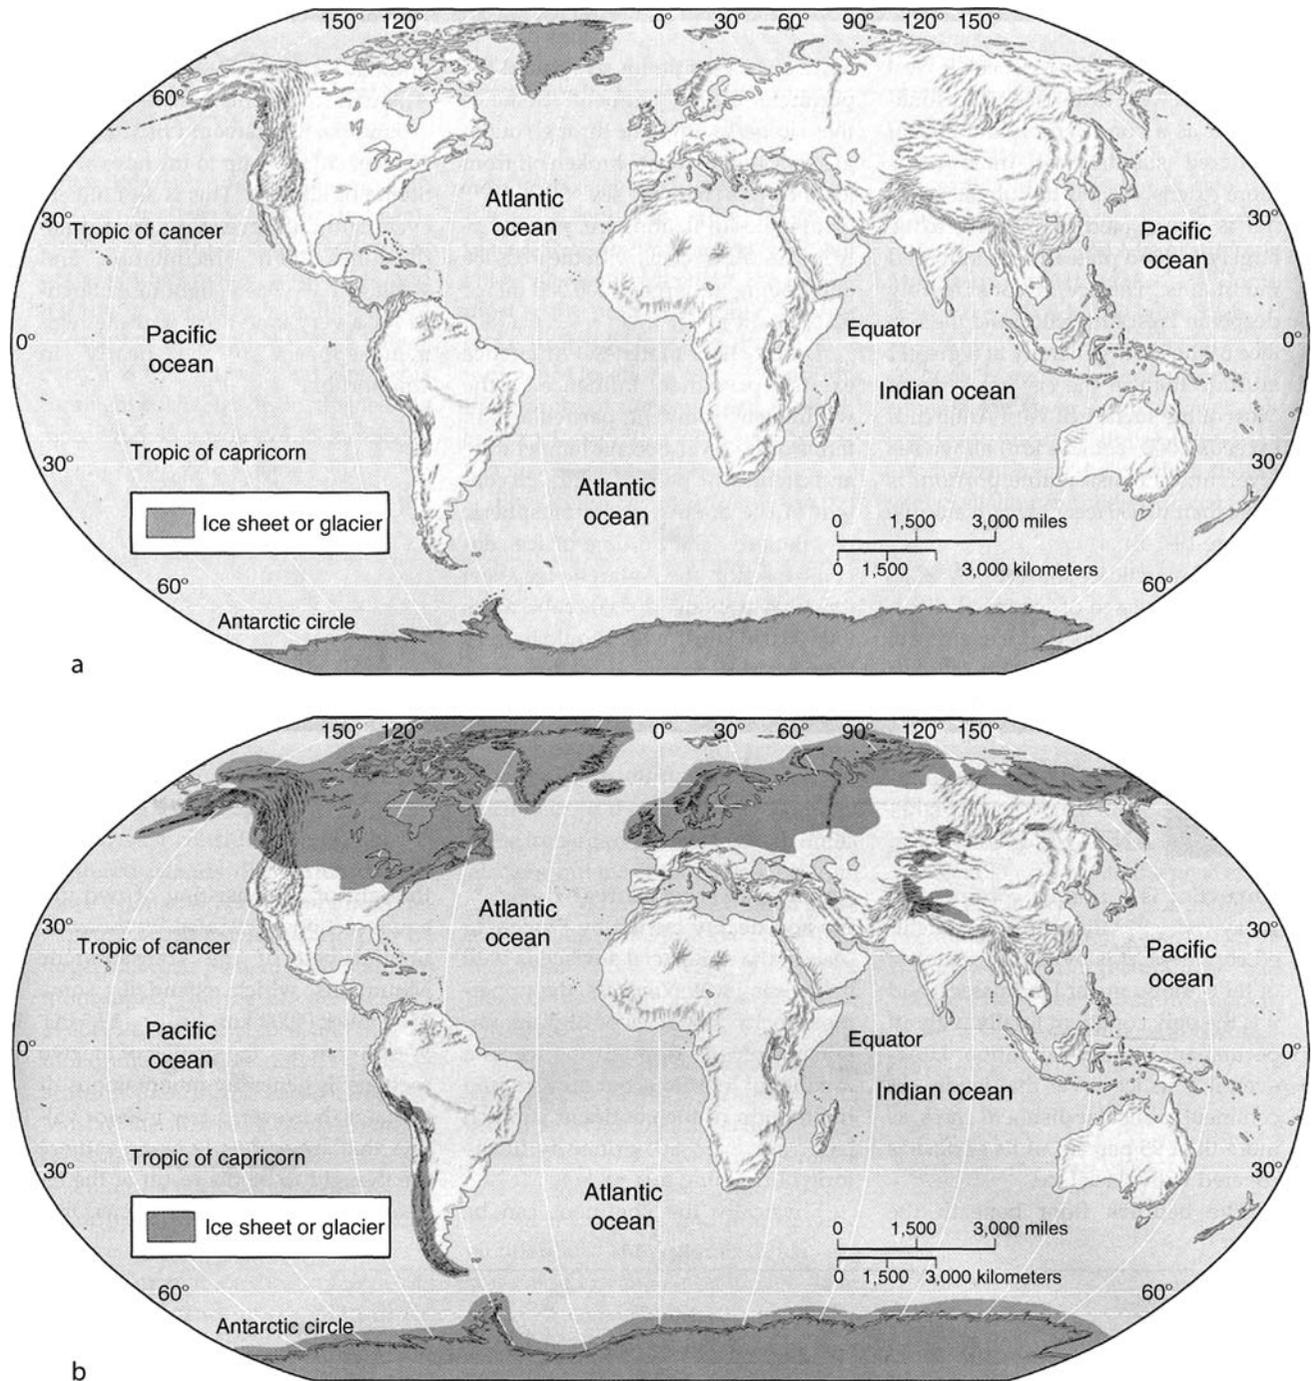

Figure G18 (a) Present worldwide distribution of glacial ice (modified from McKight and Hess, 2000). (b) Extent of worldwide glaciation approximately 18,000 years ago, at the maximum of the Late Wisconsinan (modified from McKight and Hess, 2000).

The Earth as a “Glacial Planet”

The Earth has alternated between interglacial and glacial conditions on an approximate 100,000–150,000 year cycle during most of the Quaternary. Recognition of the recurrence of glaciation in the geologic past is a relatively new concept. In

the nineteenth Century, glacial lithified sediment (the Talchir Boulder Beds) had been recognized in India, and the Permian glacial sediments of Shropshire in England had been identified, but a full recognition of repeated global glaciations only became established in the mid-twentieth Century.

In Europe and North America, during the late nineteenth and early twentieth Centuries, only one single glacial period, the Pleistocene (“The Ice Age,”) was initially recognized. The “Ice Age” was perceived as an unusual aberration of nature, not a repetitive cyclic event. During the Pleistocene, which began around 1.8 million years ago (Ma), much of today’s flora and fauna developed and evolved, and likewise the emergence of our human ancestors stemmed from this period. The Pleistocene was also a time of considerable upheaval in terms of plant speciation and the demise of several larger animals, such as the woolly Rhinoceros, the giant Elk and the Mammoth, towards the end of this period.

As ice ages began to be recognized in Europe, a subdivision of 4 major glaciations was established (Table G1). This four-fold division was further used in North America. Only with oceanic deep drilling programs (ODP) in the North Atlantic and Pacific Oceans that began in 1968 did it become apparent that instead

of 4, at least 17, if not 20, major glaciations had occurred during what was a much longer and colder Pleistocene Period. In the past, it was thought that glaciations worldwide were synchronous in their advances and retreats, but it has become apparent that fluctuations in ice mass margins vary considerably between continents and along different margins of the same ice sheet. For example, along the margins of the Laurentide Ice Sheet in North America, retreat and advance of margins differed considerably between the east coast of New England and the Canadian Maritimes as compared with the margin in the Dakotas and the Canadian Prairies. This lack of synchronicity, certainly over periods of time less than 2,000 years, suggested a much more complex glacial history than previously considered. With modern dating methods and the use of oxygen isotope ratios (establishing the basis for marine Oxygen Isotope Stages), warm (interglacial) and cold (glacial) periods can be determined where the sediment record permits (Figure G19). We now appear to live an interglacial period that may be further prolonged in time or heightened in temperature due to global “greenhouse” warming.

Interglacials in *italics*; glaciations in **bold**.

Glacial landscapes – today

In the Pleistocene, vast ice sheets covered the Earth’s surface beginning with a relatively slow build up to repeated maximum extensions into the mid-latitudes (Figure G18b). These ice sheets had an enormous impact in moving across terrain and eroding, transporting, and depositing vast quantities of sediments both on land and in the ocean basins. The surface topography of the continents today, for example in the northern states of USA and throughout Canada and northern Europe, was totally modified, with distinctive landscapes and landforms repeatedly overprinted until the terrain was finally exposed from beneath the ice some 10,000 years ago. Although ice

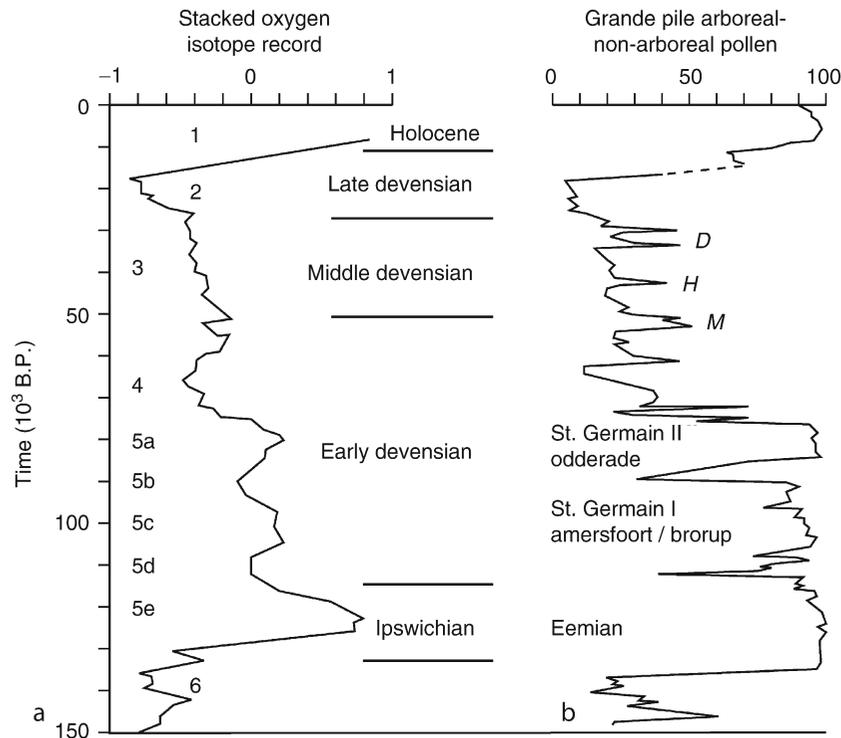

Figure G19 Oxygen isotope record of glaciations for the past 130,000 years (modified after Bowen, 1994).

sheet build-up was relatively slow, the downwasting and melting of the ice sheets was remarkably fast. With the rapid demise of the ice sheets, sea level very quickly rose and, since the ice sheets had isostatically depressed the continental land masses, in many instances sea level rose above present levels, drowning large coastal areas. Much later, continental land masses readjusted to the loss of the ice sheet load and slowly rose. Raised shorelines and cliffs began to re-appear above sea levels. These raised beaches and strandlines, for example in Europe, became the colonization pathways for early humans as they moved northward.

Glacial erosion can be seen on bedrock surfaces in the form of glacial striae and chattermarks, and the effects of high

Figure G20 Striated boulder within a clast-rich till, Steingletscher, Switzerland (boulder is approximately 11 cm across).

pressure meltwater scour (Figure G20). Evidence of glacial transport can be observed in the form of boulder trains and isolated erratic boulders left strewn across glaciated landscapes (Figure G21). Finally, the effects of glacial deposition can be seen as thick glacial sediments, and landforms such as moraines, drumlins and eskers, glacial lake sediments, and immense thicknesses of glacial sediments within marine environments (Menzies, 2002).

Glacial erosion – processes, landforms, and landscape systems

The processes of glacial erosion produce sediments for transport and later glacial deposition. Processes of erosion occur in all glacial environments. Although rather limited, supraglacial erosion in the form of abrasion and meltwater action occurs on the surfaces of ice masses, especially during the summer months when melted ice and snow move across glacier surfaces. In mountainous areas, considerable windblown detritus and debris deposited by avalanches and mass movement often ends up in the supraglacial environment where it may undergo abrasion and meltwater action. Even more limited is the amount of erosion that occurs within ice masses in englacial tunnels where glacial sediment is transported spasmodically depending on meltwater activity within an ice mass. Proglacial erosion is considerable since significant volumes of debris are released from ice masses either along lateral and frontal margins in valley glaciers, along the front margins of large ice sheets, or into oceanic basins where ice margins are floating or have attached ice shelves and thus debris is removed via a grounding-line. In all these locations, sediment entering the proglacial environment is subject to substantial erosion largely due to meltwater transport and mass movement. Most glacial erosion, however, occurs in the subglacial environment where high stress levels, meltwater under hydrostatic pressures, and a vast source of erodable material are available (Figure G22).

Figure G21 Erratic boulder sitting on outwash plain in front of the Mont Miné Glacier, Valais, Switzerland (boulder approximately 2 m high).

Figure G22 Subglacial deposits directly beneath a glacier in Switzerland.

Processes

Glacial erosional processes can be subdivided under five main headings: abrasion, plucking/quarrying, meltwater action, chemical action, and freeze-thaw processes. In general, all of these processes may operate on the same rock surfaces such that examples of glacial erosion typically possess all the characteristic “marks” of all these processes Benn & Evans, 1998; Menzies, 2002.

Abrasion is the wearing down of bedrock and rock fragment surfaces by the scouring of debris-laden ice and meltwater. In both instances, as the debris at the base of the ice or moving within high pressure meltwater passes over the surface of bedrock or other rock surfaces, scratching and wearing down of the surface occurs. The evidence takes the form of minute scratches or striae (Figure G20) on rock surfaces, or extremely polished rock faces with smoothly sculpted geometries that illustrate rapid wear. These latter forms of erosion are termed P-forms (Figure G23). To be effective, such abrasion processes demand high basal ice debris concentrations and/or elevated debris content in high pressure meltwater streams – debris that is sharp, angular, and harder than the rock surfaces being cut; sufficiently strong basal ice pressures; and finally an effective means of evacuation of the abraded debris. This latter requirement is essential if the abrasion process is to continue and not become “clogged.” The production of immense volumes of abraded debris is apparent in the down-stream “milky” nature of glacial streams that exhibit a blue or greenish-blue color due to the high fine debris content referred to as “glacial milk” or “rock flour.”

Plucking or quarrying is a set of processes that removes fractured, jointed, or disaggregated rock fragments from bedrock or the rock surface. Typically, rocks fracture under tensile or compressive stresses produced by the overall stress levels created by the overlying moving ice mass, or by percussive processes where rock fragments crash against rock surfaces and produce flakes and shards of rock materials. Rock plucking can produce enormous boulders and minuscule rock flakes.

Figure G23 P-forms from Espanola, Ontario (scale card 8.5 cm long).

Where large bedrock knobs have been overridden, roche moutonnée may be produced as distinctive erosional landforms with smooth up-ice (stoss) sides and steep craggy down-ice (lee) sides (Figure G24). Where percussive plucking occurs on rock surfaces, tiny chattermarks and lunate fractures develop (Figure G23).

Meltwater, in association with high debris content and high pressure discharge, creates other forms of abrasive wear on rock surfaces. A little-understood process is the effects of chemical weathering beneath ice masses where hydrostatically pressured meltwater, high stress levels, and fluctuating temperatures lead to carbonate, silicate, and iron solution and re-precipitation down-ice. Characteristically, such chemical processes can usually be observed as distinctive stains or “trails” on rock

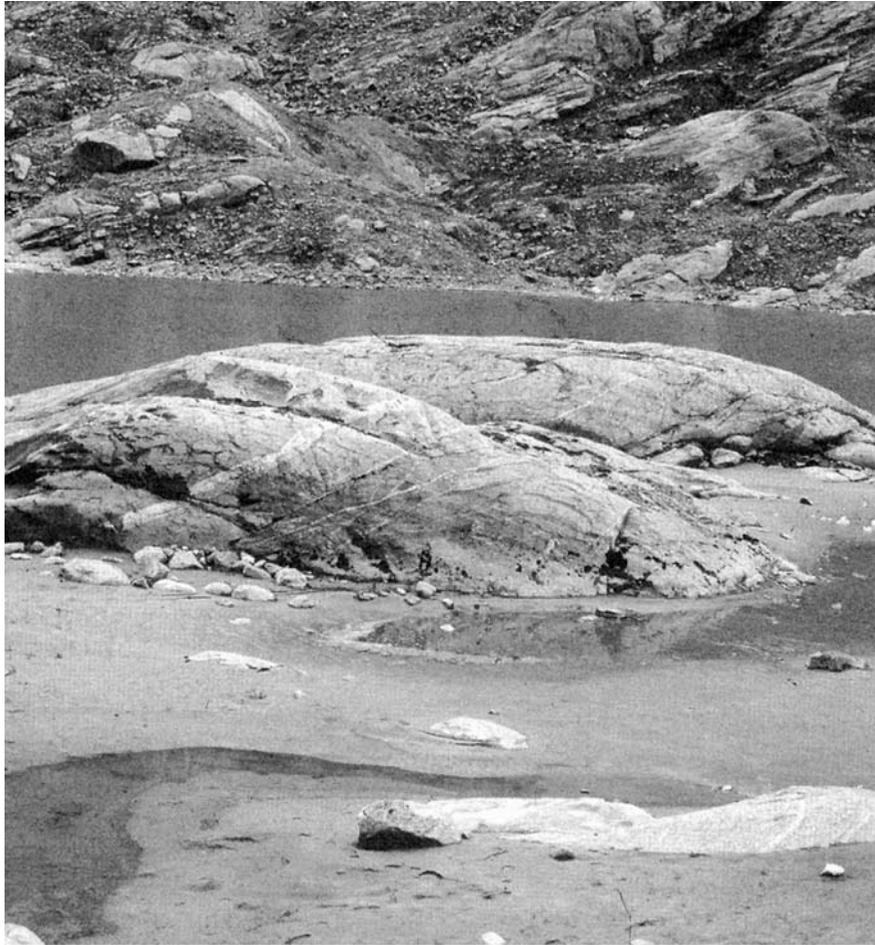

Figure G24 Roche moutonnée (approx. 25 m in length) in front of Nigardsbreen, Norway; ice moving from right to left.

surfaces, often on the lee-side of bedrock protrusions. Finally, in glacial environments, freeze-thaw processes are active, seasonally and diurnally, producing large volumes of frost shattered rock materials.

Landforms

Glacial erosional landforms can be subdivided into areal and linear forms. The range of scale of these landforms can be immense, from centimeter sized “rats-tails” and flutes on rock surfaces (Figure G25) to roche moutonnée, tens of meters in height (Figure G24). Vast areas of the Canadian and Fennoscandian Shields best portray widespread areal glacial erosion (Figure G26). Linear forms such as fjords, troughs (U-shaped valleys) (Figure G27), finger lakes, tunnel valleys, and, at a much smaller scale, fluted bedrock knobs (P-forms) and roche moutonnée, occur in all glaciated regions. All of these landforms reflect the erosive power of glaciers and ice sheets, and their associated meltwater action.

Landscape systems

Perhaps the best known example of a glaciated landscape system is that of high mountain glaciation where pyramidal peaks

Figure G25 Various fluted and streamlined bedrock forms – small-scale flutes, Wilton, Ontario.

(horns), arêtes, cirques, tarn lakes, rock steps (riegels), and hanging valleys are found in close association (Figure G28). No similar landscape system exists for ice sheet erosive landscapes except for the areal scour, bedrock trough, fluted

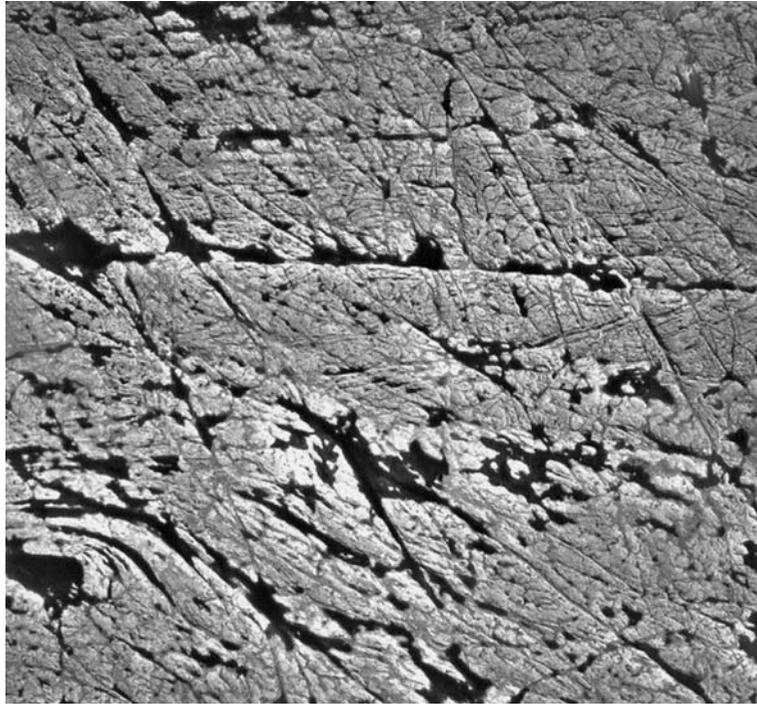

Figure G26 Aerially scoured glacialiated terrain near Lac Troie, Quebec, Canada.

bedrock knob landscapes, such as the Canadian and Fennoscandian Shields, for example Bennett & Glasser, 1996; Benn & Evans, 1998.

Glacial transport

Glaciers and ice sheets transport vast quantities of sediment from fine-grained clays and silts to huge boulders. Sediment is transported on the surface of the ice as supraglacial debris, within the ice as englacial debris, beneath the ice as subglacial debris, and beyond the ice margins as proglacial sediment. Each environment affixes the transported sediment with a potentially distinctive signature that, although complex due to overprinting and re-transportation, can be used, at times, to differentiate glacial sediment types Bennett & Glasser, 1996; Benn & Evans, 1998; Menzies, 2002. Sediment is transported encased within the basal layers of the ice, on the surface of the ice, and beneath the ice within deforming soft sediment beds.

Glacial deposition: processes, landforms, and landscape systems

The deposition of glacial sediment is largely a function of the means of sediment transportation. Since ice masses scavenge sediments from their glaciated basins, and in the case of ice sheets this may be continental landmasses, the provenance of glacial sediment is typically immense, containing far-traveled sediment and boulders as well as local rock materials. In fact, most glacial sediments reflect a provenance only a few 10s of kilometers up-ice from any point of deposition. However, repeated glaciation may greatly increase the original distance from the origin to the final deposition site.

Glacial deposits occur as unsorted sediments with a wide range of particle sizes and as sorted sediments deposited by meltwater. Unsorted sediments are typically referred to as till or glacial diamicton. These sediments are exceedingly complex sedimentologically and stratigraphically. They occur in all sub-environments of the glacier system and range from subglacial clay-rich,

consolidated lodgement tills to coarse supraglacial flow tills, and subglacial and submarginal areas of basal ice melting leading to melt-out tills. However, this classification with reference to subglacial tills is probably inaccurate. It would be more rigorous to term these tills “tectomicts,” products of the complex subglacial environment.

The sorted or fluvio-glacial sediments range from fine-grained clays deposited in glacial lakes (glaciolacustrine) to coarser sands and gravels deposited in front of ice masses as outwash fans or sandur, and rain-out sediments deposited in marine settings (glaciomarine).

Processes

The processes of glacial deposition range from direct smearing of subglacial debris as lodgement tills to mass movement of sediments from the frontal and lateral margins of glaciers as flow tills, and to direct ablation of ice forming melt-out tills in front of ice masses in proglacial areas and within subglacial cavities.

Landforms

Glacial landforms include those formed (a) transverse to ice motion, (b) parallel to ice motion, (c) unoriented, non-linear, (d) ice marginal, and (e) fluvio-glacial. Although a complex myriad of glacial depositional forms occur in most glaciated areas, the dominant landforms discussed below include (a) Rogen moraines, (b) drumlins and fluted moraines, (c) hummocky moraines, (d) end moraines, and (e) eskers and kames.

Rogen moraines or ribbed moraines are a series of conspicuous ridges formed transverse to ice movement. These ridges typically rise 10–20 m in height, 50–100 m in width, and are spaced 100–300 m apart. They tend to occur in large numbers as fields, for example, in the Mistassini area of Quebec. They are composed of a range of subglacial sediments and are

thought to be formed by the basal deformation of underlying sediment, possibly in association with a floating ice margin at times (Figure G29) Menzies, 2002.

Drumlins are perhaps one of the most well known glacial landforms. Considerable literature exists on their formation and debate continues on their mechanic(s) of formation. Drumlins are streamlined, roughly elliptical or ovoid-shaped hills with a steep stoss side facing up-ice and a gentler lee-side facing down-ice (Figure G30a). Drumlins range in height from a few meters to over 250 m, and may be from 100 m to several kilometers in length (Figure G30b). They tend to be found in vast swarms or fields of many thousands (Figure G30b). In central New York State, for example, over 70,000 occur, and vast fields likewise exist in Finland, Poland, Scotland, and Canada. Drumlins are composed of a wide range of subglacial sediments and may contain boulder cores, bedrock cores, sand dikes, and “rafted” non-glacial sediments. It seems likely that these landforms develop below relatively fast moving ice beneath which a deforming layer of sediment develops inequalities and preferentially stiffer units become nuclei around which sediment accumulates and the characteristic shape evolves. Other hypotheses of formation range from the streamlining of pre-existing glacial sediments by erosion, to changes in the dilatancy of glacial sediments leading to stiffer nuclei at the ice-bed interface, fluctuations in porewater content and pressure within subglacial sediments again at the ice-bed interface, and the infilling of subglacial cavities by massive subglacial floods.

Fluted moraines are regarded as subglacial streamlined bedforms akin to drumlins (Figure G31). These landforms are typically linked in formation with drumlins and Rogen moraines. They tend to be much smaller in height and width than drumlins but may stretch for tens of kilometers in length. They are typically composed of subglacial sediments. Fluted moraines have been found to develop in the lee of large boulders

Figure G29 Rogen moraine near Uthusslön, Sweden (photo from Jan Lunqvist).

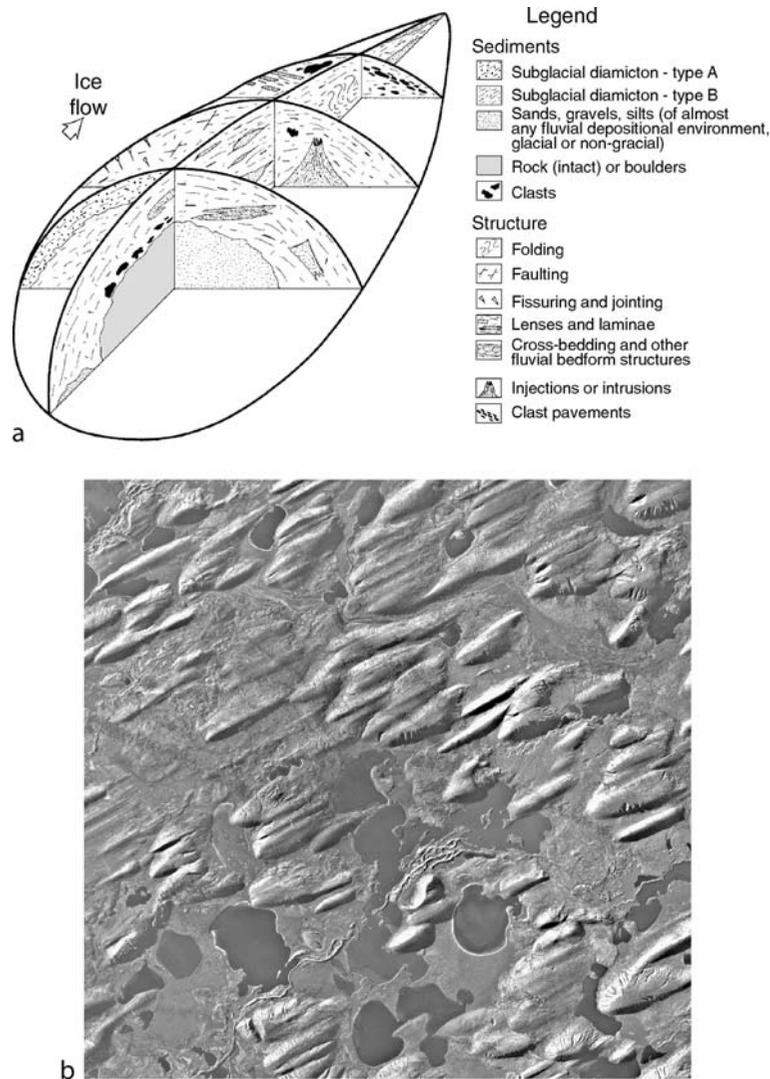

Figure G30 (a) General model of drumlin plan and variability of internal composition, (b) drumlin field in Saskatchewan (ice direction from upper right to lower left).

but may also be attenuated drumlin forms, the result of high basal ice shear stress and high ice velocities. In central New York State, fluted moraines occur beside and amongst the large drumlin fields.

Hummocky moraine is a term used to denote an area of terrain in which a somewhat chaotic deposition pattern occurs, similar to a series of small sediment dumps (Figure G32). These moraines rarely rise above a few meters but may extend over considerable areas. Hummocky moraines often mark locations where massive down-wasting of an ice mass may have occurred.

End or terminal moraines and retreat or frontal moraines occur at the front margins of ice masses. Typically, these landforms, transverse to ice motion, are a few meters to tens of meters in height and, if built-up over several years, may be even higher and of some considerable width (1–5 km). Moraines contain subglacial and supraglacial debris, and often have an accurate shape closely mirroring the shape of an ice front. Since these moraines mark the edge of an ice mass at any given

time, the longer ice remains at that location, the higher and larger the moraines become. However, as an ice mass retreats, with periodic stationary periods (stillstands), a series or sequence of moraines (i.e., recessional moraines) develop that mark the retreat stages of the ice (Figure G33). Sequences of end moraines can be observed in the mid-west states of Illinois, Ohio, and Michigan Mickelson & Attig, 1999.

Eskers are products of subglacial meltwater streams in which the meltwater channel has become blocked by fluvio-glacial sediments. Eskers are long ridges of sands and gravels that form anatomizing patterns across the landscape (Figure G34). They range in height from a few meters to > 50 m and may run for tens of kilometers. In Canada, some eskers cross the Canadian Shield for hundreds of kilometers. These landforms often have branching ridges and a dendritic morphology. Eskers are dominantly composed of fluvio-glacial sands and gravels with distinctive faulted strata along the edges where the ice tunnel wall melted and collapsed. In many instances

Figure G31 Fluted moraine, Storbreen Glacier, Norway (boulder at the head of the flute; ice direction bottom right to middle left).

Figure G32 Hummocky moraine, Glen Turret, Scotland.

eskers are observed “running” uphill or obliquely crossing over drumlins, a testament to their formation within high pressure subglacial meltwater tunnels Benn & Evans, 1998.

In many glaciated areas during ice retreat, large, roughly circular dumps of fluvio-glacial sands and gravels occur. These forms, termed kames, appear to form when infilled crevasses

or buried ice melt, leaving the sediment behind in a complex but chaotic series of mounds. The term kame or kame-delta has been applied to fluvio-glacial sediments that have formed temporary deltas into long-gone glacial lakes. In Finland, a long line of such kame-deltas formed into a moraine-like series of linear ridges transverse to ice front retreat (Salpuasselkä).

Figure G33 Late Wisconsinan end moraines (black) of the Green Bay Lobe (Wisconsin), Lake Michigan Lobe, and Huron-Erie Lobe (Indiana) (modified after Frye and Willman, 1973).

Glacial depositional landscape systems

Distinctive suites of glacial depositional landforms can be found in valley glacier, and ice sheet settings (Figure G35). Typically, these sequences of landforms are often overprinted due to subsequent glaciations but in the mid-west of the USA, such suites of depositional landforms from the last glaciation to affect the area (Late Wisconsinan) can be clearly discerned (Figure G33). Distinctive landscape systems attributable to the marginal areas of ice sheets also carry a unique supraglacial suite of landforms, as can be observed in parts of the mid-western USA (Figure G36).

The impact of glaciation beyond ice limits

Areas beyond the ice limits are greatly influenced by glaciation due to deteriorating climatic conditions, the deposition of wind-blown dust (loess), the divergence of river systems where headwaters or partial drainage basins may be intersected by advancing ice, the impact of outburst floods from ice fronts (jökulhlaups), and major faunal and floral changes due to encroaching ice. In terms of the impact of ice masses on human life and society, the only evidence is somewhat anecdotal. At the close of the Late Wisconsinan, ice masses may have acted to spur human migration, for example through the short-lived ice-free corridor between the Cordilleran and Laurentian Ice Sheets in central Alberta, Canada into the prairies to the south.

Within a few hundreds of kilometers of the vast ice sheets that covered North America and Europe, significant climatic conditions must have been severe with strong katabatic cold winds descending from the ice. Associated with these severe climates, periglacial conditions must have prevailed, in which the ground became permanently frozen to a considerable depth. The effects of periglacial activity produced frozen ground phenomena such as solifluction sediments down slopes, ice and sand wedges, and localized ice lenses and pingo formation. Dramatic changes in vegetation types and animal life occurred, with the southern migration of many species in the Northern Hemisphere. For example, unlike today, central southern Texas

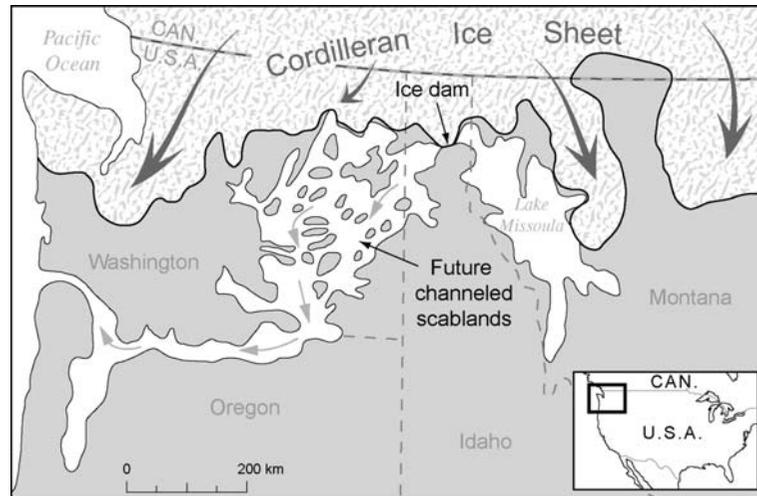

Figure G37 Jökulhlaup resulting from catastrophic drainage of glacial Lake Missoula has led to the formation of the Channeled Scablands of Washington and Oregon.

would have supported hardwood forests of the type now found in Ohio and Pennsylvania.

Due to the katabatic winds, fine sediments were picked up from the proglacial areas along the margins of the ice sheets and the dust was transported away from the ice and deposited as thick, massive loess sediments (glacioaeolian sediments). Considerable thicknesses of these sediments occur in the mid-western states of the USA, especially in Iowa and Kansas, and also in central Europe, Hungary, Central Asia, and China.

In some instances, vast outpourings of meltwater (jökulhlaups) flooded from the ice fronts, leading to distinctive, heavily dissected terrains being formed (badlands). Such an occurrence is recorded in the Columbia River Badlands of Washington and Oregon States where a huge lake formed and then dramatically drained (Lake Missoula floods) (Figure G37).

GLACIAL ISOSTASY

Glacial isostasy refers to the response of the solid Earth to any changes in the planet's ice sheets. The Earth is not a rigid body and it will deform when subjected to forces or to changes in surface loads. The nature of this deformation depends largely on the time scale, magnitude, and wavelength of the deforming force or load. Examples include the very rapid crustal fracturing at the time of earthquakes, the semi-diurnal and diurnal tidal deformations of the solid planet due to the changing gravitational attraction by the Sun and Moon, and the seasonal changes in the mass distribution within the atmosphere. Examples on longer, geological timescales include the redistribution of surface loads during erosion and sediment deposition or by the formation of large volcanic complexes. At the high frequency part of the spectrum, the response is primarily elastic but with decreasing frequency the response becomes increasingly viscous.

To a first approximation, the Earth is a layered body whose outer shell, the lithosphere, acts essentially as an elastic layer. The mantle below is more viscous and flows when subject to non-hydrostatic stress and for very long term loads, of the order of a million years or more, this region behaves largely as a fluid. The outer core acts as a fluid even at high frequencies. The lithosphere comprises the crust, which is relatively cold and brittle, and the uppermost part of the mantle that is relatively cool, strong, and elastic.

Isostasy is a concept that describes the response of the planet to a change in surface load. It was originally developed to describe the mechanism by which mountains and plateaus were supported by the crust for long periods of time. In its simplest

form, the surface load is assumed to be underlain by lower-than-normal densities such that below the crust or lithosphere the pressures are hydrostatic everywhere. The manner in which this “compensating” mass is distributed gives rise to different models of isostasy: Airy, Pratt, or regional. The first two models are local compensation models in which the compensating mass is located immediately below the load but in the third model, a local load is supported regionally. The underlying assumption in these models is that the surface loads are supported by stresses within the crust-lithosphere and that the sub-lithospheric mantle is fluid, an assumption that is operationally effective on long timescales of many tectonic processes.

Glacial isostasy is concerned with the planet’s response to the changing surface loads of ice and water during the waxing and waning of large ice sheets. To a first approximation of local isostasy, the crust beneath the ice sheet is depressed by the product of the ratio of ice and mantle densities and the thickness of the ice, such that somewhere below the ice-loaded lithosphere the vertical pressures are constant at constant depth. For a 3 km thick ice cap, this would mean a crustal depression of about 800 m. On timescales of glacial cycles (10^4 – 10^5 years), the mantle does not behave as a fluid and the load will be partly supported by viscous stresses in the sub-lithospheric region. Thus, the initial response to a large ice load will be by elastic deformation of the entire lithosphere-mantle followed by a viscous creep as the mantle stresses relax and the load is increasingly supported by the lithosphere. The local isostatic depression will be attained as a limit. Likewise, when the ice sheet is removed, the initial response is elastic followed by a viscous rebound. The rate at which this occurs will be a function of the mantle viscosity and observations of this rebound, in fact, provide the primary evidence for this viscosity.

Large ice sheets have periodically formed on the Earth’s surface in response to changes in planetary configurations and the resulting changes in solar insolation (e.g., the Milankovitch theory). Thus, water mass is withdrawn from the oceans and localized at high latitudes when large ice sheets form, and more than 50×10^6 km³ of water is periodically moved between the ice sheets and the oceans, resulting in a global lowering of sea level by 130–150 m. This is the most direct consequence of glacial isostasy: global fluctuations in sea level that mirror the growth and decay of ice sheets during the glacial cycles of the past two million years. The spatial pattern of this sea-level change is, however, complex. What is observed is that the position of past shorelines relative to the present shoreline position and the crust – which forms the reference surface for the measurement – is itself displaced during the surface-loading cycles. Moreover, as the Earth deforms and mass is redistributed around the globe, the gravity field of the planet changes and surfaces of constant gravitational potential, e.g., the geoid or sea level in the absence of oceanographic and meteorological forcing, are modified as well. Thus, the relative sea-level observation at a locality is a measure of the change in ocean volume, of the radial deformation of the Earth’s surface under the changing surface load, and of the change in gravitational potential. The globally averaged sea-level change resulting from a change in ice volume is referred to as the ice-volume-equivalent sea-level change and, in the absence of other processes that change ocean volume, this corresponds to eustatic sea-level change.

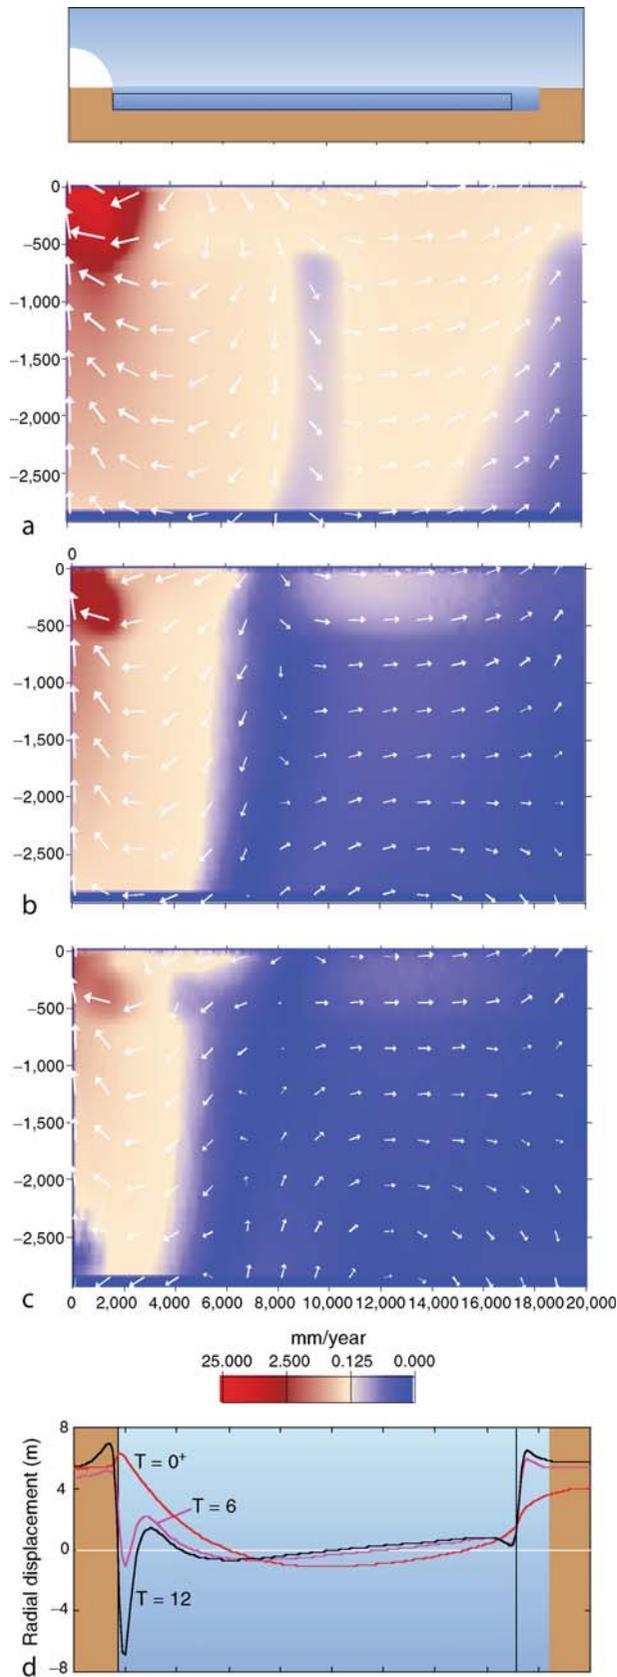

The Earth is presently in an interglacial period and the last of the large ice sheets over North America and Europe disappeared before ~7,000 years ago. The remaining ice sheets of Greenland and Antarctica also, in a first approximation,

stabilized by about this time. However, while ocean volumes remained nearly constant during the interglacial period, sea levels have continued to change as a result of the viscous or delayed response of the Earth to the removal of the ice load and the redistribution of the melt water into the oceans. The amount of this post-glacial change at any location depends on the relative importance of the different components contributing to the sea-level change: the crustal deformation under the changing ice and water load, the changes in gravitational potential, and the changes in ocean volume. The relative sea level changes with location and with time and gives rise to the complex spatial and temporal pattern of sea-level change that has been observed.

The most obvious deformational effect of the glacial cycles occurs in the areas of glaciation where, as illustrated above, the crust may be depressed by hundreds of meters beneath large ice sheets. However, the removal of water from the ocean basins also adds to the deformation. The removal of 150 m of water from an ocean basin would result in a rebound of the ocean floor, and of islands within the basin, of up to 30–40 m according to the local isostatic formulation. Thus, in any rigorous formulation of glacial isostasy the total load of the ice and oceans needs to be considered.

Sea level is not the only process perturbed by the glacial cycles. Gravity is time dependent and this can be measured instrumentally in areas of ongoing rebound. The radial and horizontal changes in position of the crust can also be measured by space-geodesy methods (the glacial rebound contains a horizontal surface velocity signal as well as the radial signal). The planetary rotation is modified as the inertia tensor evolves through time, and the motions of satellites around the planet are perturbed. All of these signals provide evidence for the Earth’s viscous response function, but the sea-level signal remains the most important because it has been preserved in the geological record, primarily for the period since the last deglaciation and, in a more fragmentary form, for earlier periods.

If the Earth’s viscosity and elastic structure as well as the history of the ice sheets are known, then physically consistent models can be developed that rigorously predict the observed phenomenon: models that describe the deformation of the entire planet, that distribute the meltwater in a self-consistent way into time-dependent and realistic ocean basins, and that include the effects of the changing water load as well as ice load. The theory has to be a global one because all parts of the mantle are affected by the deglaciation of one ice sheet. This is illustrated in Figure G38 for a simplified model in which the ice sheet, land mass, and ocean basin are longitude independent. In this case, a continent-based ice sheet at the north pole, with dimensions approximating the North American Ice Sheet, has been rapidly removed and only the rates of mantle displacement caused by the changing ice loads are shown for three epochs, 100 years after the unloading, and 6,000 and 12,000 years later. The deformation extends throughout the mantle, down to the core-mantle boundary at ~2,900 km depth, and to the antipodes of the ice cap. The contribution to this deformation field from the water loading is much smaller in amplitude and this is shown here only as the radial displacement of the sea surface for three epochs, immediately after unloading and showing the elastic deformation, and at 6,000 and 12,000 years later. These signals, while relatively small, are observationally significant and important for estimating the mantle rheology, particularly at margins far from the former ice sheets, such as across the antipodal margin illustrated.

If the parameters defining the Earth's response function (its rheology) are only partly known, then the comparison of predictions with observations provides a means of estimating this function. If the ice history, the location and thickness of ice through time, is not fully known then such a comparison may contribute to the description of the past ice sheets. In fact, neither the rheology nor ice history are perfectly known and the primary motivation for the study of glacial isostasy is to better understand the solid planet's response to stress in support of dynamical planetary studies, and to improve the description of the past ice sheets in support of palaeoclimate studies.

As sea level rises and falls, it leaves behind signals of its past position. Submerged terrestrial materials, such as in-situ tree stumps, indicate that sea levels were lower at the time of tree growth than today. Coral reefs above present sea levels are indicative of sea levels having been higher in the past. Thus, if the age of the tree stump or of the coral can be measured, limiting values to past sea levels can be established. In some instances, high resolution observations are possible. The submerged sediments may contain faunal or floral fossils of species that lived only in a narrow tidal range or the morphology of the reef may indicate that it formed at the upper growth limit of corals. In either case, the paleoshoreline can be precisely identified. Some examples of results from different parts of the world are illustrated in Figure G39 and these, for the period since the Last Glacial Maximum (LGM) at $\sim 30,000$ – $20,000$ years ago, reveal some of the principal spatial variabilities of the sea-level signal.

The results for Ångermanland, northern Sweden, and Richmond Gulf, Canada, are characteristic for locations that are near the former centers of glaciation, where the dominant contribution to the relative sea-level change is from the crustal rebound upon removal of the ice. Note that in the Swedish example, the last ice disappeared about 9,000 years ago but since then more than 200 m of rebound has occurred, testimony to the viscous relaxation of the mantle. The example from the Norwegian coast at Andøya is characteristic of the sea-level signal from near ice margins. A similar result is observed at Vestfold Hills in Antarctica, although the early part of the record here does not appear to have been preserved in the sediments, or deglaciation occurred late. The result from the Bristol Channel is representative of areas beyond but not far from the ice margins and here sea levels have not been higher than present at any time since the LGM. Similar signals are seen along the North American Atlantic coast south of around New York. The observations from

Figure G38 Mantle deformation as the result of glacial loading at one pole. The model is axisymmetric about the pole of the ice sheet, which rests on a continent of the same dimension (*left hand side, top panel*). A second, unloaded continent occurs at the antipodes (*right hand side*). The ice sheet is assumed to melt instantaneously and the water is added into the ocean basin between the two continents. The panels (a–c) illustrate the rates of displacement of mantle material at three epochs: (a) soon after the unloading and upon completion of the elastic response, (b) 6,000 years after unloading, and (c) 12,000 years after unloading. The *arrows* indicate the direction of flow and their lengths are proportional to the magnitude of the flow rate on a logarithmic scale. The *color coding* indicates the magnitudes of the rates. Panel (d) gives the radial displacement of the ocean surface immediately after melting (at time $T = 0^+$) and at 6,000 and 12,000 years ago ($T = 6, 12$ ka) due to the addition of the water load into the ocean basin.

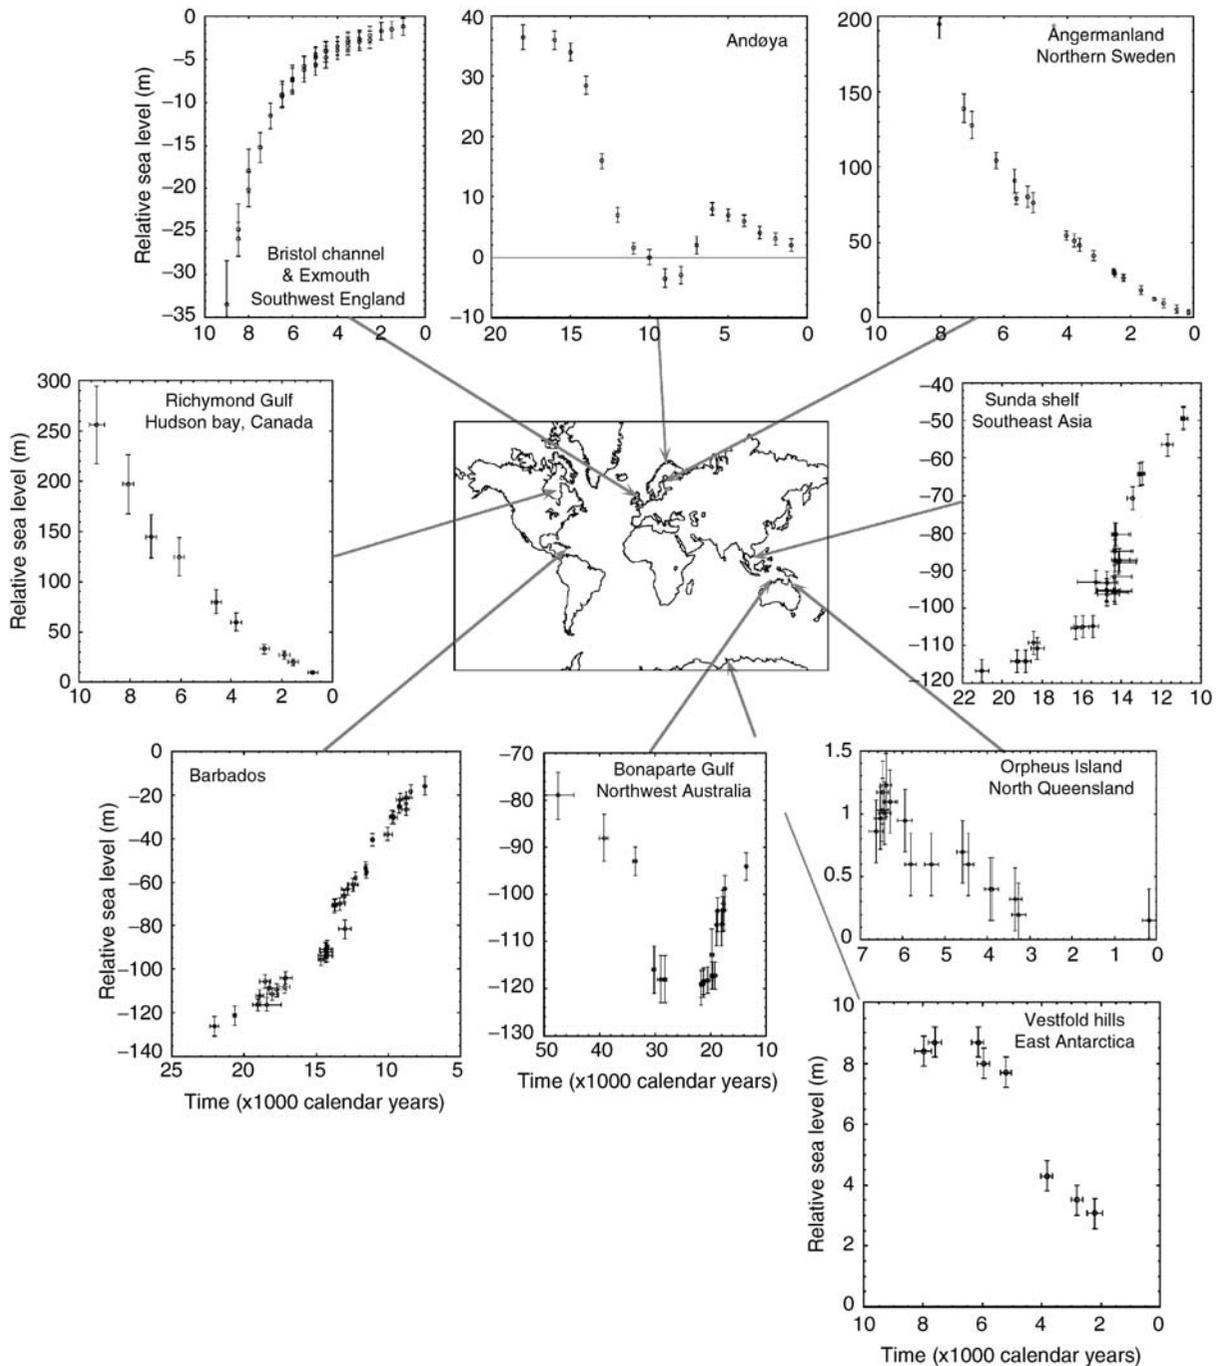

Figure G39 Observations of relative sea-level change from different locations and for different time intervals. All observation sites are believed to have been tectonically stable except for Barbados where a small correction for such motion has been applied. Note the different scales used for the various time-height plots. All observed depths and elevations have been reduced to mean sea level and all timescales correspond to calendar years (adapted from Lambeck and Chappell, 2002).

Barbados, the Sunda Shelf, and the Bonaparte Gulf are representative of sites far from former ice margins, where sea levels experienced a sustained rise until about 7,000 years ago. The onset of this rise appears to occur shortly after 20,000 years ago and its rate appears to have been variable. The record from the Bonaparte Gulf indicates that the low sea levels persisted for

an interval of about 10,000 years, starting at ~30,000 years ago. Detailed observations for the past 7,000 years from such localities distant from the former ice sheets, e.g., Orpheus Island, Australia, also indicate that sea levels at continental margins have actually been falling slowly as a result of the oceanic mantle response to the changing water load.

This spatial variability can be understood in terms of the several components contributing to the signal and, in particular, from the interplay between local rebound and global ocean volume change. For sites far from the ice sheets, the isostatic contributions are relatively small, about 10–15% of the eustatic change, and insensitive to the details of the melting history. Observations from “far-field” sites such as Barbados or the Bonaparte Gulf therefore constrain the change in total ice volume once the small isostatic corrections are applied. For the sites near the centers of former glaciation, the observed signal is predominantly from the crustal rebound that dominates the ocean volume signal. If the eustatic change is known from the analysis of far-field data, the rebound term can be determined and this is primarily a function of rheology parameters and ice thickness. When melting ceases abruptly, a small cusp may occur in the sea-level data and this becomes more pronounced when the rebound contribution is reduced relative to the eustatic change. This occurs, for example, at Andøya and establishes the time of the end of major glaciation. At these sites the signal is initially dominated by the rebound but at a certain time this is reduced and equal in magnitude but opposite in sign to the global eustatic term so that sea level is constant for a period. Later the eustatic term dominates and sea level again rises until melting ceases and it is the residual relaxation of the unloading that dominates the signal. This latter part of the signal provides a useful constraint on mantle rheology while the earlier part of the signal provides constraints on the ice distribution at its margins. The Andøya signal, for example, indicates that the outer Vesterålen of Norway were ice free at about 19,000 years ago, but that the ice must have extended offshore before that time in order to produce the elevated sea levels once the area became ice free.

Beyond the ice margin, the rebound signal during deglaciation becomes one of subsidence. During the loading phase, mantle material is displaced beneath the area of loading and because mass is conserved, a broad but shallow bulge forms around the periphery of the ice sheet (c.f. Figure G38). Then, as the ice melts, this bulge subsides and results, in the absence of other contributions, in an apparent rise in sea level. Thus, here the sea-level change is initially rapid as the ice decays and, when melting has ceased, the rise is slow and reflects the isostatic change. The early part of the record represents mainly the eustatic contribution and the latter part reflects mainly the rheology. Much further from the ice sheets, the deformation resulting from the changing ice load is reduced and the major isostatic term comes from the change in water load (Figure G38). This effect is most pronounced at continental margins where the extra water during deglaciation depresses the ocean floor, pulling sea level down with it, and resulting in a fall in sea level at the coast. This signal becomes most visible when melting has ceased and results in small-amplitude highstands at about 6,000–7,000 years ago, as observed in many places along the Australian coast (the Orpheus Island result).

What these examples illustrate is that the isostatic signals, by taking advantage of their spatial and temporal variability, provide a means of estimating both the mantle rheology and aspects of the ice history. This is important because generally the distribution of the ice during the recent glaciation is not well known. Most of the observational evidence is from the last 20,000 years, older information being scarce because it has been largely destroyed by an earlier ice advance or phase of sea-level rise and also because the commonly used radiocarbon dating method becomes unreliable or imprecise.

The limits of the ice sheets over North America and Europe for the LGM and for the subsequent ice retreat have been mostly well mapped but major differences of opinion remain for some locations, most notably for Arctic Russia. Sea-level observations may help here. For example, if a large ice sheet existed over the Kara Sea and western Siberia during the LGM, then a raised shoreline pattern similar to that observed for adjacent Fennoscandia resulting from glacial rebound would be expected, but the absence of such a pattern indicates that any LGM ice over the region must have been unimportant. For regions such as this, the glacial isostasy analysis provides more insight into the ice history than into the Earth rheology. Debate also occurs over the extent to which the large ice sheets extended onto the continental shelves. Did the Scandinavian Ice Sheet extend across the North Sea and overrun the northern British Isles or did the two ice sheets form separately? Again, the glacial isostatic analyses for the two areas provide useful constraints. If thick ice did extend across the North Sea during the LGM then the rebound in southwestern Norway would have been greater than that actually observed and the center of rebound over the British Isles would lie in eastern Scotland rather than where it is observed in western Scotland. Where were the LGM North American ice margins in northeastern Canada? Was the ice restricted to the upper fiords of Baffin Island or did it extend far onto the continental shelf? The presence of well-elevated shorelines at outer coastal sites, with early Holocene ages, points to substantial rebound having occurred here and to early ice over the region and onto the shelf. Another area of uncertainty concerns the ice thickness at the LGM and during the subsequent deglaciation phase. Only in special cases where mountains protruded through the ice are there observational constraints on the thickness and this is not the case for the large former ice sheets other than near their margins. Instead, the ice thickness is based on glaciological and climate assumptions, for example about the conditions at the base of the ice sheet, the coupling of the ice to the underlying rock and sediments, and the supply of moisture. Alternative, but yet plausible, assumptions can lead to distinctly different results for the ice thickness, and the glacial isostatic inversions must include a strategy for estimating ice thickness. Because of the good distribution in time and space of the observational evidence across northern Europe, the Fennoscandian rebound problem is particularly well posed and inversion schemes can be developed that solve the problem for both rheology and ice sheet parameters.

Figure G40 illustrates the isostatic rebound of Scandinavia based on model calculations constrained by a variety of geological, geodetic, and geomorphological data. The results are shown for three epochs: (a) an early stage of the LGM when ice margins were at their maximum extent, (b) about 12,000 years ago when the southern ice margins had retreated across the Baltic Sea and when the retreat was momentarily halted during the climatic cold interval of the Younger Dryas, and (c) at present, some 9,000 years after all the Scandinavian ice had vanished. At the time of the second epoch, the Baltic was closed to the Atlantic both by the ice barrier in southern Sweden and by the land barrier through the Danish Bælts. This formed the Baltic Ice Lake at an elevation of about 25–30 m higher than coeval sea level. It left well-defined shorelines across the region, which today are strongly inclined relative to present sea level, and this information has been used to constrain the model parameters. Tide-gauge observations of sea-level change for the past century as well as Global Positioning

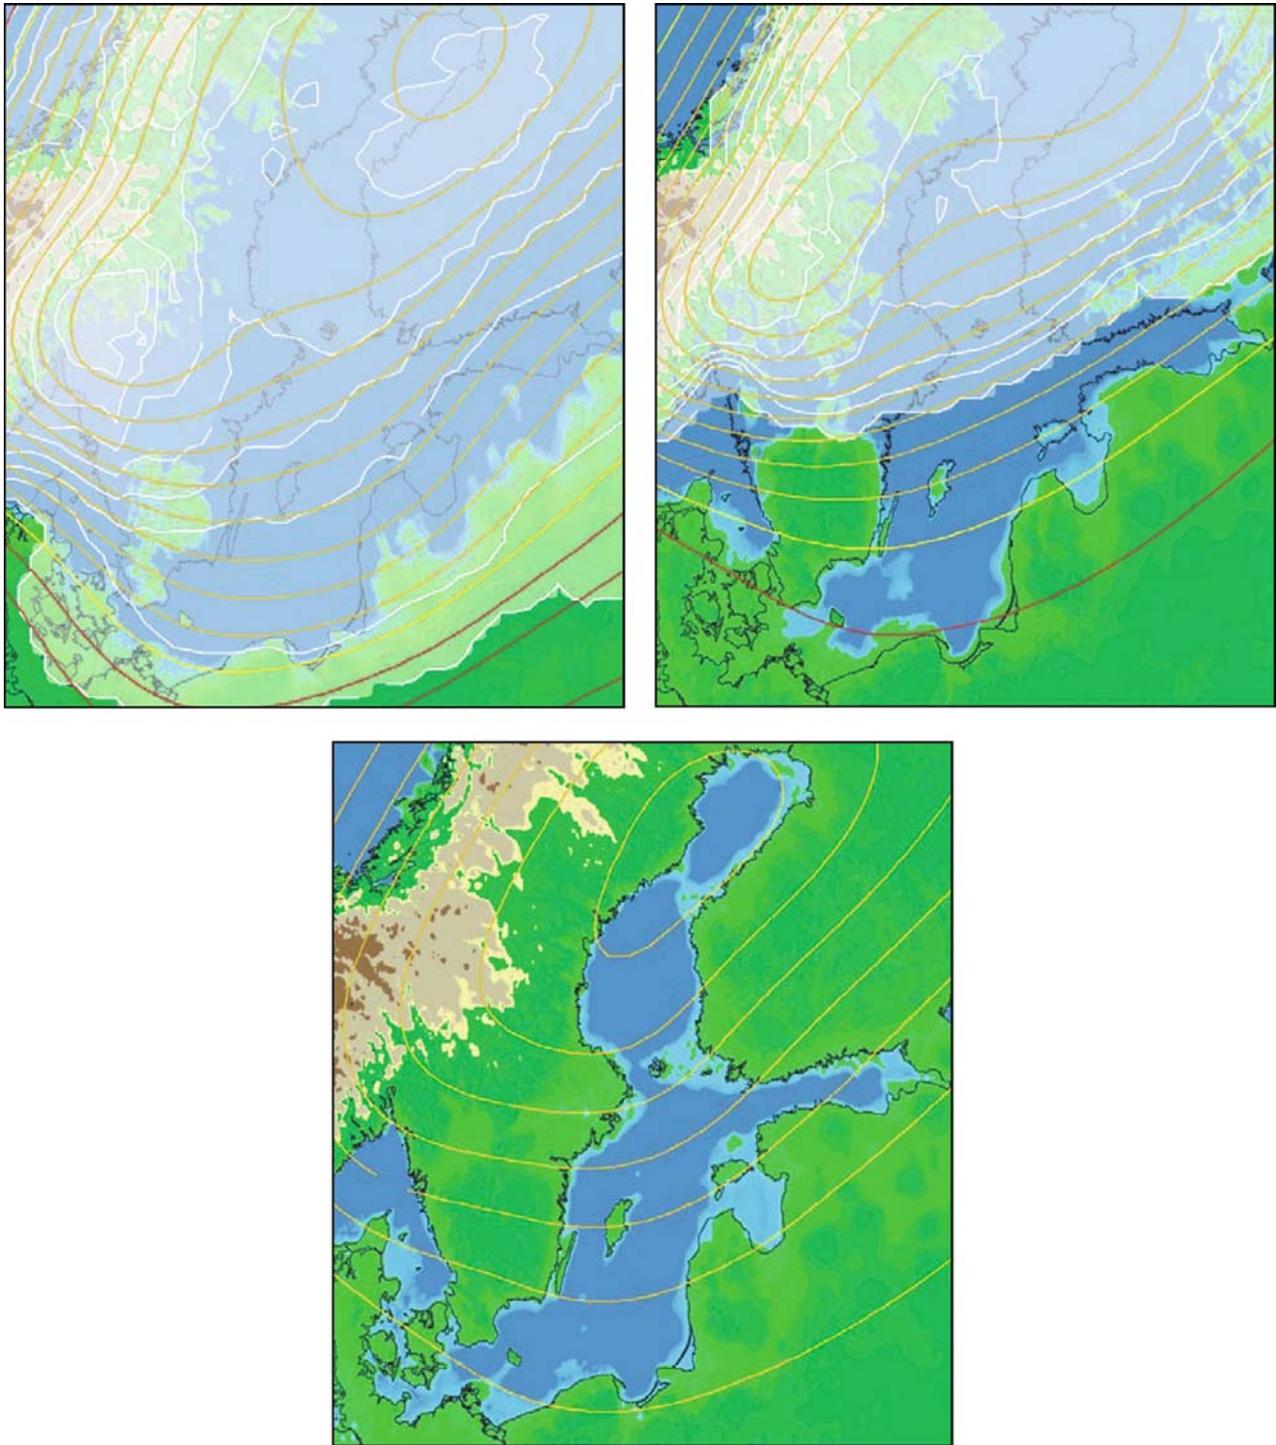

Figure G40 Paleogeographic reconstructions for Fennoscandia at three epochs: ~20,000 years ago corresponding to the end of the Last Glacial Maximum (LGM), ~12,000 years ago, corresponding to the Younger Dryas (YD), and for the present. The ice sheets are shown by the translucent regions with the ice thickness contours, in *white*, corresponding to 400 m intervals. Areas with underlying blue correspond to regions below sea level for the epoch given. The paleoshorelines are defined by the *green-blue* boundary for each epoch. During the Younger Dryas, the Baltic Ice Lake was about 25–30 m higher than the Atlantic Ocean and formed a frozen freshwater lake. For the LGM and YD the *yellow* and *red* contours correspond to the change in local sea level that occurred since the present. The *yellow* contours are positive and in this area the paleoshorelines, if preserved, will occur above present sea level. The zero value is identified as the first *yellow* contour. The *red* contours are negative. The contour values are 100 m for the LGM, and 50 m for the YD. The third panel illustrates the present-day rate of change in sea level rise (contour interval is 1 cm yr^{-1}) with the maximum rate in the northern Gulf of Bothnia approaching 8 cm yr^{-1} .

System (GPS) observations of crustal rebound for the past decade provide additional constraints on the rebound models.

The essential rheological result from this and inversions of data sets from other localities is that the viscosity can be adequately described by a linear relation between stress and rate of strain over the range of stress magnitudes and duration of stress cycles encountered. The resulting “effective” viscosity is depth-dependent, with the lower mantle below about 670 km depth being of distinctly higher viscosity than the upper mantle. Some viscosity stratification occurs within the upper mantle, with the depth dependence broadly following the depth of seismic parameters of shear velocity and attenuation. Lateral variation in the upper mantle also occurs, again broadly following the seismic parameters. Beneath the continental margins of Australia, for example, the upper mantle viscosity is less than beneath Scandinavia, where in the former case the estimates of viscosity come from analysis of the water loading effects. Such variation is not unexpected since both mantle viscosity on time scales of thousands of years and the propagation of seismic waves at periods of seconds and minutes are likely to be temperature controlled.

Mantle viscosity is a fundamental parameter for describing the Earth’s dynamical behavior because it controls the rates of convection and thermal evolution of the mantle. The challenges for future work in glacial isostasy are to refine this viscosity structure, not only its depth and lateral variability but also its behavior over time. Is the evidence for linear behavior supported when some of the longer cycles in glacial loading are examined? This will require new information for the earlier periods of the glacial cycles of both the ice sheets and the Earth’s response. Improved observational evidence for the present rates of post-glacial deformation will also contribute to an improved understanding of the viscosity structure. These measurements will include high-precision measurements of the displacements of points on the Earth’s surface and changes in gravity. The challenge here will be to separate these changes from tectonic signals.

GLACIAL MEGALAKES

Continental ice sheets that form during epochs of glaciation exert immense influences on water drainage across the land. Their huge loads depress the underlying land surface, and lakes

form in the moats that surround the ice sheets. They can block the lower courses of major rivers, impounding flow, and even diverting it into adjacent drainage basins. Meltwater from glacial margins may introduce huge discharges into land-surface depressions that hold much smaller lakes during nonglacial periods. The lakes may climatically alter water balances, promoting further glaciation by a kind of positive feedback.

Glacial megalakes are exceptional for their extent and/or their volume. They may form in direct contact with glacial ice, or they may form in nearby depressions under the pronounced influence of glaciers in the regional drainage basin. There are modern examples for all these situations, but the relatively small size and different thermal regimes of modern versus ice-age glaciers pose problems of extrapolation to the past conditions of major continental glaciation that favored the development of glacial megalakes.

Types of glacial megalakes

Ice-marginal lowland megalakes

The classic example of an ice-marginal lowland megalake is the Baltic Ice Lake, which formed about 14,500 calendar years ago, in the ice-marginal moat to south and east of the retreating Fennoscandian Ice Sheet. Prominent, well-dated glacial moraines mark the recession of this ice sheet from northern Germany and Poland to positions in Denmark and southern Norway and Sweden, which blocked the outlet of glacial meltwater from the Baltic to the North Sea until about 11,200 years ago. The lake then drained through a spillover across the Mt. Billingen Area, southern Sweden (Björck, 1995). There followed a period of alternation between marine and saline conditions, as land rebounded from the load of the disappearing ice sheet and global sea level rose from the melting of ice on all the continents. At its maximum extent, the Baltic Ice Lake covered nearly 400,000 km² in a relatively shallow inundation with a volume of about 9,000 km³. Its modern successor, the Baltic Sea, is the world’s largest brackish water body.

Structural/tectonic basin megalakes

Basins formed by tectonic processes may hold lakes that are strongly influenced by glaciers in their drainage basins. Classic examples occur in the Basin and Range tectonic province of the western United States, where Lake Bonneville, the mega-lake predecessor of the Great Salt Lake, formed during the last ice age. This paleolake achieved a maximum area of 52,000 km² and a volume of 7,500 km³ between about 22,000 and 17,500 calendar years ago. The lake filled to the level of a spill point in south-central Idaho, and then dropped 100 m as it eroded into the outlet, releasing the catastrophic Bonneville Flood down the Snake River (O’Connor, 1993).

Another megalake formed at the elevation of 3,800 m in the Altiplano of southern Bolivia and northern Peru. The modern Altiplano depression contains Lake Titicaca (8,800 km² in area), Lake Poopo, and the great salt pans of Ciopasa and Uyuni. Paleolake Tauca covered the whole depression (about 50,000 km²) to a depth of around 100 m. It achieved its maximum stage after the Last Glacial Maximum in the nearby mountains (about 22,000–20,000 calendar years ago).

Intermontane, ice-dammed megalakes

Very deep lakes can form when a glacier advances down a mountain valley to block a river. Perhaps the most famous example is Glacial Lake Missoula, which formed between about

17,500 and 14,500 calendar years ago (Atwater, 1986). At maximum extent this lake covered 7,500 km², and it held a volume of about 2,500 km³. Cataclysmic failure of the ice dam impounding this lake resulted in the release of water over 600 m deep, thereby generating some of the largest known glacial megafloods (Baker and Bunker, 1985).

Subglacial megalakes

Ice-penetrating radar mapping of the sub-ice floors of portions of the Antarctic Ice Sheet has identified over 70 subglacial lakes. Largest of these is Lake Vostock, which occupies an interior subglacial trench of tectonic origin. The lake measures 240 by 50 km and holds between 2,000 and 5,000 km³ of water (subject to interpretive uncertainty as to the lake depth). Because the water in this lake is isolated from the surface environment by 4 km of overlying ice, it likely contains very interesting biota, surviving in an extreme environment similar to those inferred to be present on Mars and on Jupiter's icy moon, Europa. A project is currently underway to sample the water in this remarkable lake.

Glacial Lake Agassiz and the Laurentide Ice Sheet

Perhaps the largest well-documented glacial megalake formed in north-central North America in association with the largest glacier of the last ice age, the Laurentide Ice Sheet. This ice sheet is known to have been highly unstable throughout much of its history. Not only did freshwater discharges from the glacier result in ice-marginal lakes; outbursts of meltwater into the Atlantic Ocean may have generated climate changes by influencing the thermohaline circulation of the North Atlantic Ocean (Teller et al., 2002).

During the Last Glacial Maximum, the Laurentide Ice Sheet achieved its maximum extent about 20,000 years ago. The initial glacial retreat generated relatively small lakes because of the regional river drainage to the south, away from the ice front. The ice sheet surged and readvanced at times, leading to a very complex history in the basins that now contain the Great Lakes. However, when the ice sheet advanced north of this area into the Canadian Shield, Lake Agassiz formed in the trough between the ice and drainage divides to the south and west, in parts of present-day North Dakota, Manitoba, and western Ontario. The megalake seems to have been initiated close to the time of the Younger Dryas cooling event, which began about 12,700 years ago. One explanation for this cooling is diversion to the St. Lawrence River of the Laurentide meltwater that previously flowed to the Gulf of Mexico via the Mississippi. The outflow of great quantities of freshwater into the North Atlantic disrupted the salinity gradient that drives the thermohaline circulation of the oceans by the formation of deepwater in the North Atlantic (Broecker and Denton, 1989).

As the southern margin of the Laurentide Ice Sheet retreated northward into the present Hudson Bay region, Lake Agassiz adjusted to a succession of overflow or spill points, approximately as follows: (a) It drained southward via the Minnesota River to the Mississippi and Gulf of Mexico (about 12–13,000 years ago). (b) It then entered Lake Superior via a route near Thunder Bay. (c) It shifted to the northwest via the Clearwater spillway to the Mackenzie River and the Arctic Ocean (about 11,000 years ago). (d) It then flowed eastward again to Lake Superior through a succession of spillways (about 10,000 years ago). (e) It shifted to the Ottawa River and the St. Lawrence. (f) Finally, it flowed to the Hudson Bay area (about 8,400 years

ago). This 5,000-year history resulted in inundation at one time or other of 1.5 million km², but its maximum one-time extent was not achieved until a union occurred with glacial Lake Ojibway in northern Ontario about 8,400 years ago. At this maximum, terminal stage, the resulting megalake covered about 840,000 km², and held about 160,000 km³ of water (Leverington et al., 2002). This is double the volume of the largest modern lake, the Caspian Sea, but the paleolake was highly unstable. It was dammed by remnants of the Laurentide Ice Sheet, which was severely weakened by the influx of marine water into Hudson Bay. The stage was set for a massive sub-glacial outburst of the Lake Agassiz water through Hudson Strait into the Labrador Sea, a probable trigger for the 8,200 yr B.P. cold event – the most abrupt and widespread global climatic cooling event to have occurred within the last 10,000 years (Clarke et al., 2003).

Central Asian paleolakes

In the mountain areas of central northern Asia, there were probable ice-dammed expansions of modern Lakes Baikal (31,500 km² area; 23,000 km³ volume) and Issyk-Kul (6,000 km² area; 4,000 km³ volume). In the Altai Mountains, great megafloods emanated from the late Pleistocene ice-dammed Chuya-Kuray paleolake, covering 12,000 km² and holding 1,000 km³ of water, perhaps 900 m deep at the ice dam (Baker et al., 1993).

The lowland glacial lakes of Siberia involved the expansion of huge ice sheets that covered the shallow seas north of Eurasia and blocked north-flowing rivers, notably the Ob, Irtysh and the Yenesei. Grosswald (1980) interpreted this blockage to be Late Weichselian in age (about 15–20,000 years ago), but more recent work considers the events to be Early Weichselian (about 90,000 years ago) (Arkhipov et al., 1995). The largest lake, formed on the west Siberian plain, was estimated by Mangerud et al. (2001) to cover 600,000 km² at a surface elevation of 60 m. However, both Arkhipov et al. (1995) and Grosswald (1980) postulate a much larger paleolake, about 1,200,000 km² in area, with a volume of about 75,000 km³ at a surface elevation of 128 m. This west Siberian megalake was the Asian equivalent of Agassiz. It drained southward, through the Turgai divide of north-central Kazakhstan, to the basin of the modern Aral Sea. The latter rose from its 1960 elevation of 53 m to 70 or 80 m, enlarging from 60,000 km² (1960 area) to about 100,000 km² in the Pleistocene. This paleolake then drained southwestward through the Uzboi Channel into the basin of the modern Caspian Sea. Also fed by glacial meltwater from northern Europe via the Volga, the Caspian expanded during its late glacial Khvalyn phase to an area of 950,000 km², holding a volume of 135,000 km³ at an elevation of 50 m (the modern Caspian level is –28 m). The Khvalyn paleolake drained via the Manych paleochannel and the Don River to the basin of the modern Black Sea. The Black Sea was then disconnected from the Aegean and filled by freshwater (the New Euxine phase); the glacial meltwater filled the basin to an elevation of –60 m. This basin functioned in two modes during the Quaternary. Its cold-climate mode was a freshwater lake (that may have filled and drained through the northwestern Turkey to the Aegean). Its warm-climate phase involved rising global sea level, inducing salt-water invasions through the Turkish straits to form the saline Black Sea, the last of which occurred about 8,000 years ago, an inundation that may have inspired the story of Noah (Ryan et al., 2003).

GLACIAL SEDIMENTS

Glacial sediments are formed in association with glacier ice in subglacial, ice marginal, lacustrine and marine environments. In such diverse environments, sediment can be reworked and deposited by a very wide range of processes, including subglacial lodgement, deformation and melt-out, subaerial and subaqueous mass-movements, fluvial processes, and settling through a water column. Numerous attempts have been made to classify the resulting range of sediments in schemes of greater or lesser complexity (Dreimanis, 1989), incorporating many varieties of “till” (e.g., flow till, lowered till, waterlain till, iceberg till). Many of these proposed sediment types are difficult to distinguish in the field, however, and a simple classification scheme is now favored by most workers. A fundamental distinction can be made between *primary glaciogenic deposits*, formed by exclusively glacial processes (such as subglacial lodgement, melt-out and deformation),

and *secondary deposits*, formed by the reworking of glaciogenic debris by processes not unique to glacial environments (Lawson, 1989). In terms of their internal characteristics, secondary glaciogenic deposits can be indistinguishable from sediments formed by similar processes in non-glacial environments and so, seen in isolation, they do not provide unequivocal evidence for the former presence of glacier ice. A glacial origin, however, can be determined from the *context* of such sediment facies, particularly the range of associated facies and structures, and the form and distribution of overlying landforms. It is therefore helpful to take a hierarchical approach to the analysis and interpretation of glacial sediments, in which individual facies are interpreted in terms of their *process* of deposition, and sediment-landform associations (comprising suites of genetically-related facies) are used to reconstruct former depositional *environments* (cf. Walker, 1992; Benn and Evans, 1998).

The characteristics of glacial sediments reflect the processes of entrainment, transport, and deposition experienced by debris as it travels through a glaciated basin. One of the most distinctive characteristics of glacial sediments is the presence of *erratics*, or exotic, far-traveled material. For Quaternary deposits, the provenance of erratics can often be pinpointed, allowing patterns of glacier flow to be reconstructed with some accuracy. For older successions, however, this may not be possible, especially if sediment exposure or preservation is poor. Erratics do not occur in all glacial deposits, however, and some are dominated by local material, eroded and redeposited close to its source. Transport processes can also impart a distinctive glacial signature on sediments. Debris transported at glacier beds is commonly subjected to high inter-particle contact forces, and the resulting abrasion and crushing of particles produces distinctive clast morphologies and particle size distributions. Clasts are commonly striated (particularly finer lithologies) with smooth, polished facets on their upper and lower surfaces, and may have asymmetrical *stoss-lee* or bullet-shaped forms. The presence of such clasts in a deposit does not necessarily mean, however, that it was deposited in a subglacial environment, because glacial debris can be carried far beyond glacier margins by various processes prior to final deposition. Some of these processes (such as fluvial transport) will result in rapid clast rounding and obliteration of striae and other glacial signatures, whereas others (such as iceberg rafting) may carry debris for hundreds of kilometers with little or no modification. Particle size distributions of subglacially-transported debris commonly exhibit a very broad range of grain sizes, from clay or silt up to pebbles or larger, and are typically bimodal or polymodal. The finer particles (<63 μm) are formed during subglacial abrasion, and are sometimes known as *rock flour*. Other particle size modes may reflect fracturing or crushing of larger clasts along joints, grain boundaries and other weaknesses. Whereas subglacial transport produces distinct debris characteristics, debris transported in englacial and supraglacial positions generally undergoes little or no modification and commonly retains the character of the parent debris. For this reason, supraglacial and englacial debris transport is known as *passive transport*, in distinction to *active* subglacial transport (Boulton, 1978; Benn and Evans, 1998), although some limited clast modification can occur during passive transport. Passive transport is particularly important in mountain environments, where large quantities of debris are delivered to glacier surfaces by rockfall and other mass movement processes. Fluvial processes can also transport significant quantities of sediment through some glaciers, resulting in significant clast rounding and size sorting. Thus, although striated, faceted clasts and rock flour are typical of subglacially transported debris, they are not essential

characteristics of glacial sediments, nor do they provide unequivocal evidence of ice-contact deposition.

Debris can be released from glacial transport at the glacier bed, or at subaerial or subaqueous glacier margins. In the former case, *tills* can be formed by the frictional lodgement of particles against the bed, the deformation of weak subglacial materials, or the melt-out of debris-rich ice. Subglacial deformation is now thought to be a very important till-forming process, especially where ice-sheets override soft sedimentary rocks or unlithified sediments. High cumulative strains may result in the complete mixing of the parent materials, creating diamicts which may be hard to distinguish from other till types. Paradoxically, subglacially deformed sediments are often easier to identify where cumulative strains are lower, because structures and textures inherited from the parent material are more likely to survive, and patterns of deformation easier to recognize. Such *glaciotectonites* are typically heterogeneous, incorporating laminae, boudins or rafts of pre-existing materials, often complexly folded and faulted. Glaciotectonites and deformation tills often occur in close association. Lodgement is an important process beneath wet-based ice; large boulders are especially likely to lodge against the bed, and are then molded by overpassing ice into asymmetrical stoss-lee forms resembling roches moutonnées. Although the term *lodgement till* is widely used (especially in the older literature) it is unlikely that lodgement, acting alone, can result in thick till units, and it is likely that most subglacial tills have undergone some degree of deformation. Melt-out tills are susceptible to reworking by slope processes or during dewatering, and thick, undeformed melt-out till sequences generally have low preservation potential. Sediments deposited below active ice are commonly streamlined. Long, narrow ridges of till (fluted moraines, or flutes) may extend downglacier from boulders or other obstructions on the bed, reflecting till deformation into cavities at the glacier sole. Drumlins are larger streamlined bedforms, commonly with complex internal stratigraphies. They may have rock or sediment cores (which may be deformed or undeformed), with an outer carapace of till or glaciotectonite. The most widely accepted origin for drumlins involves selective deformation, erosion and deposition of a soft glacier bed, although other ideas have been proposed.

Debris released by melting at a glacier surface or along terrestrial ice margins is commonly reworked by a wide variety of processes, including debris flow, other mass movements such as falls, slides and slumps, and the action of flowing water and wind. All of these processes will modify sediment characteristics to some degree. In particular, grain-size distributions are strongly influenced by fluvial action, fall sorting, winnowing by wind, and other processes, and many secondary glacial deposits exhibit a narrower range of grain sizes than subglacial tills. The simplest ice-marginal deposits consist of aprons of diamicts (debris flow and other mass movement deposits), and gravels and sands (glaciofluvial deposits) built up around the ice margin. Such *dump moraines* have a fan-like internal geometry, with beds dipping out from the ice margin at angles up to $\sim 35^\circ$. Dump moraines are particularly common around debris-covered glaciers in high mountain environments, and may form steep-sided ramps >100 m high. In many ice-marginal environments, however, sediments may be deposited and reworked several times as the local topography is altered by ice melting and oscillations of the glacier margin. Consequently, many ice-marginal sediment sequences have complex stratigraphies consisting of complexly interbedded diamicts, gravels, sands and silts, affected by faults and folds. Advances of the ice margin can

bulldoze ice-marginal and proglacial sediments into push moraines, or larger-scale glaciotectonic thrust-block moraines, with complex internal deformation structures (Benn and Evans, 1998).

Many glaciers terminate in lakes or the sea, and a large part of the glacial geologic record consists of glaciolacustrine and glaciomarine sediments. The character of subaqueous glacial sediments depends on the activity of the ice margin, sediment supply, meltwater discharges, and whether the ice is grounded or floating. At temperate glacier margins, where meltwater discharges are high, sedimentation may be dominated by subaqueous outwash, forming fans of crudely-sorted gravels and sands interbedded with fine-grained drapes deposited from meltwater plumes. If glacier margins are sufficiently stable, subaqueous fans can accumulate to the waterline, whereupon they evolve into ice-contact deltas. These have a three-fold internal stratigraphy, consisting of (a) low-angle topsets of gravel or sand, formed at the delta top; (b) dipping foresets formed on the delta foreslope; and (c) low gradient bottomsets, formed by the settling of fine sediments from turbidity currents beyond the delta front. Progradation of a delta can result in these sediments forming a vertical succession. Some subaqueous ice margins are dominated by mass movements, including debris flows, slumps and slides. Such mass movements tend to become more dilute and finer-grained down-flow, forming turbidity currents. These are particularly common in glaciolacustrine environments, where they form distinctly laminated successions consisting of basal graded sands, rippled sands and silts, laminated silts, and an upper drape of fine-grained sediment. Glaciolacustrine turbidites should not be confused with varves, which are annually deposited couplets consisting of a clay layer deposited during the winter (when the lake surface is frozen and sediment input is small) and a coarser layer deposited in summer. In contrast, turbidites are deposited rapidly (over a few minutes to hours in glacial settings), and lack a winter clay layer. Where glacier ice is in direct contact with lake- or seawater, calved icebergs can transport debris far beyond ice margins, then release it as they progressively melt or overturn. Dropstones can occur as isolated particles within fine-grained sediments, or in iceberg dump mounds. Sediments with high concentrations of dropstones are termed dropstone muds or dropstone diamicts.

During the last three decades, glacial geologists have amassed a large amount of data on modern glacial sedimentary environments in different climatic and topographic settings. This information has been used to define a range of glacial land system models, which can guide the interpretation of the glacial geologic record of the Pleistocene and older glacial epochs (Evans, 2003). Caution must be employed when appealing to modern analogs in glacial geology, because some former events or environments may not have modern equivalents, either in kind or in magnitude. With due care, however, modern analogs provide a powerful means of extracting maximum information about former depositional processes, environments, ice-margin activity, and climatic setting from Earth's rich glacial geologic record.

GLACIATIONS, PRE-QUATERNARY

Introduction

Earth has experienced recurring periods of glaciation (icehouse climatic conditions) alternating with periods of warm climate (greenhouse climatic conditions) (Figure G41; Hambrey and Harland, 1981; Eyles, 1993; Crowell, 1999). Glaciations have occurred on one continent or another, except for the Mesoproterozoic (ca. 2–1 Ga) in Precambrian times and the Mesozoic (250–65 Ma) in Phanerozoic times (Figure G42).

Changes in insolation, agglomeration, splitting and drifting of continents and associated orogenies are the first-order controls for changing climatic conditions on Earth. Some glacial periods correlate reasonably well with major orogenic phases (Figure G41); that is, with the agglomeration of continents and the change in distribution and volume of oceanic basins. The relative position and elevations of continents affected oceanic and atmospheric circulation, along with redistribution of heat, as well as degree of weathering of exposed rock and associated sequestration of atmospheric CO₂. These factors all contributed to the development of greenhouse and icehouse conditions and glaciations. Other factors such as orbital parameters further modulated the behavior of glaciers during ice-house periods.

Recognition of ancient glaciations is based on type and distribution of sedimentary deposits, fossil assemblages and their isotopic composition, and, in some cases, on erosional features. However, the older the glaciation, the less reliable and abundant the information is. Ancient glacial deposits may have been deeply buried, modified by metamorphism or selectively preserved in basins not subsequently affected by erosion. In addition, it is more difficult both to interpret the paleoenvironment of older deposits as different processes may have formed similar features, and also to date them because fossils or other suitable dateable material may be absent, and chemical (isotopic) composition of waters and atmosphere may have been different or altered.

The following are the most common, effective lines of evidence used to establish the occurrence of an ancient glaciation. No single indicator, however, provides unequivocal proof of

glaciation; it is the assemblage of several criteria, abundantly present in an area, which can be used to infer cold climate and presence of glaciers.

Depositional features

The presence of widespread *diamictite* (thick when marine), associated with cold-climate indicators is the most frequently used criterion to establish glacial conditions. Diamictite is a rock derived from diamicton – a poorly sorted mixture of mud, sand and gravel (Figure G43). Diamicton may be deposited directly by glaciers (till; tillite when cemented), or formed by other sedimentary processes, such as rainout of fine-grained suspended sediment and ice rafted debris, and debris flow in terrestrial or subaqueous conditions. The presence of extensive diamictite that contains faceted clasts is a strong initial clue of glaciation, when tectonic influences (such as non-glacial debris flow caused by tectonic activity) can be confidently discarded. However, it is difficult to determine whether diamictite is of glacial or non-glacial origin. It is therefore critical to look at the characteristics and distribution of associated deposits in order to establish the paleoclimatic significance of diamictite. When abundant, *shape and surface texture of clasts*, from bullet-shaped, faceted, and striated pebbles and boulders, to imprints and chattermarks on sand grains, are powerful indicators of glacial action. However, these may not always demonstrate direct deposition by ice, as clasts may be reworked under other depositional conditions. Although *boulder pavements* are commonly used as glacial indicators in the Quaternary, they are rarely identified in more ancient examples. *Dropstones* (lonestones) and deposits with textural inversions (such as randomly distributed lenses or pockets of sand and/or coarser-grained material in fine-grained deposits) are interpreted to indicate ice rafting and dumping from iceberg and seasonal ice floes, although they need to be distinguished from material rafted by floating organic debris (algae, trees) in the Phanerozoic. Presence of sand, silt, and clay *rhythmites* in lacustrine and marine deposits may contribute to a glacial interpretation, although they may also be formed by turbidity currents not necessarily derived from glaciers. True *varves*, the typical clay-silt or silt-sand couplets formed annually in ice-covered lakes, are rarely identified in pre-Quaternary successions because it is usually impossible to confirm that each couplet represents a year of deposition. Of interest is the fact that loess, so common in Pleistocene periglacial settings, is rarely reported from pre-Quaternary glacial deposits. This may be a matter of poor preservation of exposed terrestrial material; its ancient equivalent would likely be subaqueous silty deposits. Depositional landforms such as drumlin and eskers have rarely been used to establish glaciation, one of the debatable exceptions being for the Carboniferous in Brazil.

Biological and geochemical features

Cold climate *flora* (mainly terrestrial) and *fauna* (terrestrial and marine) and their related deposits, such as coal and ooze, are strong indicators of cold settings during Phanerozoic times. *Isotope* (such as O, C) analyses of skeletal marine microfossils can also provide indication on the presence and amount of glacial ice.

Erosional/deformation features

Abraded pavements on bedrock are often found with striations, and some chatter marks, crescent gouges, and lunate fractures.

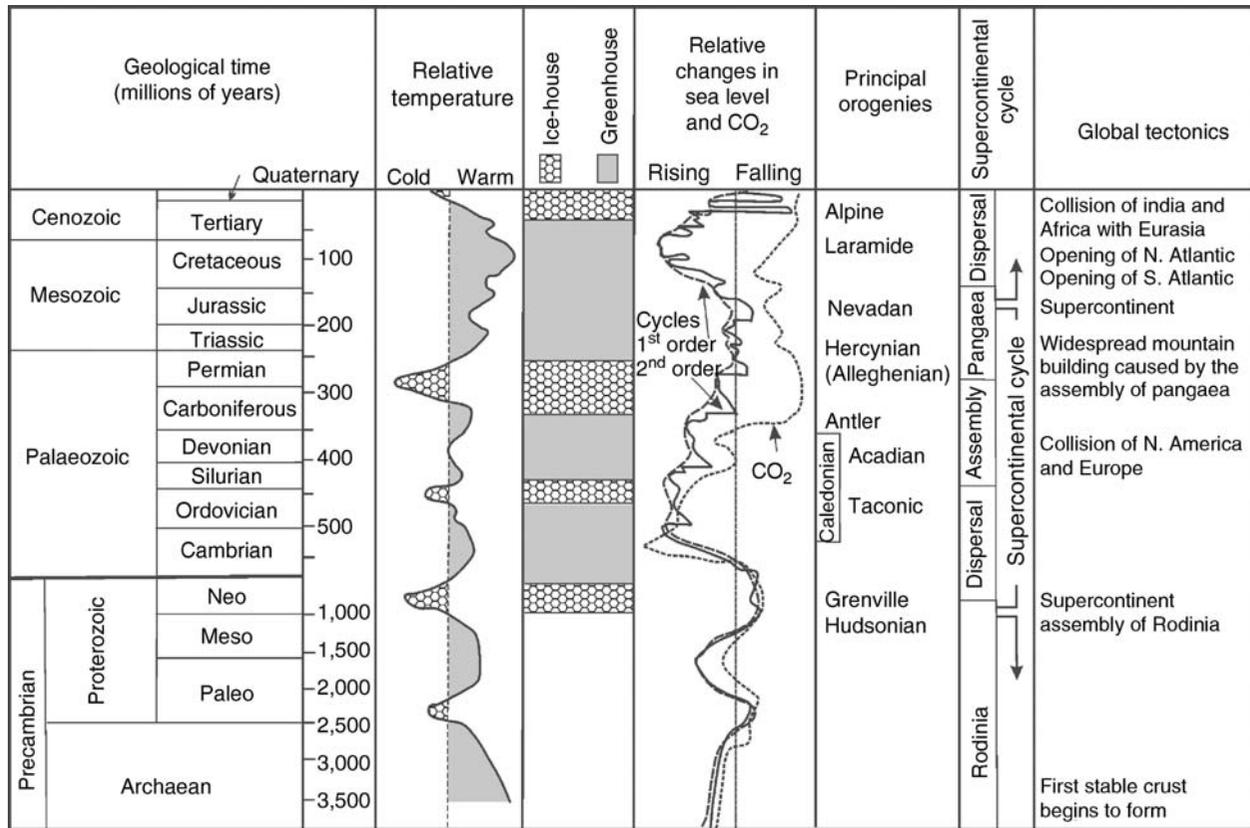

Figure G41 Major tectonic, environmental and climatic change on Earth (after Doyle et al., 1995; with data from Berner, 1990; Young, 1999).

Striated pavements are common throughout the ages (Laajoki, 2002). They can be formed by glaciers, but also by other unrelated tectonic (slickensides) and depositional (debris flows) processes. *Large-scale erosional features* such as *roche moutonnées*, crag and tails, and rock channels have rarely been used to establish glaciation, except in exhumed Ordovician surfaces in northwest Africa. When extensive, *furrows* in marine and lacustrine deposits are occasionally taken to indicate scouring by icebergs or seasonal ice floes (such as for the Ordovician in Brazil). Associated with other cold climate evidence, *sandstone wedges* have also been used to infer frozen ground conditions.

Precambrian glaciations

Archean

Archean-age glacial deposits (2,990–2,870 Ma) have been reported from South Africa. Diamictites are observed with occasional striated and faceted clasts at three different stratigraphic levels within the Witwatersrand Basin, both in outcrops and subsurface mining walls. Diamictite up to 80 m thick containing glacially striated and faceted clasts has also been found in the Pongola Basin. Other diamictites have been observed in northern Europe and North America but their glacial origin is debated.

Paleoproterozoic

Glacigenic deposits of Paleoproterozoic age have been documented in North America (Huronian), South Africa (Makganyene),

Finland-Russia (Karelian) and western Australia (Hammersley). Good exposures of Paleoproterozoic glacial deposits occur within the Huronian Supergroup in Ontario, Canada. The Gowganda Formation consists of diamictites with some faceted clasts overlying striated pavements, and thinly laminated argillites with abundant dropstones. These diamictites have accumulated in a predominantly glaciomarine setting. The laminated argillites were thought to be varves formed in a glacially influenced, subaqueous setting, but this cannot be confirmed in the absence of high resolution (annual) dating of these deposits.

The age of the Gowganda Formation has been bracketed between 2,670 and 2,220 Ma by underlying volcanic rock and a cross-cutting diabase. The ages of other Paleoproterozoic glacigenic successions are equally poorly constrained and range between 2,050 and 2,700 Ma, whereas the deposits in South Africa, Finland-Russia and western Australia are thought to be broadly correlative with the North American Huronian glacial deposits, their synchronous deposition is speculative.

Neoproterozoic

The striated pavement and overlying diamictite exposed on the shores of Varangerfjorden, Norway (Figure G43) were first described in 1891 and used to infer a Precambrian-age glaciation. This was one of the first Neoproterozoic glacial deposits to be described; others have since been documented from every continent (Crowell, 1999). Evidence for glacial conditions includes striated pavements, striated and faceted clasts, marine diamictite and laminated mudstone with dropstones.

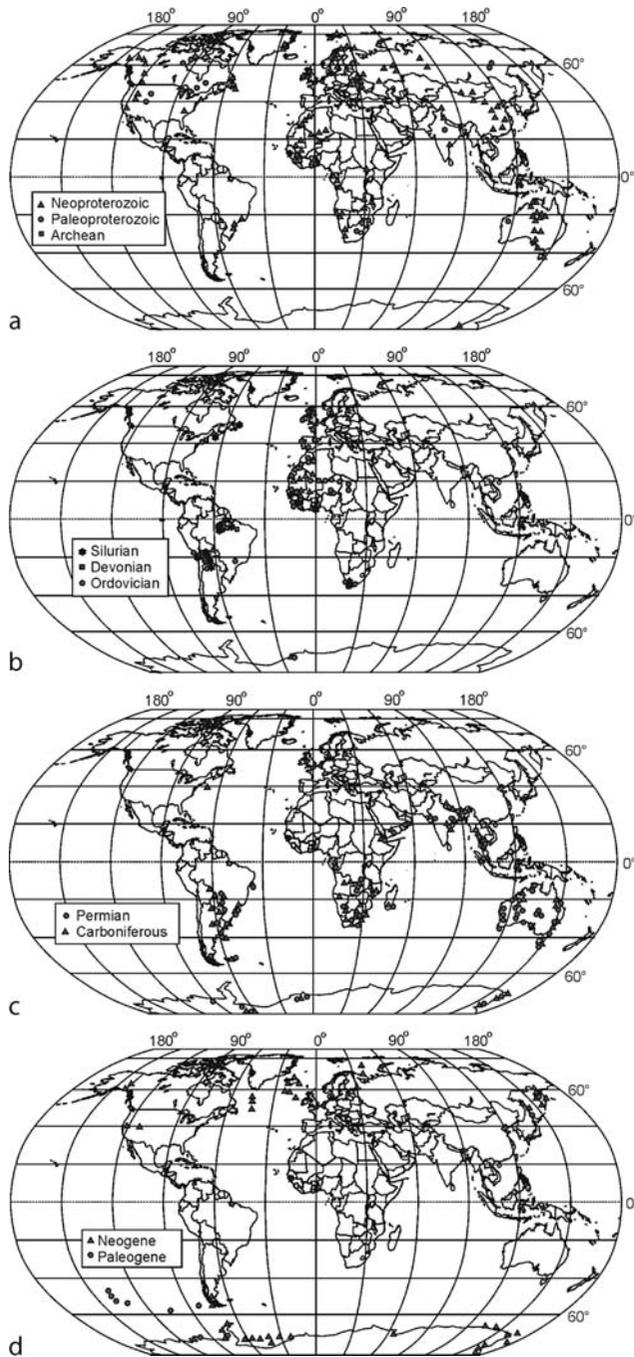

Figure G42 Maps of locations showing the recorded glacial features on Earth: (a) Precambrian; (b) Early Paleozoic; (c) Late Paleozoic; (d) Cenozoic (after Hambrey and Harland, 1981; Martini et al., 2001; and some data from Evans, 2000).

Two major glacial periods have been established in the Neoproterozoic, with growing evidence for a third. Glacial deposits are commonly ascribed to either of the two glacial periods based on lithological characteristics, biostratigraphy (acritarchs and Ediacaran fauna), chemostratigraphy ($\delta^{13}\text{C}$) of associated carbonates and radiometric dates (Hambrey and Harland,

Figure G43 Neoproterozoic diamictite of the Smallfjord Formation overlying a striated pavement, Bigganjargga, northern Norway.

1985; Knoll, 2000). The oldest glaciation (ca. 750–670 Ma) is commonly referred to as Sturtian, whereas the youngest (ca. 635 Ma) has been referred to as Marinoan (Australia, Canada) or Varangian (North Atlantic). However, there is still much debate about the age and stratigraphic correlation of these glacial deposits and the number and extent of Neoproterozoic glaciations (Knoll, 2000; Kendall et al., 2006).

Various aspects of the Neoproterozoic geologic record suggest that glaciations of this time may have been more severe than those of the Phanerozoic. The widespread distribution of diamictites, including some at low paleolatitude, has been used to infer that ice possibly covered the entire world (Harland, 1964). Inferred glacial deposits are commonly associated with carbonates that exhibit strong fluctuations in $\delta^{13}\text{C}$. The close juxtaposition of glacial deposits and presumably warm water carbonates has been used to suggest relatively rapid climate change between glacial and warm conditions, whereas the $\delta^{13}\text{C}$ fluctuations imply significant perturbations in seawater geochemistry (Harland, 1964; Hoffman et al., 1998). The low latitude (equatorial) deposition of some glacial deposits has been suggested by paleomagnetic analyses, although it has only been confidently demonstrated for the Elatina Formation in Australia (Evans, 2000). Nevertheless,

several scenarios have been proposed to explain low latitude glaciations, including a “snowball” Earth encased in ice as a result of increased reflectivity or “runaway albedo,” glaciations during a significant change in tilting of the Earth’s rotating axis, and high-mountain glaciers associated with tectonic uplift. Further research on Neoproterozoic successions and a more robust geochronological framework are needed to fully evaluate the plausibility of these scenarios.

Phanerozoic glaciations

Extensive glaciations occurred during the Phanerozoic. The Ordovician and Permo-Carboniferous ones were widely distributed across mid-to high-latitudes (Evans, 2003). No glaciations have been recorded during the Mesozoic, although the presence of ice at the poles has been suggested by local occurrence of rafted debris.

Paleozoic glaciations

The Paleozoic is characterized by three periods of icehouse conditions centered over North Africa and South America (Ordovician), South America (Devonian), and Australia, Africa, South America, India and the Arabian Peninsula (Carboniferous) (Figure G42). This reflects, for the most part, polar wandering and drifting of the continents into and away from mid-high latitudes where glaciers could develop (Caputo and Crowell, 1985).

The *Ordovician* glaciation (ca. 440 Ma) was the first major Phanerozoic glaciation; it was centered in northwestern Africa (Ghienne, 2003). The evidence consists of a widespread exhumed surface with striated pavements, polished surfaces and other erosional features, and well-developed diamictites (presumably tillites). Glaciomarine deposits of equivalent age are reported from farther south, in Sierra Leone. One apparent anomaly is that the Ordovician glaciation occurred when the tropical water temperature was just 3 °C cooler and the CO₂ partial pressure was about 15 times higher than the present (Figure G41). This suggests that cooler conditions are not always related to low concentrations of CO₂ in the atmosphere. Perhaps the location of continents near the poles offset these apparently adverse conditions in order for glaciation to occur.

The Ordovician glaciation had a worldwide effect on relative sea-level change. It contributed to the interruption of the major, early Phanerozoic transgression, forcing a regression from the Ordovician to the Silurian. The postglacial transgression led to the re-establishment of normal fauna, and extensive development of reefs and of several, early Silurian euxinic basins. This cycle is recognized in various places, such as South Africa, Turkey, South America, Europe and North America, where either thin diamictites and/or significant unconformities mark or occur stratigraphically close to the Ordovician-Silurian boundary.

Though not yet well studied, early *Silurian* deposits of possible glacial origin have been reported from southwestern South America (Argentina, Brazil, Bolivia).

The *Devonian* glaciation was mostly limited to South America (Caputo and Crowell, 1985). The evidence consists mainly of widespread, thick (up to 600 m) marine diamictite whose origin has been indirectly related to regional glaciations.

During the *Late Carboniferous–Early Permian* (~350–250 Ma), Earth experienced some of the most widespread and longest glaciations recorded during the Phanerozoic. These glaciations affected the southernmost part of Pangea with terrestrial (tillites?) and widespread marine diamictites occurring

primarily in Australia, South Africa, South America and southern Asia. The growing and waning glaciers also had significant impact on distant northern lands, where thick, coal-bearing deposits show cyclicity (cyclothems) that ultimately records relative sea-level changes. For the first time in Earth’s history, cold climate conditions are also indicated by terrestrial plants and coal deposits (Figure G44). Although these ancient plant assemblages were very different from the present ones, they occupied analogous environments and produced similar products (peat; coal upon diagenesis). In most cases, the Permian-Carboniferous diamictites are overlain by marine deposits, and these in turn by continental deposits, some bearing coal derived from warm-climate peat. In other instances though, glacial deposits are interlayered with and overlain by coal-bearing units, where the cold climate origin of the coal can be established through pollen and plant macrofauna analysis. A good record of climatic changes from Upper Carboniferous-lowermost Permian glacial cold conditions to middle-upper Permian-Triassic warm settings has been established in South Africa (Figure G44; Falcon, 1989).

Cenozoic glaciations

The Tertiary (65–2 Ma) and Quaternary (2 Ma to Present) periods constitute the Cenozoic Era. Here we deal with the deteriorating Tertiary climate and possible glaciations that developed at high latitudes. The warm climate conditions persisted throughout the globe during the early Tertiary with its warmest time about 50 Ma (Eocene); this is indicated by vertebrate fossils such as alligators in Arctic islands and tropical marine microfossils (foraminifera and coccoliths) in North Atlantic deposits. Climatic deterioration occurred from 40 to 25 Ma (late Eocene and Oligocene), leading to the colder conditions of the late Cenozoic Era. Ice rafted material and $\delta^{18}\text{O}$ of marine microfossils indicate that Antarctic polar sea ice and continental glaciations may have developed by about 36–34 Ma (early Oligocene). The Antarctic glaciations expanded considerably between 15–10 Ma (Miocene). Associated large sea-level changes dramatically influenced distant areas. For example, the connection between the Mediterranean Sea and the Atlantic Ocean was cut off at this time, leading to widespread deposition of evaporites and what is commonly referred to as the Mediterranean (or Messinian) salinity crisis. The onset of glaciations in the Northern Hemisphere dates from about 6 Ma and the mid-latitude continental ice sheets started developing approximately 3 Ma ago (Pliocene). This is indicated by variations in marine microfossil fauna and abundance of ice-rafted material in northern seas.

Conclusion

Glaciations have existed on various continents throughout Earth history, although some local records are still debated. Many hypotheses have been put forward to explain the distribution of glacial periods in time and space, none of which is all encompassing. Every major glaciation has its own peculiarities, but all appear to require a cool atmosphere, the presence of continents at or near the poles, and some region-wide obstruction that impedes the redistribution of heat across latitudes. An intriguing correlation that has long been noted is the development of icehouse conditions with major orogenies that change the physiography of a significant part of the Earth’s surface and may indirectly affect the composition of the atmosphere. In addition, the two longest cold periods (Neoproterozoic and Permian-Carboniferous) coincide with periods of time where global

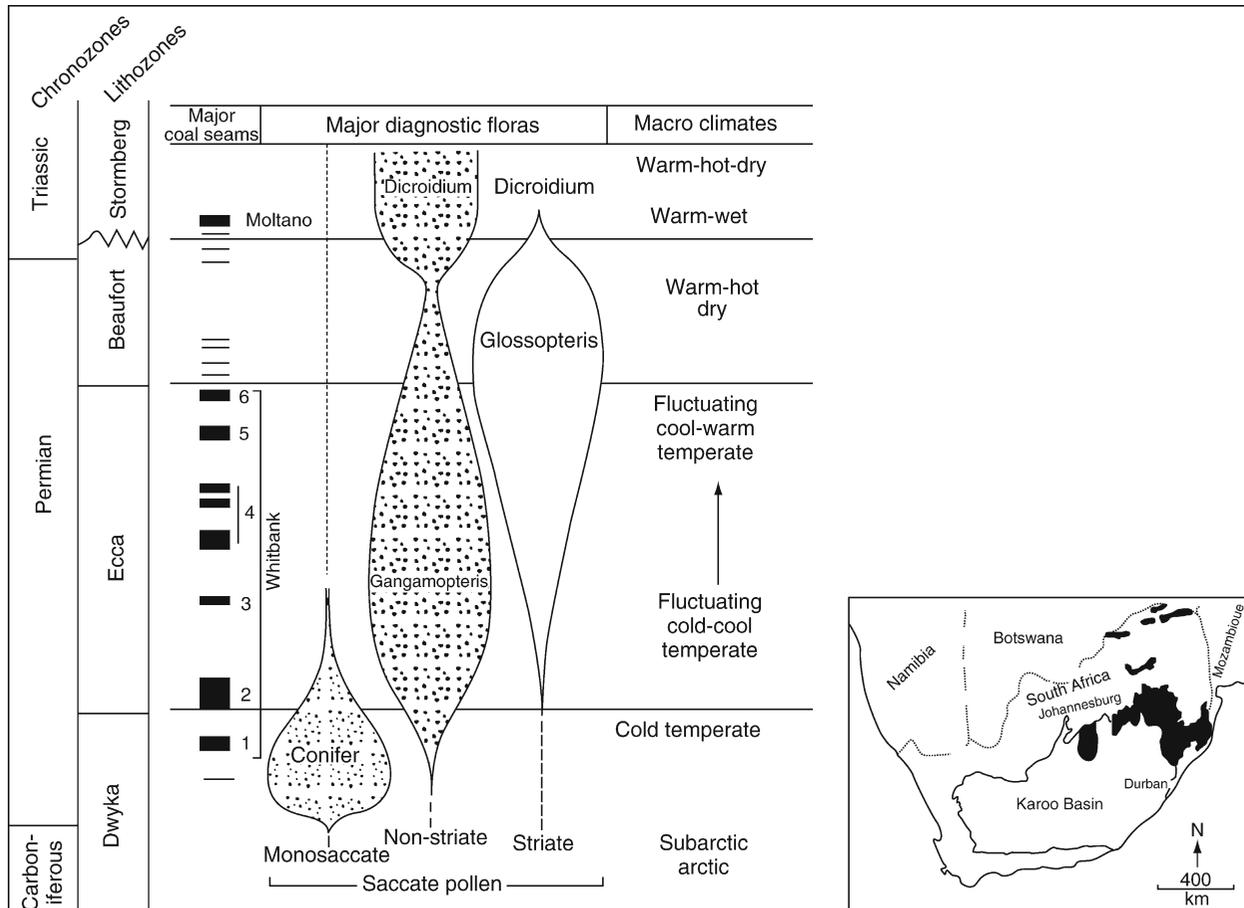

Figure G44 Schematic diagram showing the stratigraphy, major coal seams, diagnostic floras and inferred macroclimates for the Upper Carboniferous to Triassic succession in South Africa. The succession records the following changes in depositional environment: glacially-influenced marine conditions (Dwyka Group), deep to shallow marine environments (Ecca Group) and fluvial environments (Beaufort and Stormberg Groups). Note the change in diagnostic flora from the glacial conditions of the Late Carboniferous-early Permian to the temperate-cold middle Permian, and to the warm late Permian-Triassic (from Martini et al., 2001; after Falcon, 1989). Inset: distribution of coal.

paleogeography was characterized by supercontinents. Recent developments in various fields of geology (such as isotope geochemistry and geochronology) provide promising avenues of research in pre-Quaternary glacial geology.

GLACIATIONS, QUATERNARY

Overview

The Quaternary Period spans the last 2 million years (Myr) and includes the Pleistocene Epoch of Earth history, which prevailed for most of the Quaternary, and the Holocene Epoch beginning around 11,000 years ago. The Quaternary Period has been a time of profligate environmental and climatic change, characterized by a sequence of roughly 30 glacial-interglacial cycles in the Northern Hemisphere (Figure G45). This period of Earth history is colloquially known as the “Ice Age,” the time when ice sheets rolled up and down “like great white window blinds” over the landscape (Annie Dillard, *Pilgrim at Tinker Creek*).

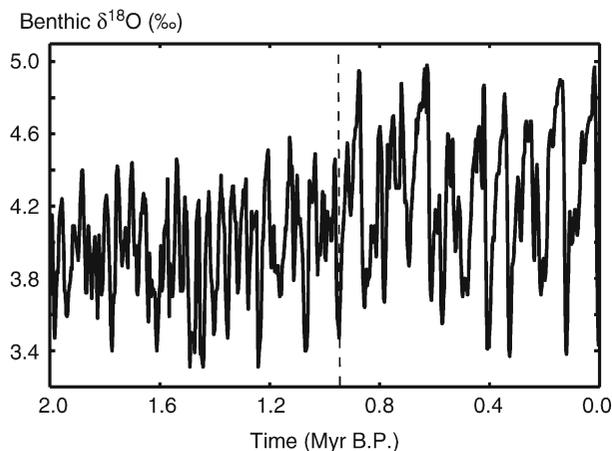

Figure G45 Marine benthic $\delta^{18}\text{O}$ variability over the last 2 Myr, from ODP core 677 (0.4–2 Myr B.P.) and SPECMAP stacked data (0.4 Myr B.P. to present) (based on Imbrie et al., 1993, SPECMAP Archive #4; IGBP PAGES/World Data Center-A for Paleoclimatology, data contribution series 93-031, NOAA/NGDC Paleoclimatology Program, Boulder CO).

This article summarizes the geological and paleoceanographic evidence of the Quaternary ice sheets, with emphasis on the chronology of glacial-interglacial cycles and the geographic distribution of the ice sheets. This is followed by an expanded discussion of ice sheet-climate interactions and the potential causes of Quaternary ice sheet growth and decay. Although the exact forcing mechanisms and internal climate-system interactions that cause glacial-interglacial cycles are not fully understood, many of the principal ingredients in Quaternary climate dynamics have been identified. Outstanding questions and puzzles about the Quaternary glaciations are highlighted throughout the discussion.

Observations

The glacial-interglacial cycles that distinguish the Quaternary are recorded in a number of geological and paleoceanographic archives, including deep-sea and lake sediments, ice cores, glacial landforms, coral reefs, ancient groundwater, cave records, over-consolidated sediments, loess deposits, fossil pollen, and relative sea-level reconstructions. This rich array of geological data cannot be fully summarized here, but interested readers are referred to Bradley (1999) for an expanded discussion of methods of paleoclimate reconstruction.

Marine sediments

The most detailed record of glaciation during the Quaternary comes from the marine deep-sea sediment record (e.g., Figure G45). Foraminifera in both the surface- and deep-sea (benthic) water column make use of ambient seawater to build calcium carbonate shells. Individual planktonic shells are labeled with oxygen isotope ratios, $\delta^{18}\text{O}$, that are representative of the local water. Upon their demise, foraminifera sink to the bottom and are entombed in sediments. Rainout of marine sediments and carbonate shells is slow in deep-water environments, typically on the order of cm per 1,000 years. Deep-sea sediment cores therefore permit continuous stratigraphies that extend millions of years into the past, with numerous chemical and isotopic signatures of paleoenvironmental conditions.

Oxygen-18 in the CaCO_3 of marine foraminifera varies as a function of both ocean temperature and overall ocean chemistry (see *Oxygen isotopes*). During evaporation of surface water, it is energetically favorable to vaporize the lighter isotope ^{16}O in H_2O . This causes a net depletion of ^{16}O in surface waters and a concomitant enrichment of ^{18}O . In an equilibrium state of the hydrological cycle, water vapor precipitates over the ocean and continents, and continental precipitation returns to the oceans as river runoff, giving a net isotopic balance on time scales of months to years. During glacial times, however, continental ice sheets build up on the land and there is a net accumulation of light water isotopes on the continents. Sea level falls and the oceans become isotopically heavier. In Figure G45, benthic $\delta^{18}\text{O}$ therefore indicates the history of continental ice volume through the Quaternary. Heavy $\delta^{18}\text{O}$ values correspond to glacial times and light values represent interglacial conditions, such as the contemporary Holocene epoch. Modern benthic values in this reconstruction are 3.43‰, while the mean Quaternary value is 4.10‰. Up to 30 glacial-interglacial cycles are apparent in Figure G45, increasing in both amplitude and duration during the last 900 kyr.

Ice cores

While the marine sediment record provides the best available chronology of Quaternary ice volume, more direct proxies of Quaternary temperature are available from ice cores (see *Ice cores*,

Antarctica and Greenland). Ice from the summit region of the Greenland Ice Sheet provides high-resolution records of the last glacial cycle, ca. 120 kyr B.P. to present, with $\delta^{18}\text{O}$ and δD in the ice providing a proxy for glacial-period atmospheric temperatures in central Greenland (Figure G46; Dansgaard et al., 1993). The Greenland ice cores also illustrate a complex array of millennial-scale climate variability during glacial periods. In Vostok, East Antarctica, a 3,623-m ice core provides a detailed record of the last 420 kyr, a period that spans three glacial-interglacial cycles (Figure G47a; Petit et al., 1999). Accumulation rates are lower on the Antarctic Plateau than in Greenland, so climate reconstructions for the last glacial cycle

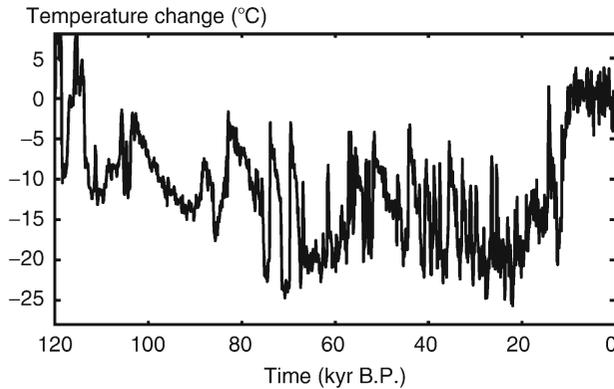

Figure G46 Temperature reconstructions for the last 120 kyr from the GRIP ice core, Summit Greenland (Dansgaard et al., 1993). Temperature reconstructions are based on $\delta^{18}\text{O}$ in the ice core and are expressed as perturbations from the modern surface temperature, using the isotope-temperature transfer function derived by Cuffey and Clow (1997).

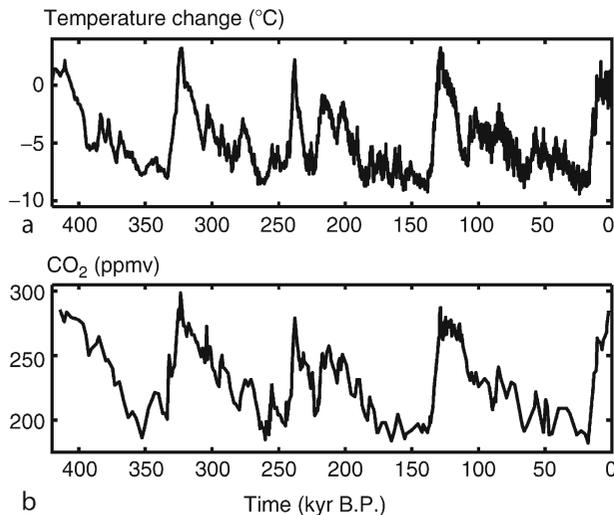

Figure G47 Temperature and carbon dioxide reconstructions for the last 420 kyr from the Vostok, Antarctica ice core. Temperature reconstructions are based on δD in the ice core and are expressed as perturbations from the modern surface temperature at Vostok (data from Petit et al., 2001, IGBP PAGES/World Data Center for Paleoclimatology, data contribution series 2001-076, NOAA/NGDC Paleoclimatology Program, Boulder CO).

have lower temporal resolution. Taking this into account, the record from Antarctica closely mirrors what is seen in Greenland.

Many other paleoenvironmental records are available from ice cores of Antarctica, Greenland, tropical glaciers, and Arctic icefields (see *Ice cores, Antarctica and Greenland*, this volume). These include samples of atmospheric gases in air bubbles that are trapped in the ice cores (Figure G47b), atmospheric aerosols and dissolved ions, and both direct and indirect climate proxies (for temperature and snow accumulation rates). While ice core stratigraphies offer superb detail, they broadly reflect what is seen in less-resolved stratigraphies from lake, loess, marine, and cave records in many regions of the world.

The last glacial cycle

The glacial geologic record on land does not afford the continuous chronology available from marine or ice cores, but it offers insights into the geographic distribution of ice sheets during glacial episodes. Evidence of multiple glaciations is clear in most regions of the Northern Hemisphere, but the terrestrial record has been largely obliterated by the most recent (Wisconsinan) advance and retreat of ice, beginning about 120 kyr B.P. Ice sheet nucleation appears to have occurred at this time in the Scandinavian mountains, Russian Arctic islands, and northeastern North America, with ice dispersal centers in the Queen Elizabeth Islands and highlands of Labrador and Quebec. There is no evidence of major ice advance in western North America at this time.

Multiple sequences of advance and retreat are apparent in the geologic record as ice sheets in North America and Eurasia grew fitfully to their Last Glacial Maximum (LGM) configuration at roughly 21 kyr B.P. (Dyke and Prest, 1987). The timing of maximum ice sheet extent differed in different regions, with 21 kyr B.P. marking the minimum sea level of the last glacial cycle (120–130 m below present). Ice sheets then melted back over the period 21–8 kyr B.P., with ice retreat punctuated by periods of rapid sea-level rise.

Table G2 presents estimates of present-day and LGM global ice sheet volume. Modern ice sheets harbor an amount of ice equivalent to almost 69 m of global sea level. At the peak of the last glaciation, terrestrial ice volume increased by roughly 270%, to 179–198 m sea-level equivalent. All of the world's ice masses grew during the last glaciation, including the Antarctic Ice Sheet and icefields in New Zealand, Patagonia, and tropical mountains. However, the bulk of additional ice at the height of the last glaciation built up in the Northern Hemisphere, when the confluent Laurentide, Cordilleran, and Innuitian ice complexes in North

Table G2 Ice sheet volume reconstructions for modern day and at the Last Glacial Maximum, 21 kyr B.P., expressed as sea-level equivalent

America were greater in size than modern-day Antarctica. A recent special volume of *Quaternary Science Reviews* (vol. 21, 2002) presents details on ice sheet, ocean, and climate conditions at the LGM.

Ice sheet area and volume at the Last Glacial Maximum is believed to be close to the maximum Quaternary extent of ice sheets in many regions. However, earlier glaciations reached further south in parts of the northern interior USA, and Quaternary ice sheet maxima in most of the high Arctic also predates the LGM. This is consistent with glacial-interglacial chronologies in marine and ice cores (Figures G45, G47a), which indicate a remarkably similar structure and amplitude of glacial-interglacial cycles over the last 900 kyr. The seemingly sudden switch in demeanor of glacial-interglacial cycles at 900 kyr, known as the mid-Pleistocene transition, is discussed in the next section on Quaternary climate dynamics.

Quaternary climate processes

Orbital variations

The underlying causes of Quaternary ice sheet advance and retreat are not fully understood, although there are convincing links with variations in the Earth's axis of rotation and its orbit around the Sun. Most important among these astronomical variations are changes in the eccentricity of Earth's orbit, the tilt of the rotational axis relative to the plane of the ecliptic, and the orientation of Earth's tilt axis (see *Astronomical theory of climate change*; Imbrie et al., 1993). Tilt axis orientation varies as Earth precesses like a top, with the effect of changing the latitude (hemisphere) that receives the most direct solar radiation at perihelion. This effect, known as the precession of the equinoxes, combines with orbital eccentricity to produce seasonal variations in insolation on long time scales; there would be no effect if Earth's orbit were circular.

These "Milankovitch" variations are regular cycles with periodicities of 100 kyr (eccentricity), 41 kyr (tilt), and 19 and 23 kyr (precession). Of these influences, only the first changes global annual insolation. Variations in tilt and precession change the geographic distribution and seasonality of insolation, and this appears to be key for triggering Northern Hemisphere (NH) glaciation and deglaciation. Cool NH summer configurations occur when there is high eccentricity and low axial tilt, and when NH summer coincides with aphelion, the moment in Earth's orbit when it is furthest from the sun.

Following up on the theoretical suggestions of Adhemar and Croll, Milankovitch surmised that cool summers at high northern latitudes were the key to ice sheet nucleation. His calculations of the orbital parameters and the associated variations in NH insolation bear a remarkable correlation with the marine record of continental ice volume (Figure G45). While the orbital variations are more purely periodic, orbital periodicities of 19, 23, 41 and 100 kyr are clearly evident in the marine sediment and ice core records. Therefore, astronomical variations have been called the "pacemaker of the Ice Ages" (Imbrie and Imbrie, 1979).

The orbital theory of the Ice Ages cannot explain many aspects of glacial-interglacial cycles, however. The direct radiative forcing associated with Milankovitch variations is too small to have acted as the sole control of glaciations. Orbital variations also produce insolation perturbations that are out-of-phase in the Northern and Southern Hemispheres, whereas both hemispheres experienced essentially simultaneous episodes of ice sheet advance and temperature depression during the Quaternary glaciations.

Additional difficulties are introduced by the time scales of variability. As detailed in Imbrie and Imbrie (1979) and Imbrie et al. (1993), the dominant period of late Pleistocene glacial cycles is close to 100 kyr, while orbital forcing is strongest at 19, 23 and 41 kyr. The mid-Pleistocene transition that is vividly evident in Figure G45 represents a switch from an early Pleistocene "Milankovitch world," where glacial-interglacial cycles occurred at 40-kyr time scales, to the late Pleistocene 100-kyr cycles noted above. This switch must have been caused by changes in internal climate and ice sheet dynamics, as the periodicity and amplitude of orbital variations have not changed during the Quaternary. Millennial-scale climate variability during glacial periods (Figure G46) also requires a non-orbital explanation, as the dramatic temperature changes witnessed in the Greenland ice cores occur at sub-Milankovitch frequencies (Clark et al., 1999a).

In summary, orbital influences are clearly evident in the timing and duration of glacial-interglacial cycles, but orbitally-driven insolation changes cannot explain many important aspects of ice sheet growth and Quaternary climate. Internal climate system amplifiers and feedbacks must have acted in concert with orbital variations to produce glacial-interglacial cycles. Subsections below introduce a number of these internal dynamical processes. Interested readers are referred to Clark et al. (1999a) for expanded discussion.

Internal dynamics: greenhouse gases

The Vostok ice core provides a remarkable record of carbon dioxide and methane variations over the last 420 kyr (Figure G47b; Petit et al., 1999). These gases are trapped in air bubbles in the ice, providing samples of the ancient atmosphere. Because CO₂ and CH₄ are well mixed in the troposphere, with a mixing time of less than a decade, these gas concentrations represent global levels of CO₂ and CH₄ through the last three glacial cycles. Concentrations closely track the change in atmospheric temperature that is recorded in the Vostok ice core (Figure G47a), which is calculated from deuterium and oxygen isotope ratios in the ice crystals.

CO₂ and CH₄ are radiatively active greenhouse gases and the reduced glacial concentrations of CO₂ and CH₄ would cause a direct global cooling effect, reinforcing cold conditions in glacial times. Similarly, elevated interglacial CO₂ and CH₄ concentrations are certain to have augmented interglacial warmth. Temporal variability in these gases therefore represents a significant internal climate feedback/forcing that is essentially phase-locked with global temperature and ice volume, within dating uncertainty. Because greenhouse gas impacts are global (that is, hemispherically-mixed), the reductions in glacial CO₂ and CH₄ concentrations help to transform the Northern Hemisphere orbital forcing into a global temperature perturbation.

The causes of glacial-interglacial CO₂ and CH₄ variations are a matter of debate. Variability in CO₂ concentrations arises from transfers between carbon reservoirs in the atmosphere, terrestrial biosphere, ocean mixed layer, and deep ocean. Because the deep ocean has a long residence time and is capable of holding huge carbon reserves, most theories of glacial CO₂ sequestration involve increased biological and physical uptake in the oceans. Glacial-interglacial variations in CH₄ are expected to have different causes and are more likely related to low-latitude terrestrial biological activity. Ruddiman (2001) offers a thorough introduction to Quaternary fluctuations in CO₂ and CH₄ and potential causes of CO₂ and CH₄ variability on glacial-interglacial time scales. Improved understanding of the glacial carbon cycle poses a high-priority challenge in current studies of Quaternary climate dynamics.

Internal dynamics: ice sheets

Glaciers and ice sheets exert a cooling influence on the climate by increasing the average topographic elevation of the landscape and by reflecting a large fraction of incoming solar radiation back to space. Both of these influences act as positive feedbacks to promote ice expansion once ice sheets are nucleated and to accelerate ice sheet retreat during deglaciation. These influences, particularly the ice-albedo (reflectivity) feedback, are believed to be critical to amplifying the modest changes in insolation associated with orbital perturbations. In modeling studies, cooling feedbacks from these processes make it difficult to melt away an ice sheet once it has established itself; model studies that permit free simulations of the ice-climate system have yet to simulate glacial terminations – transitions from glacial to interglacial conditions – in a satisfactory manner.

Additional ice sheet feedbacks arise due to internal, long-timescale processes associated with ice dynamics and glacial isostasy. Ice sheets flow by two principal mechanisms: (a) internal visco-plastic deformation (“creep” flow), and (b) basal flow, via either decoupled sliding over the bed or subglacial sediment deformation. The first mechanism, internal deformation, produces relatively low ice fluxes in most situations, giving rise to steep, thick ice sheets such as those of present-day Greenland and East Antarctica. In West Antarctica, where basal flow dominates ice-sheet flux, ice sheets are low-sloping and significantly thinner. Ice streams that drain the West Antarctic Ice Sheet appear to flow over a thin layer of deforming sediment, lubricated by high subglacial water pressures. Melting conditions and free water at the bed enable this fast-flow mechanism, and it creates a situation where the West Antarctic Ice Sheet has a high rate of ice transport to the continental margins and a relatively short response time to climate perturbations.

A growing body of geologic evidence suggests that fast-flowing ice lobes and marine ice sheet instabilities were prevalent in the Eurasian and Laurentide Ice Sheets during the glacial period (Clark, 1994; Heinrich, 1988). Modeling studies indicate that the largest former ice sheet, the Laurentide, could have been substantially thinner and more responsive to climate change in a flow regime dominated by basal flow (Fisher et al., 1985), similar to modern-day West Antarctica. This would sensitize the ice sheet to warming trends and make it easier to achieve ice sheet deglaciation during warm orbital periods.

The geological record is inconclusive with respect to the reconstructions of the thickness and dynamics of the former ice sheets, but ice sheet modeling studies indicate a potential connection between intrinsic time scales of ice sheet thermodynamic evolution and the 100-kyr glacial cycle (Marshall and Clark, 2002). Basal flow cannot become widespread until the ice sheet reaches the pressure-melting point at the base. This takes on the order of tens of thousands of years, such that a switch to West Antarctic-style ice dynamics is not possible until late in the glacial cycle. Once a large fraction of the ice sheet bed is at the melting point, subglacial water builds up at the bed and basal flow takes over from internal deformation as the dominant flow mechanism. This transfers large quantities of ice to the southern and marine margins, where there is surplus energy available for ablation, greatly facilitating ice sheet retreat during glacial terminations.

This internal ice sheet instability offers one means by which orbital forcing on 19, 23, and 41 kyr cycles is filtered to produce a 100-kyr response time in the Earth system. Glacial isostasy offers another long-timescale mechanism. The weight of

the ice sheets and the changing ocean-water load causes elastic deflection of the Earth’s crust and viscous flow of deep mantle material, giving rise to topographic deflections of more than 1,000 m in central regions of the former ice sheets. This isostatic response has a timescale of several kyr, introducing a lag between ice volume and isostatically-driven surface draw-down. This effect is believed to be critical to ice sheet deglaciation and the 100-kyr glacial cycle because the thick, mature (e.g., LGM) ice sheets will depress their bed enough to lower a large portion of the ice sheet to altitudes where melting dominates snow accumulation.

Internal dynamics: ocean circulation

Ice sheets also interacted in complex ways with the oceans during glacial episodes. There is strong evidence that changes in the freshwater budget of the North Atlantic during the glaciation were sufficient to weaken or shut down deepwater formation, reducing North Atlantic thermohaline circulation. This diminished the poleward transfer of heat and increased the intensity of cold conditions in the mid-latitude and subpolar North Atlantic.

Reduced deepwater formation was probably a consequence of decreased evaporation and increased freshwater runoff from the continents during the glacial period, through both meltwater runoff and circum-Atlantic iceberg fluxes. It is also believed that the location of meltwater injections to the North Atlantic is critical for destabilizing the thermohaline circulation. Retreating ice sheets during the last deglaciation caused a runoff diversion from the Mississippi River Basin (Gulf of Mexico) to the eastern North American seaboard, via the Hudson and St. Lawrence Rivers, which appears to have perturbed the North Atlantic and sent the Northern Hemisphere climate into a temporary return to glacial conditions, known as the Younger Dryas cold episode (see Clark et al., 1999b).

North Atlantic deepwater communicates with the global ocean on times scales of the order of 1 kyr, while ocean-atmosphere interactions via energy, moisture, and momentum exchange are essentially instantaneous. These exchanges appear to have been important during glaciations, as North Atlantic thermohaline changes are rapidly communicated throughout the Northern Hemisphere, and possibly the globe. Cold/warm cycles associated with North Atlantic variability are accentuated in the North Atlantic region, however, and are widely considered to be the cause of the dramatic millennial-scale climate variability seen in Greenland ice cores (Figure G46; Dansgaard et al., 1993; Clark et al., 1999b). This high-frequency temperature flicker is a significant fraction of the glacial-interglacial temperature shift in Greenland, so the dynamics of the paleohydrological cycle and the ocean-atmosphere-ice sheet system are likely to prove integral to Quaternary climate dynamics.

Other climate system influences

Clark et al. (1999a) list a number of additional ways in which ice sheets influence climate, including topographic perturbations to atmospheric circulation. This alters storm tracks and probably contributes to the specific geographic pattern of glaciation. Other factors that contribute to global cooling during glacial episodes include an order-of-magnitude increase in windblown atmospheric dust and an expected reduction in water vapor, the most powerful tropospheric greenhouse gas. Enhanced dust content of the ice age atmosphere is evident in ice cores and may contribute to cooling during glacial periods

through the role of dust in scattering (hence, diminishing) incoming solar radiation. Airborne dust levels increase during the glaciation as a result of several influences, including: (a) more arid conditions in many regions of the world, (b) exposed continental shelves due to sea-level drawdown (creating a larger terrestrial source area), and (c) higher surface winds, due to increased baroclinic instability as a result of greater meridional temperature gradients.

While there is no clear geological proxy for water vapor content in the ice age troposphere, globally depressed temperatures would cause reduced evaporation rates and lower saturation specific humidity values. These effects would have the greatest impact in tropical regions, where more than two-thirds of the total present-day evaporation occurs. The tropics cooled by as much as 5°C at the LGM. The resulting effects on the atmosphere are more difficult to predict. Reductions in greenhouse gas effects would cause a cooling, but changes in cloud cover could provide either warming or cooling influences. With less water vapor in the atmosphere, less cloud cover might be expected, causing a warming effect due to increased global albedo. However, the cooler glacial atmosphere would have a lower saturation threshold, meaning that cloud cover during the glacial period may have increased or been similar to present in some regions.

Summary

The discussion above identifies the roles of orbital forcing and internal climate feedbacks in generating glacial-interglacial cycles in the Quaternary. While the exact processes that give rise to ice sheet nucleation and decay have yet to be elucidated, the feedbacks and internal mechanisms introduced in this article are all expected to play a role in amplifying the insolation changes caused by orbital variations. These internal amplifiers include ice-albedo feedbacks, orographic changes, shifts in ocean and atmospheric circulation, and major regime changes in the carbon cycle and global hydrological cycle during glaciations. In addition, isostatic adjustments and internal dynamical processes in ice sheets probably play a role in the 100-kyr glacial cycle of the last 900 kyr, through the introduction of long-timescale lags in the ice sheet system. This essentially acts to precondition the ice sheets for collapse over tens of thousands of years, delaying the glacial termination until a warm orbital period when the ice sheet is prone to instability and is capable of rapid response to climate warming.

Many outstanding questions remain, including the cause(s) of millennial-scale climate variability during the Quaternary and the puzzle of the mid-Pleistocene transition from 40-kyr to 100-kyr glacial cycles. It is possible that early Pleistocene ice sheets were small enough to remain climatically sensitive, making it easier to precipitate a deglaciation. The shift to higher-amplitude glaciations at ca. 900 kyr B.P. still needs to be explained, but it may reflect a non-linear threshold response to a gradual Quaternary cooling trend, similar to what must have occurred at the Pliocene-Pleistocene transition that ushered in the Quaternary ice ages.

GLACIOFLUVIAL SEDIMENTS

Glaciofluvial (also known as glacifluvial or fluvio-glacial) sediments are deposited by glacier melt-streams, in either ice-contact or proglacial settings (Benn and Evans, 1998). Glacier-fed rivers exhibit large diurnal and annual fluctuations in discharge, and commonly have an abundant supply of coarse, cohesionless sediment. Sediment motion is strongly episodic, with entrainment and transport occurring during rising discharge, and deposition during falling stages. Typically, large amounts of sediment are transported as bedload (rolling or sliding close to the stream bed) especially during high stages, when even large boulders can be set in motion. Suspended sediment concentrations can also be high, particularly during early summer when they can reach a few tens of grams per liter. (Glacier meltstreams often also have high dissolved loads, but this is not considered here.)

Proglacial river networks tend to consist of braided channel networks with intervening gravelly barforms. Active channels periodically switch position or are abandoned as the evolving sediment surface interacts with patterns of water flow. The dynamic nature of proglacial streams is reflected in the characteristics of glaciofluvial sediments. The two most important effects of glaciofluvial transport on sediments are *size sorting* and *particle rounding*. Glaciofluvial gravels, sands and silts are typically well sorted, with approximately Gaussian particle-size distributions, although bimodal distributions can result from the infilling of openwork gravels with finer particles during falling stages. Some facies, however, can be poorly sorted, especially those deposited from *hyperconcentrated flows* with high suspended load. Pebbles are rapidly rounded by abrasive wear (corrasion), and may evolve from sub-angular or sub-rounded forms close to glaciogenic sediment sources to well-rounded forms within a few kilometers of the source. The internal structure of glaciofluvial sediment facies reflects the local geometry of the river bed and the characteristics of the depositing flow. Horizontally bedded or laminated facies reflect *vertical accretion* (or aggradation) of sediment and cross-bedded and cross-laminated facies form during *lateral accretion* during the migration of bedforms such as ripples, dunes and bars. Glaciofluvial sediments tend to exhibit recurrent large-scale structures mirroring the three-dimensional form of elements such as channels and bars, and their evolution through time. Miall (1985) recognized eight such architectural elements in fluvial sediments: (a) channel fills (CH); (b) downstream accretion macroforms (DA), recording the downstream migration of ripples, dunes and bars; (c) lateral accretion macroforms (LA) recording lateral migration of bank-attached or mid-channel bars; (d) gravel bars and bedforms (GB) consisting of extensive tabular gravel sheets; (e) sediment-gravity flows (SG); (f) sandy bedforms (SB), deposited in chutes and minor channels and on bar tops; (g) laminated sand sheets (LS) laid down in ephemeral sheet floods; and (h) overbank fines (OF), deposited by the settling of suspended load following flood events. These architectural elements occur in different combinations in different settings, and can be used to reconstruct aspects of the hydrology of former fluvial systems, yielding important paleoenvironmental information.

Accumulation of glaciofluvial sediments forms outwash plains, also known by the Icelandic word *sandar* (singular = *sandur*). These typically exhibit down-stream reduction of channel gradient and sediment grain size. Sandar commonly have multiple levels, which may be terraces that are formed by sediment incision due to changes in hydrology, sediment availability, or a drop in local

base level that leaves abandoned terraces above the active part of the sandur. Terraces may be paired (at the same height on both sides of the sandur) or unpaired, depending on the relative rates of incision and lateral channel migration. The retreat of ice can cause the abandonment of outwash surfaces, leaving a steep reverse slope at the up-valley limit of glacio-fluvial deposits. Such slopes are known as *outwash heads*, and are particularly common in humid climatic settings with high water and sediment discharges. Where glaciofluvial sediments are deposited in contact with buried ice, subsequent melt of the ice causes subsidence and collapse of the overlying sediment forming *kettle holes*. In the case of isolated ice blocks, ice melt creates *pitted outwash*, but where buried ice bodies are more extensive, the resulting landforms consist of irregular mounds and ridges of sediment known as *kame* and *kettle topography*. Eskers are a distinctive type of glacio-fluvial deposit, formed in ice-walled channels or tunnels in supraglacial, englacial or subglacial positions. On ice melting, eskers are left as upstanding, often meandering ridges of sand and gravel. These may exhibit widespread internal collapse structures resulting from the disappearance of supporting ice.

The highest discharges in glacierized catchments occur in association with *glacier lake outburst floods* (GLOFs), triggered by the failure of moraine- or ice dams, or subglacial volcanic activity. GLOFs, also widely known by the Icelandic term *jökulhlaups*, can have discharges several orders of magnitude greater than normal peak flows, and are capable of transporting and depositing large volumes of material, including very large boulders and ice blocks. GLOF deposits are very variable, depending on discharges, sediment availability and topographic setting (see Maizels, 1993, 1995; Lord and Kehew, 1987). Massive facies deposited by hyper-concentrated flows and debris flows are common, although they may be extensively reworked during the falling stage of the flood. The largest GLOF known was the drainage of Glacial Lake Missoula across Idaho, Washington and part of Oregon at the end of the last glaciation. Giant fluvial forms, including networks of channels, and huge ripples and bars in the channeled scablands record glaciofluvial erosion and deposition on a truly massive scale (Baker, 1981).

GLACIOMARINE SEDIMENTS

Glaciomarine sediment is a general term to describe inorganic and organic material deposited in a marine setting by a combination of glacier- and marine-related processes. (This term is equivalent to glaciomarine and glacial marine). These sediments provide valuable records of ice sheet fluctuations because they occur beyond the limit of glacial erosion or cover older glacial erosional surfaces. The appearance and physical characteristics of glaciomarine sediments can be highly varied depending on the relative influence of marine and glacial depositional processes. Primary factors controlling the sediment characteristics include: volume of meltwater input, residence time and melt rate of icebergs, and biogenic production (Figure G48). Debris concentrations in glacier ice, extent of sea ice, and the strength of ocean currents are also important. Sediment redeposition by mass movements is common in glacio-marine environments; debris flow and turbidite deposits may be interbedded with primary glaciomarine sediments. Glaciomarine sediments exhibit gradational changes in particle size, depositional rates and organic content with distance from the glacier front. Generally, the particle size and depositional rate of inorganic material decreases with distance from the glacier front whereas the organic fraction increases (Figure G49).

The processes controlling the characteristics of glaciomarine sediments are related to climate conditions (e.g., Powell and Domack, 2002). In polar regions where summer temperatures are $<0^{\circ}\text{C}$, ablation is the result of sublimation and calving; little meltwater is produced. Most marine-terminating Antarctic glaciers are in this group and they deliver glacial sediment via icebergs with a minor contribution from subglacial meltwater (Anderson, 1999). In temperate regions, such as southeast Alaska, where summer temperatures are $>10^{\circ}\text{C}$, ice is at the pressure melting point and ablation is dominated by melting. Sediment is primarily delivered by debris-laden meltwater plumes and sedimentation from icebergs is minor. In these regions sediment accumulation is strongly seasonal. Between these two end members, where summer temperatures are $<10^{\circ}\text{C}$, the dominant mechanism of sediment delivery varies spatially and temporally and spans the continuum between iceberg- and meltwater-dominated systems.

Rates of deposition decrease in a non-linear fashion away from the grounding line (Figure G49) (Boulton, 1990). In the ice-proximal zone, sediment accumulation rates vary widely depending on the flux of debris-laden meltwater. For instance, glaciomarine sediments deposited within 2 km of the ice front on the Antarctic margin typically have accumulation rates $<2\text{ cm yr}^{-1}$ whereas accumulation rates within 2 km of the ice front in southeast Alaska are $200\text{--}2,000\text{ cm yr}^{-1}$ (Cowan and Powell, 1991). Since Earth's climate changes over time, glaciomarine sediment accumulation rates change with time as well.

Diamictos

Glaciomarine diamictos are poorly-sorted sediments that may be stratified or structureless with particle sizes ranging from clay to boulders. Glaciomarine diamictos are typically associated with ice-proximal environments. In polar regions, these diamictos originate as debris meltout from the base of glacier ice within a few kilometers of the grounding line where the glacier terminates as an ice shelf or ice tongue (Anderson, 1999). In sub-polar fjords, glaciomarine diamictos may be deposited beyond the limit of meltwater influence within a zone dominated by iceberg rafted debris (O'Cofaigh et al., 2001). The abundance of fine particles is a function of current strength. Strong currents may advect fines prior to deposition or may winnow fine-grained sediment deposited near the grounding line. Late Quaternary ice-proximal glaciomarine diamictos from the Antarctic (Ross Sea) continental shelf are extremely similar in appearance to glacial till, suggesting little meltwater and weak ocean currents at the time of deposition (Licht et al., 1999).

At the front of meltwater-dominated glaciers, diamictos may be deposited locally at the site of meltwater discharge from the ice front as fan-shaped or delta-like deposits (Powell, 1990). These ice-proximal diamictos are dominated by sand and gravel and may be stratified; the grain size distribution changes toward a higher proportion of fine-grained material with distance from the meltwater source. In addition to point-source deposits, glaciomarine diamictos may be deposited relatively continuously along the ice front from debris melting out of the ice front or falling off a debris-rich ice surface.

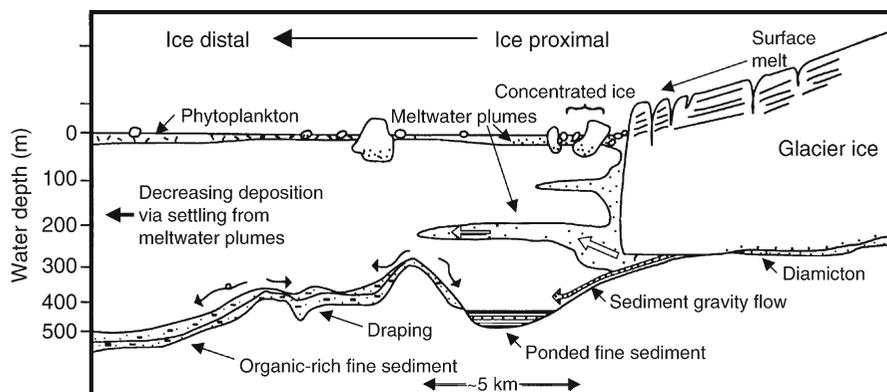

Figure G48 This conceptual model shows the depositional processes and glaciomarine sediment types for a subpolar glacier. Density of meltwater plumes controls their position in the water column and iceberg concentrations partially control the nature of ice-distal sediments. Sea-ice cover may affect iceberg drift and primary productivity. The geometry of sedimentary deposits is controlled by the position of the glacier front, seafloor bathymetry and ocean currents (Syvitski et al., 1987; Anderson, 1999) (modified from Powell and Domack, 2002).

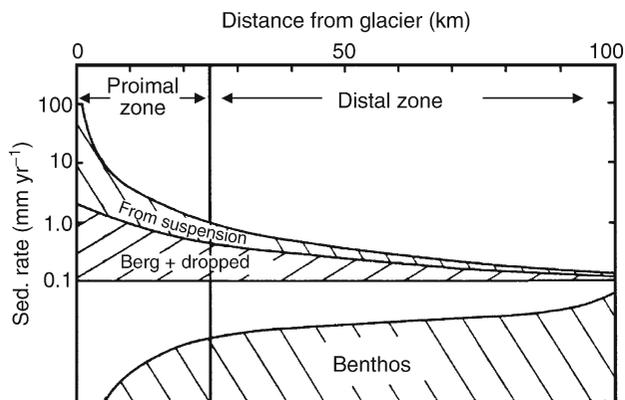

Figure G49 Generalized relationship between glaciomarine depositional processes and distance from glacier front. Sediment accumulation rates decrease in non-linear fashion away from the ice front (modified from Boulton, 1990).

Fine sediment

Fine sediment refers to that which is dominated by silt and clay with minor amounts of sand and pebbles; these sediments may be massive or stratified. The appearance of these fine sediments can be highly variable over small spatial scales in the glaciomarine environment because the depositional processes may be localized. Fine sediment is usually associated with ice-distal deposits on continental margins and in fjords. These glaciomarine sediments settle through the water column after being released by meltwater plumes or icebergs. Stratification may be caused by annual variations in meltwater production, iceberg rafting events or turbidites. Accumulation rates are highly variable and are related to climate conditions. Fine sediments from East Greenland fjords look nearly identical to those deposited in southeast Alaska, however the rates of deposition differ by several orders of magnitude (Smith and Andrews, 2000). Organic carbon content is typically higher in fine sediment than in diamictos because there is less dilution by inorganic (terrestrial) material. Biologically-produced siliceous muds and ooze are extensive in the modern glaciomarine environment on Antarctica's continental shelves and the total organic carbon content of the sediments is commonly 1–3% (Domack et al., 1999).

GLENDONITE/IKAITE*

The term “glendonite” does not refer to a mineral, but to a class of pseudomorphs. A pseudomorph is a mineral that has taken the characteristic crystal shape of another mineral by processes such as replacement or recrystallization. Glendonites are pseudomorphs after the mineral ikaite, a monoclinic mineral with composition $\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$.

Ikaite forms in near-freezing waters. It requires pressures exceeding those of the deepest ocean to be thermodynamically stable (Marland, 1975). Therefore when present in recent sediments it is always metastable. Ikaite may be “stabilized” by the presence of orthophosphate, an inhibitor of the precipitation of anhydrous CaCO_3 .

There have been few observations of ikaite in nature, probably reflecting its rapid decomposition into water and CaCO_3 when removed from cold waters. It may well be a rather common mineral. It appears to occur in two forms: as crystals (Stuess et al., 1982), often in muddy sediment, and as massive tufa towers; e.g., Ikka Fjord, southwest Greenland (Buchardt et al., 1997).

Dana (1884) examined the pseudomorphs and observed “a square prism,” and in cross-section “two sets of distinct diagonal lines intersecting at right angles,” characteristic of tetragonal symmetry. This led to several false attributions as to the precursor mineral. Monoclinic ikaite strongly approximates such orthogonal forms (to within ca. $\pm 0.5^\circ$) due to an accidental near-equivalence in the crystallography (Swainson and Hammond, 2001). Canted pyramidal faces usually terminate the prism. More common than well-formed isolated crystals are multi-crystal rosettes, consisting mostly of pyramidal faces, or their molds (Figure G50).

The use of pseudomorphs as proxies for ancient climates is unusual, yet it seems that the case for the use of glendonites is strong. The unusual morphology of glendonites provides a strong link to the crystallography of ikaite, which has highly specific conditions of formation.

*All rights reserved

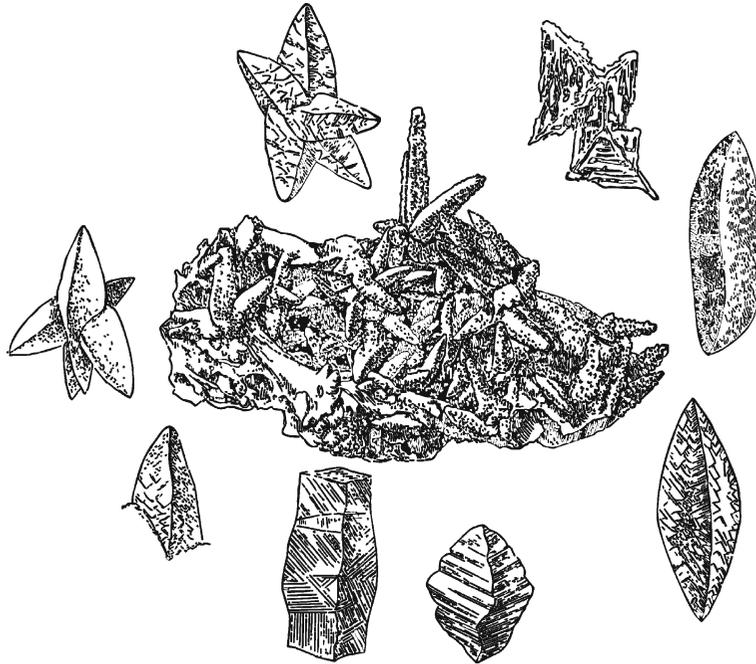

Figure G50 Images of some pseudomorphs after ikaite (Dana, 1884, U.S. Geological Survey).

While many glendonites are found in high latitudes associated with cold climates, they should not be used in isolation as paleolatitude indicators: e.g., ikaite has been reported in deep sea fan sediments off Congo, and in the Nankai Trough off Japan. Ikaite is not exclusively marine. Pseudomorphs have been reported in estuarine deposits. The famous 'thinolite' pseudomorphs of western Nevada and eastern California, USA, formed in a Pleistocene lake and may represent pseudomorphs of the tower-like tufa form.

"GREENHOUSE" (WARM) CLIMATES

Definition and origins of the term "greenhouse"

The term "greenhouse" is defined, as follows, from a climatological standpoint in the online 'Oxford English Dictionary' (OED), based on the textbook by Trewartha (1937, p. 25):

"The phenomenon whereby the surface and the lower atmosphere of a planet are maintained at a relatively high temperature owing to the greater transparency of the atmosphere to visible radiation from the sun than to infra-red radiation from the planet."

It is now becoming clear that although Trewartha (1937) may have been the first person to use the term "greenhouse effect," the concept and discussion of ancient cold/warm climates began in the previous century. Although many sources cite Jean Baptiste Joseph Fourier as the originator of the greenhouse effect (Fourier, 1827), this has been called into question. The most significant attack on the abuse of Fourier's work has been published by Fleming (1999), who states that most of the citations regarding Fourier are "unreliable, misdirected and anachronistic," and possibly stem from one of the most cited pieces of work on global warming (Arrhenius, 1896) that originally misquoted Fourier (1827). Although Fourier (1824, 1827) made analogies to the greenhouse effect, his work was focused more on terrestrial temperatures and ultimately the theory of heat (Fleming, 1999).

Charles Babbage in 1847 may have been the first person to propose the greenhouse effect (Steel, 1992) in the following text taken from 'The Works of Charles Babbage' (Campbell-Kelly, 1989),

"It is on this principle that greenhouses act as traps for catching and imprisoning the sun's rays: probably some very slight difference in the composition of the glass of which they consist may considerably alter this power. . . If the solids of the fluids on the surface,

or if the atmospheres of distant plane[t]s possess the properties of reflection, radiation and absorption in certain degrees, it is by no means impossible that some of the most remote of them may be hotter than those which are much nearer to the central body. . . . When however the heat communicated from the sun is confined and prevented from escape, and so forced to accumulate, very high temperatures are attained. . . . Under the varied circumstances of climate, which might arise from differences in the reflecting, the radiating, the absorbing, and the conducting power of the moon's surface, as well as from different degrees of central heat, the presence of water upon its surface might produce very different effects."

A major advance in understanding climates and climate change was published by John Tyndall (1861) who conducted physical experiments demonstrating that vapors and gases are able to absorb and subsequently emit radiative heat. Some thirty-five years later, Arrhenius (1896) took the findings of Tyndall and others and showed that the Earth's heat budget could be dramatically affected by the abundance of carbonic acid (a reaction product of water and CO₂) in the atmosphere. Arrhenius (1896) went on to conclude, with the assistance of geologist Arvid Gustaf Högbom, that changes in the total abundance of carbonic acid in the atmosphere could have been effective enough to cause glacial/interglacial cycles. Based on his model, Arrhenius made calculations as to the effect of increased (and decreased) carbon dioxide on temperature, and his results are very similar to modern sophisticated models.

Chamberlain (1897) used the findings of Arrhenius and Högbom in order to understand the development of glaciations in the geological record through a drawdown in carbon dioxide and hence mountain uplift and, consequently, increased weathering. Although many researchers highlight Chamberlain as one of the fathers of the global carbon cycle model, Berner (1995) demonstrated that a great deal of Chamberlain's work was actually based on Högbom's work. However, it was Chamberlain who further developed the CO₂ theory of climate change, which forms the basis of many paleoclimatic investigations of the geological record (see Berner, 1995; Fleming, 2000).

Arrhenius subsequently published a general audience book entitled *'Worlds in the Making'*, wherein he discusses the

effects of greenhouse gases in the atmosphere and their contributions towards climate change (Arrhenius, 1908). In this book, he gave an account of the "hot-house" theory, hence the birth of the concept of "greenhouse" (warm) climates.

The greenhouse effect and the climate system

The Earth is a unique dynamic system, with close links and feedbacks between the hydrosphere, atmosphere, biosphere, lithosphere, convecting mantle and outer space. Changes in these links and feedback mechanisms can dramatically affect the magnitude of exchange between the components of this dynamic system that ultimately drive climate and determine whether the environment remains in a warm or cool mode (Figure G51). Although the importance of the atmosphere as a geological agent was recognized long ago, it has been somewhat neglected in studies of past climate change until fairly recently. It is now widely accepted that greenhouse gases significantly affect the Earth's climate both on short- and long-term cycles, especially the global carbon cycle (Berner, 1999). Many greenhouse gases can cause both warming and cooling, due to the absorptive and radiative properties of those gases (Khalil, 1999). The most common greenhouse gases that are considered when discussing climate change on glacial/interglacial cycles and short- and long-term geological cycles are provided in Table G3.

One of the key components in Figure G51 is the amount of incoming radiation versus that which is being emitted back to space. In principle, if the budget of incoming *versus* outgoing radiation were equal and all components within the climate system were static then the climate would also remain static. However, if radiation input is less than output, the Earth climate system would become cooler, whereas if radiation input is greater than output, the Earth would become warmer: this is essentially the "greenhouse effect." Due to the absorptive and radiative properties of the greenhouse gases listed in Table G3, their relative abundance in the atmosphere can significantly affect the global temperature of the Earth. High abundances of CO₂ and H₂O_{vap} in the atmosphere will increase re-radiation and thus prevent heat from escaping. Of great interest to society at present is CO₂, mainly because of the effects of

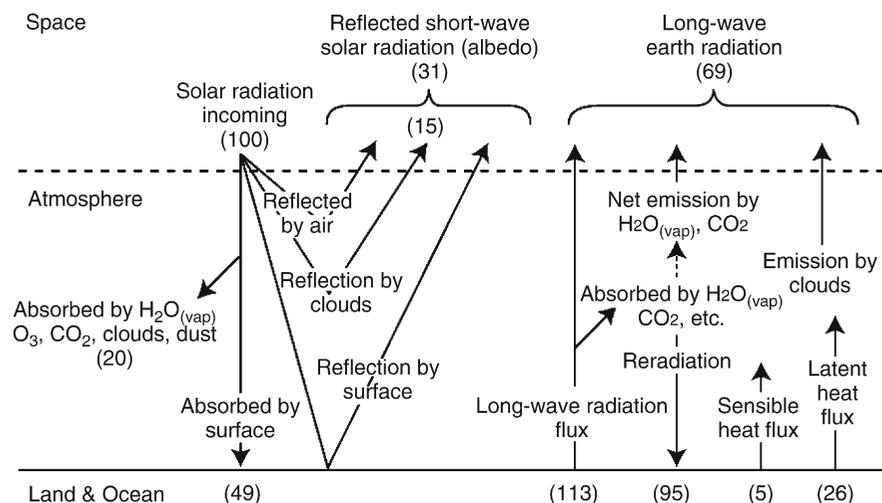

Figure G51 The mean annual radiation and heat balance (modified from Berner and Berner, 1996). Numbers in brackets represent percentages that are either absorbed or re-radiated.

Table G3 Common greenhouse gases

Greenhouse gas	Formula
Carbon dioxide	CO ₂
Methane	CH ₄
Water vapor	H ₂ O
Nitrous oxide	N ₂ O
Sulfur dioxide	SO ₂
Ozone	O ₃

the rise of industrialization and burning of fossil fuels and thus an increased abundance of atmospheric greenhouse gases. However, in recent years carbon-isotope ratios in the deep geologic record have been applied to infer methane dissociation events and subsequent global warming (Hesselbo et al., 2000; Dickins, 2001; Beerling et al., 2002).

The abundance of greenhouse gases in the atmosphere is not the only factor influencing the global climate on geological timescales. The schematic diagram in Figure G52 includes the long-term and short-term carbon cycle (Jenkyns, 2003), primarily identified through our ability to obtain high-resolution records in the deep geologic record. This figure illustrates the majority of pathways in the short- and long-term carbon cycle, and in particular considers the most relevant processes that imprint on and affect the geoclimatic record. Long-term events can be referred to as "greenhouse (warm) episodes", while short-term events are termed a "transient climate events". More detailed analyses of biotic feedbacks in paleoclimatology are given in Woodwell and Mackenzie (1995), Hay et al. (1997), Berner (1999) and Huber et al. (2001).

Paleoclimates in the geologic record

Understanding the causes and consequences of global climate change is one of the most important issues of modern science, and includes the investigation of climatic variations in the geologic record (paleoclimatology). Fueled by concerns about the impact of human activities on the physical and biological environment of the Earth, an increasing amount of research has been devoted to untangling records and mechanisms of past and present climate variation. The Intergovernmental Panel on Climate Change (IPCC, 2007) constitutes a large international assemblage of scientists and data that attempts to investigate the effects of modern climate change (in part induced by anthropogenic activities) through modeling projections of future climatic scenarios (see <http://www.ipcc.ch/>). Although largely focused on recent and future climate change until recently, the latest assessment of the IPCC includes many research areas that attempt to uncover the causes of ancient climatic variability, including its magnitude, variability, frequency, and impacts on the Earth system. Our understanding of ancient climates, let alone rapid climate change in the geologic record, is still in its infancy even 100 years since the work of Arrhenius and others. This is reiterated by Huber et al. (2001), who write in the preface of *Warm Climates in Earth History*:

"In spite of the prevalence of warm climates in Earth history and the potential practical significance of understanding them, the fundamental causes, nature, and mechanics of warm climates are still poorly understood. . . Perhaps most importantly, though, integrated studies have revealed consistent areas of disagreement between empirical and theoretical analyses. Increasing temporal and geographic resolution in models and proxy data will only improve the ability to use deep time as a testing ground for our understanding of the causes, nature, and mechanics of globally warm climates."

Many methods can be used to determine whether a time period in the geological record experienced a warm or cool climate, for example, the presence or absence of climate-sensitive sediments (e.g., evaporites, coals, corals, bauxites), geochemical data (e.g., negative and positive excursions in oxygen- and carbon-isotope ratios of foraminifera), faunal distributions (e.g., the presence of crocodiles at high latitudes), floral physiology (e.g., stomatal indexes, leaf margin analysis), and many other techniques. It is beyond the scope of this entry to discuss all the periods in the geologic record; however, a summary of warm climate modes will be provided with appropriate references for further study (Figure G53). More specific discussion of certain key intervals that illustrate rapid climatic warming will also be provided. However, we refer the reader to the many other entries in this encyclopedia.

Figure G53 depicts the climate modes of the Phanerozoic as determined through paleoclimatic analysis (Frakes et al., 1992) and oxygen isotopic evolution of the ocean (Veizer et al., 1999; Shaviv and Veizer, 2003; Royer et al., 2004). The warm (greenhouse) climate mode, as defined by Frakes et al. (1992), is a climate that is

"globally warm, as indicated by the abundance of evaporites, geochemical data, faunal distributions, etc., and with little or no polar ice."

On the other hand, Fischer (1986) defines a greenhouse mode as a period that has low latitudinal temperature gradients, high mean ocean temperatures, a sluggish ocean, and marine anoxia. Notwithstanding variations in the definition of a greenhouse mode, there are four major warm modes in the Phanerozoic that will be discussed in detail below (note, that this discussion considers the broader nature of greenhouse modes with only minor discussion on transient climate events). What is apparent in Figure G53 is a lack of co-variation between reconstructed and modeled atmospheric CO₂ levels with warm and cool climate modes; such a finding was reported by Shaviv and Veizer (2003), and vehemently debated by Royer et al. (2004). Although this apparent disparity may invoke the conclusion that CO₂ is *not* a controlling factor on temperature in geologic time (Boucot and Gray, 2001; Shaviv and Veizer, 2003; Wallmann, 2004), it should be noted that the effect of CO₂ and many other environmental factors (e.g., carbon burial, seawater pH, sea level, volcanism, weathering, cosmic rays) coalesce to generate paleoclimatic cycles. It is apparent, however, that during periods of major glaciations (e.g., Early Carboniferous–Late Permian and Early Eocene–Present), atmospheric CO₂ levels are low, and that other cool climate modes are only 'less warm' periods (Royer et al., 2004). In general, there has been less scientific effort on the cause and effects of "greenhouse" (warm) climates in the geological record compared with "icehouse" (cool) climates.

Early Earth

Our interpretation of the early Earth climate is at best poor, and as Lyons (2004) eloquently states:

"a universal theme in studies of the early Earth is that big stories are told with little data and lots of speculation."

This applies particularly to our understanding of the faint young Sun paradox (Longdoz and Francois, 1997), which states that the power of the sun was only 70% of what it is today, and thus other mechanisms for global warmth were required to prevent the Earth from remaining frozen. The major factor causing warmer early Earth temperatures is attributed to

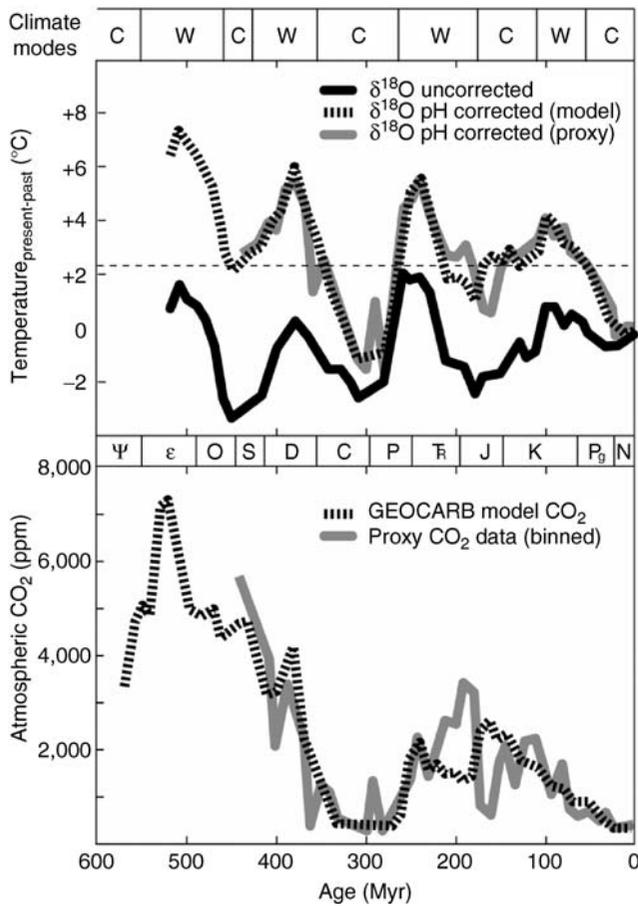

Figure G53 Climate modes through the Phanerozoic based on paleoclimatic analysis (Frakes et al., 1992) and oxygen isotopic evolution of the ocean (Shaviv and Veizer, 2003; Royer et al., 2004). Climate modes: C = cool; W = warm (see definitions in Frakes et al., 1992). *Top panel:* Temperature curves represent present global average minus the reconstructed temperatures: the modern global average temperature in the geologic record would have a value of zero (see Royer et al., 2004 for details). The three temperature curves are: (1) an uncorrected curve (Veizer et al., 1999) [solid line], (2) a pH-adjusted curve based on modeled CO₂, and (3) pH-adjusted proxy CO₂ data (Royer et al., 2004) [dashed and gray line respectively]. The horizontal dashed line is based on the Paleogene glaciation in the Cenozoic (Zachos et al., 2001), which would give a temperature of ca. +2.2°C above the present global average. If this horizontal dashed line is used as an estimate for warm (above) and cool (below) climates, then correspondence with the climate modes of Frakes et al. (1992) is much better. Ψ = Ediacaran; ε = Cambrian; O = Ordovician; S = Silurian; D = Devonian; C = Carboniferous; P = Permian; Tr = Triassic; J = Jurassic; K = Cretaceous; Pg = Paleogene; N = Neogene. *Bottom panel:* Phanerozoic atmospheric CO₂ concentrations based on the GEOCARB III model (dashed line) and proxy CO₂ data (solid grey line) after Royer et al., 2004.

exceptionally high levels of greenhouse gases, such as CH₄ (Pavlov et al., 2003) and CO₂ (Hessler et al., 2004; Ohmoto et al., 2004; Pierrehumbert, 2004; Fowler et al., 2003).

Early Cambrian to Late Ordovician periods

Our understanding of this warm episode is somewhat skewed, as continental reconstructions suggest that landmasses occupied

low latitudes (Golonka, 2002). The use of paleontology in the Cambrian as an indicator of warmth is difficult due to the great number of unoccupied ecological niches and limited biological diversification (Frakes et al., 1992). Therefore, other proxies of climatic warmth must be utilized. The earliest part of the Cambrian is poorly understood, primarily because of a lack of pristine marine carbonate available for paleotemperature reconstructions. An isotope curve indicates that by the Middle–Late Cambrian, paleotemperatures far exceeded present temperatures (Figure G53), which coincided with extremely high atmospheric CO₂ levels at that time (Royer et al., 2004), possibly as a result of intense volcanism over the Precambrian–Cambrian transition (Doblas et al., 2002). Karhu and Epstein (1986) suggest Cambrian paleotemperatures as high as 50°C, although it is not yet fully understood whether changes in the oxygen-isotope composition of seawater (δ_w) may have exacerbated the reconstructed paleotemperatures, which far exceeded normal marine faunal tolerances. However, paleotemperatures during the Ordovician became more reasonable at ~30–38°C (Veizer et al., 1999; Brand, 2004), although a suggested Ordovician δ_w value of –3‰ would have lowered the temperatures further to ~27°C (Wallmann, 2001; Shields et al., 2003). Other evidence for a greenhouse climate during this interval includes the presence of massive evaporites at low latitudes (Alvaro et al., 2000; Baikov, 2004), carbonate expansion to high latitudes (Frakes et al., 1992), lateritic and bauxitic profiles (Sturesson, 2003), and increased phosphorite accumulation (Meng et al., 1997). The presence of oolitic ironstones has also been suggested as an indicator of warmth during a marine transgressive phase (Frakes et al., 1992; Yapp, 2004). During the Ordovician, abundant black-shale deposition supports a transgressive sea-level phase, accompanied by high oceanic productivity (Easto and Gustin, 1996).

Late Silurian to Early Carboniferous periods

After the Late Ordovician glaciation, the Late Silurian still experienced relatively cool temperatures, although by the beginning of the Devonian, temperatures begin to rise sharply, reaching a peak in the Middle Devonian before decreasing again (Figure G53). By comparison to the Cambrian–Ordovician greenhouse episode, this time interval was relatively cooler and coincided with decreasing atmospheric CO₂ levels (Wallmann, 2001), increasing volcanism, and tectonic activity during the Caledonian and Arcadian Orogenies (Torsvik and Cocks, 2004). Peak paleotemperature in the Middle Devonian also coincided with large evaporite deposits in west Canada, Siberia, and North Africa (Frakes et al., 1992). Carbonate deposition increased during the Devonian, bioherms were dominant and reef systems extended latitudinally up to ~60° (Frakes et al., 1992; Dubalatorov and Krasnov, 2000; Edinger et al., 2002). A humid environment is believed to have been initiated in the Late Silurian, when the Coal Age began (Calder and Gibling, 1994), and is concurrent with the first record of fossil charcoal, suggesting wildfires (Glasspool et al., 2004). During the Devonian, marine faunas became more cosmopolitan (Babin, 2000), soils were well-developed latitudinally in the terrestrial environment, and plant communities diversified, with the occurrence of the first trees (Retallack, 1997). The most prominent feature depicting an arid climate was the widespread deposition of red beds, such as the Old Red Sandstone and Catskill Formation. As with the previous greenhouse mode, phosphorite accumulation increased (Martin, 1995), as did upwelling and oceanic productivity (Caplan and Bustin, 2001), culminating in major marine anoxia during the Frasnian–Famnenian interval

of the Devonian sea-level rise (see Rackian and House, 2002). However, the Late Devonian–Early Carboniferous climate switched dramatically from a greenhouse to icehouse world, which is believed to be caused by intensified silicate weathering and organic carbon burial (Averbuch et al., 2005).

Late Permian to Middle Jurassic periods

One of the most intensely studied greenhouse intervals occurred during the Permian–Triassic boundary (Kidder and Worsley, 2004). This boundary interval is believed to have coincided with the onset of a greenhouse climate with widespread marine anoxia (Grice et al., 2005), a global coal gap (Retallack et al., 1996), the disappearance of *Glossopteris* (Spalletti et al., 2003), and a massive increase in phosphate accumulation, classically described by the Phosphoria Formation, USA (Knudsen and Gunter, 2002). The Carboniferous–Permian record had atmospheric CO₂ levels that were comparable to present-day concentrations, although by the Middle Permian they began to rise to levels of ~2,000 ppmV, peaking at the Permian–Triassic boundary. Paleotemperatures rose sharply during this interval, from cool to warm, but peaked during the Early Triassic (Figure G53). Extensive evaporite deposits occurred in the Triassic and Early Jurassic, although the Late Triassic has scarce bauxite and laterite deposits (Frakes et al., 1992). A number of paleoproxies for the Triassic suggest that it was a period with climates alternating between arid and humid: (a) paleosols from the Middle Triassic of Argentina (Tabor et al., 2004), (b) foliar physiognomy and tree-rings from Antarctica (Cúneo et al., 2003), (c) sediment analysis from the Late Permian–Early Triassic indicating fluctuating precipitation regimes with a peak in the Early Triassic (Wopfner, 2002), and (d) clay mineral analysis from Europe (Ruffell et al., 2003). On the basis of tree-ring widths, Pires et al. (2005) suggested that the climate became more uniform by the Late Triassic, which is also indicated by clay-mineral analysis (Ruffell et al., 2003). However, the Late Triassic was heavily influenced by monsoonal conditions, as implied by the strong orbital cyclicity recorded in the Newark Basin (LeTourneau and Olsen, 2003). By the Late Triassic, a number of bolide impacts and extensive volcanism altered the Earth system, possibly resulting in a climate with less fluctuations but growing warmth (see Tanner et al., 2004). One of the major episodes that occurred at the Triassic–Jurassic boundary, which has been attributed to climate change, is the emplacement of the Central Atlantic Magmatic Province (Hames et al., 2003), which contributed to a transient climate event and possibly the turnover or extinction of many floral and faunal groups (Pálfy et al., 2000; Hesselbo et al., 2002). The Early Jurassic also witnessed the diversification and latitudinal spread of floras (Krassilov, 2003) and the global distribution of black shales, which occurred most prominently during the early Toarcian (Hesselbo et al., 2000). The early Toarcian oceanic anoxic and transient climate event has been attributed to the massive dissociation of methane gas hydrates (clathrates), as recorded by a rapid negative $\delta^{13}\text{C}$ excursion in both the marine and terrestrial carbon reservoirs (Hesselbo et al., 2000; Kemp et al., 2005). A similar explanation has also been proposed for the Permian–Triassic boundary (Krull et al., 2004). Paleotemperatures rose significantly over the Toarcian, as recorded by belemnite oxygen-isotope ratios (Jenkyns et al., 2002; van de Schootbrugge et al., 2005). However, this is not apparent in Figure G53. Both the early Toarcian oceanic anoxic event and Permian–Triassic boundary event are related to periods of major volcanism, such as the Karoo–Ferrar continental flood basalts (Duncan et al., 1997) and Siberian Traps (Renne et al., 1995), respectively. These

volcanic outpourings are potentially the original source of greenhouse gases and consequent global warming episodes (Huyn and Poulsen, 2005).

Mid-Cretaceous period to Early Cenozoic era

The initiation of this greenhouse (warm) mode has been revised from that given in Frakes et al. (1992) and is now placed at the Barremian–Aptian boundary 125 Myr ago, where it records a major shift in climate, oceanic structure, and environment (Gröcke, 2002; Jenkyns, 2003; Erba, 2004). Based on obtaining pristine marine microfossil records from Ocean Drilling Program cores, our understanding of the Cretaceous and Cenozoic climate is vastly improved (e.g., Jenkyns, 2003). Significant Pacific Ocean large igneous province formations began at the Barremian–Aptian boundary with the formation of the Ontong Java Plateau (Larson and Erba, 1999) and consequent increasing atmospheric CO₂ levels and warming (Huber et al., 2002; Leckie et al., 2002). Major sea-level transgression and regressions occurred during the Cretaceous periods, although the ocean remained sluggish, with high productivity resulting in significant deposition of black shales (Poulsen et al., 2001; Wilson and Norris, 2001; Leckie et al., 2002). The Cretaceous oceanic anoxic events record a significant temperature increase with the maximum occurring during the Cenomanian–Turonian event (Norris et al., 2002; Poulsen, 2004). However, this event also records a decrease in atmospheric CO₂ levels (Kuypers et al., 1999). Extreme Cretaceous warmth is also shown by Antarctic and Arctic floral and faunal compositions and the prevalence of opportunism (Herman and Spicer, 1996; Tarduno et al., 1998; Huber, 2000; Francis and Poole, 2002). Whether volcanism and/or methane dissociation were prevalent during the Cretaceous (e.g., the Aptian oceanic anoxic event) and Cenozoic (e.g., Paleocene-Eocene Thermal Maximum) is still a matter of debate (Bains et al., 1999; Gröcke et al., 1999; Dickens, 2001; Beerling et al., 2002). However, a number of paleoclimatic indicators (e.g., oxygen isotopes, black shales, rapid carbon-isotope excursions) suggest sustained warmth with several transient climate events (e.g., Aptian, Cenomanian–Turonian oceanic anoxic events, the Paleocene-Eocene Thermal Maximum ELMO and X-event layer). Recent evidence also indicates that the Cretaceous warmth was interrupted by rapid short-lived cooling (icehouse) episodes and potentially glaciation (Stoll and Schrag, 2000; Gale et al., 2002; Pirrie et al., 2004; Gröcke et al., 2006; Bornemann et al., 2008).

Summary

Our understanding of greenhouse (warm) climates in geologic time has been limited since a primary focus of deep time research to date has been on icehouse (cool) climates, which are more easily recognized in the sedimentological record. A concerted effort is required to integrate multi-proxy approaches to estimate ancient temperatures and atmospheric CO₂ levels more accurately. In addition, based on the modern focus on rapid climate change in today's society, there is a greater need to identify and research transient climate events in deep time. Studies of the Paleocene-Eocene Thermal Maximum, Toarcian, Aptian, and Cenomanian/Turonian oceanic anoxic events, the Permian–Triassic boundary and Frasnian–Famennian boundaries are needed. Our knowledge of early Earth climates (bar Snowball Earth episodes) is limited due to a lack of reliable proxies indicative of greenhouse modes. Four major greenhouse (warm) modes have been

identified in the Phanerozoic (Figure G53), and within these intervals, several (or many) transient climate events conducive with rapid, extreme warming can be identified. Equally important is that within these greenhouse (warm) modes, rapid icehouse (cool) climates are also becoming recognized, suggesting that the Earth's climate could flip rapidly between warm and cool modes in deep geologic time.

H

HEAT TRANSPORT, OCEANIC AND ATMOSPHERIC

Ocean-atmosphere interactions control Earth's climate in many ways. The most important of these controls is the heat transport of energy by atmosphere and ocean.

The only source of heat on Earth is solar radiation. As any physical body with a temperature above absolute zero, Earth loses heat in the form of infrared radiation proportional to the fourth power of its absolute temperature. The Earth as a planet is in almost perfect thermal steady state and therefore the top of the atmosphere must be in a complete globally-averaged radiative balance.

However, because of Earth's sphericity, solar radiation in high latitudes spreads over larger areas than in low latitudes, and the net radiative balance at the top of the atmosphere is positive in low latitudes and negative in high latitudes (Figure H1). The atmosphere and oceans must transport heat from low to high latitudes to balance these heat surpluses and deficits. In the absence of the meridional heat transport (for example, on a planet without oceans or atmospheres), the surface temperature at the tropics would be much higher than the observed temperature and would be much lower at the poles.

Meridional poleward heat transport in the atmosphere and oceans provides an effective feedback for constraining the equator-to-pole thermal contrasts to certain limits. These limits determine the Earth's climate extremes, which have varied throughout geological time. As the air and water motions depend on thermal gradients, heat transport is a highly nonlinear and sensitive feedback, and so is the climate system.

The sum of the meridional heat transport expedited jointly by the ocean and atmosphere can be determined from the divergence of the zonally averaged heat budget at the top of the atmosphere. About 5–6 PW (1 PW is equal to 10^{15} W) of energy is carried poleward by the ocean-atmosphere system in both hemispheres (Peixoto and Oort, 1992). Atmosphere carries heat directly, by transporting warmer air poleward, and indirectly, by carrying latent heat in water vapor.

Until recently, it was thought that roughly half of the poleward heat transport is expedited by the atmosphere, and half by the ocean. Based on a re-analysis of data gathered between February 1985 and April 1989, Trenberth and Caron (2001) have found that the atmospheric heat transport is at least twice larger than the oceanic in the Northern Hemisphere, with this ratio even higher in the Southern Hemisphere. However, because the heat capacity and density of sea water are much larger than those of air, changes in the oceanic budget, as reflected in oceanic heat transport, have profound and much longer-lasting effects on climate.

The atmosphere and the ocean transfer heat differently. The atmosphere transports heat meridionally mainly by large transient eddies in the middle and high latitudes. The ocean carries heat mainly by the large-scale horizontal gyres, and by the meridional overturning cells driven by the sinking and spreading of cold water. These gyres and overturning cells comprise the global ocean circulation system, also known as the global ocean conveyor (Broecker, 1991).

The meridional oceanic heat transport by ocean currents, Q_{adv} across a zonal coast-to-coast and top-to-bottom section can be computed as follows:

$$Q_{adv} = \rho_0 c \int_{-H}^0 \int_{\lambda_W}^{\lambda_E} v \theta a dz d\lambda$$

where ρ_0 is constant sea water density ($1,028 \text{ kg m}^{-3}$), c is the specific heat of water at constant pressure, v is the meridional component of velocity, H is the depth of the ocean, θ is potential temperature (i.e., in situ temperature corrected for heating by compression), a is the Earth's radius, and λ_W and λ_E are the longitudes of the west and east coasts of the ocean basin at the chosen latitude, respectively. Total water transport across such a coast-to-coast and top-to-bottom section must be zero. However, the total heat transport across this section is modulated by spatially-inhomogeneous temperature and is not zero, and the total meridional oceanic heat transport depends on both the intensity of meridional flows and steepness of temperature gradients.

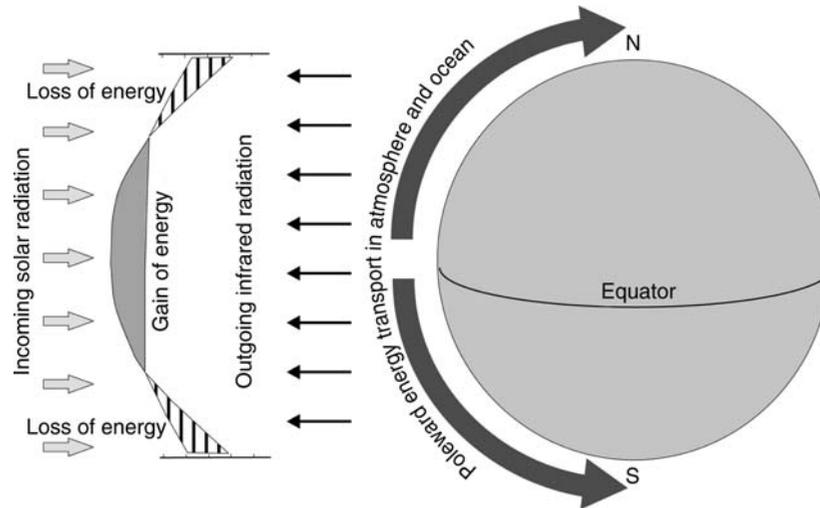

Figure H1 Simplified scheme of radiative balance and compensating heat transport in the ocean and atmosphere.

The present-day global thermohaline conveyor is driven by deep convection associated with the formation of the North Atlantic Deep Water (NADW). The North Atlantic Current carries warm and salty surface water to the northern North Atlantic and Norwegian Seas where it cools and sinks to the deep sea. Continuity of the ocean currents requires that the southward cross-equatorial deep-ocean outflow of NADW (about $16 \times 10^6 \text{ m}^3 \text{ s}^{-1}$) must be compensated by an equal amount of northward flowing water in the upper layers. The combined effect of these two opposite flows leads to large (up to 1 PW) northward cross-equatorial heat transport in the Atlantic Ocean.

Since sea water density depends on both temperature and salinity, freshwater balance at the sea surface may have a strong effect on ocean circulation and its associated heat transport (Bryan, 1986). Modeling studies have revealed that the ocean meridional overturning has strong sensitivity to relatively small inputs of freshwater, which are capable of capping the convection at key sites. Paleoclimatographic data support these simulations and indicate that changes in ocean overturning intensity and pattern might have happened many times through geologic history, especially during glacial-interglacial cycles of the Pleistocene.

The NADW dominance is challenged by a powerful southern deepwater source. In the Southern Ocean, chilled surface water descends to the bottom and forms the ocean's densest water mass – the Antarctic Bottom Water (AABW). The competition between NADW and AABW leads to unstable meridional overturning characterized by rebounds on centennial to millennial time scales. The idea of a bipolar seesaw has been invoked to explain the oscillations of meridional overturning by NADW-AABW wrestling (Broecker, 1998).

Numerical simulations offer an ocean seesaw scenario explained in Figure H2. Present-day overturning is driven by a relatively strong NADW formation instigating a strong northward overturning pattern in the Atlantic Ocean, as shown in Figure H2a. A glacial overturning pattern, e.g., during the Last Glacial Maximum, is a reduced and shallowed version of the present-day pattern, with NADW reduced yet still functioning (not shown in Figure H2). After a glacial termination,

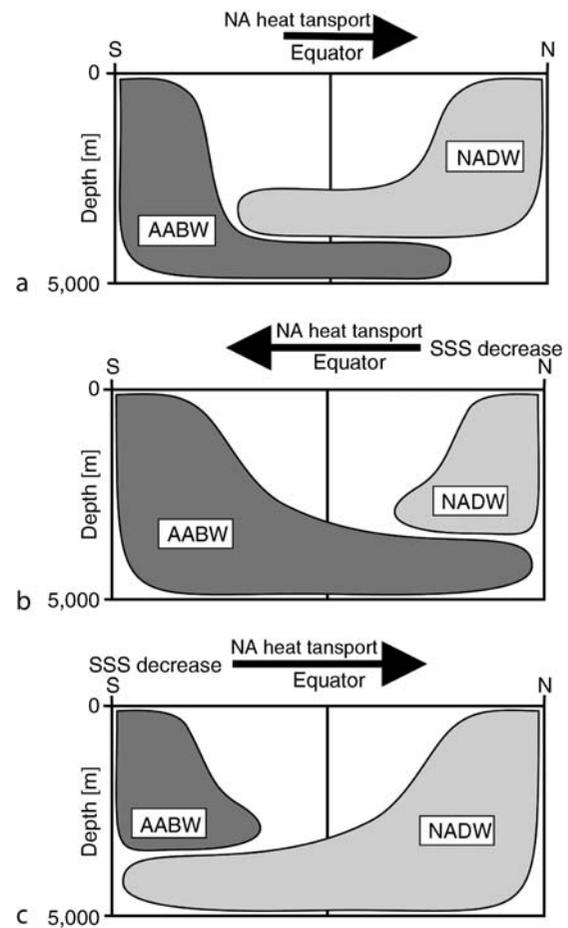

Figure H2 Schemes of water mass layering and overturning structure; (a) present-day mode of overturning; (b) northern meltwater event; (c) southern meltwater event. Direction of cross-equatorial oceanic heat transport is shown by arrows above each scheme (from Seidov et al., 2001).

a post-glacial iceberg armada from a collapsing ice sheet surged into the northern North Atlantic. Melting of the icebergs created a freshwater layer that may have capped NADW formation in key convection areas, shown as the northern low surface salinity impact in [Figure H2b](#). Paleoclimate proxies, including ice-rafted debris, suggest that such freshwater impacts, some known as Heinrich events, have indeed happened and might have caused great reductions in NADW formation. As NADW subsided, stronger AABW allowed the southward cross-equatorial heat transport in the Atlantic Ocean ([Figure H2b](#)). The heat surplus in the Southern Ocean warmed surface water in the Southern Ocean and sea ice there began to melt. Freshwater from melting ice (shown as a southern low salinity impact in [Figure H2c](#)) then slowed AABW formation, with the North Atlantic Ocean's surface water concurrently becoming colder because of southward rather than northward cross-equatorial heat transport.

The northern surface waters became colder and at some point dense enough to restore or even overshoot NADW formation ([Figure H2c](#)), followed by a seesaw-cycle repeat.

Oceanic heat transport is also thought to be a crucial element for climate change on geological time scales of millions of years and longer. Because of continental drift, the sea-land distribution has been changing throughout geologic history. The ocean circulation is sensitive to continental geometry and position, especially to opening and closing of major oceanic gateways, such as the Drake Passage, Indonesian Throughflow, Bering Strait, etc. One of the explanations of past warm climates, e.g., during the Cretaceous, is that both polar areas were open oceans.

Our knowledge of the ocean-atmosphere interactions is not yet complete. Improving this knowledge is essential for understanding past, present, and anticipated future climate change. For that reason, more research effort is still needed to observe and model heat transport in the ocean and atmosphere.

HEINRICH EVENTS

Introduction

Heinrich (1988) first reported on the occurrence of six layers with high ice-rafted detritus (IRD) concentrations within the last glacial cycle, and they have been dubbed Heinrich layers since correlative layers were discovered in marine core DSDP609 and in the Labrador Sea in the North Atlantic Ocean (Bond et al., 1992; Broecker et al., 1992; Andrews et al., 1994). The six IRD layers can be correlated across the North Atlantic ([Figures H3](#) and [H4](#)). The high percentage of IRD in Heinrich layers is due to a high IRD flux in four of the six Heinrich layers over the last 60 kyr, namely H1, H2, H4 and H5 ([Figure H5](#)). These detrital carbonate-bearing Heinrich layers (Bond et al., 1992; Andrews et al., 1994) appear to require a series of repeated, anomalous, glaciological processes in or near the Hudson Strait. They have razor-sharp bases, and thus must have had extremely sharp onsets. Broecker et al. (1993) made a detailed assessment of H1 and H2 from DSDP core 609. Their results emphasize the decline in numbers of foraminifera during the Heinrich events within the IRD belt and the change in the slope of the ^{14}C age versus depth across these intervals. Although overall foraminifera abundance is low, shells that are found are in good condition, so that it is not a question of preservation. As well as can be recorded in marine sediments, Heinrich layers occur within the coldest parts of this record. These Heinrich layers are rapidly followed by dramatic warm intervals.

Heinrich layers H3 and H6 are different from the other Heinrich layers ([Figure H5](#)). For example, they show only a modest increase in flux (McManus et al., 1998) and in the number of lithic grains per gram (Bond et al., 1992, 1993) despite their high %IRD. Gwiazda et al. (1996) concluded that H3 and H6 were not really ice-rafting events, but instead were low foraminifera intervals, which would account for the high %IRD.

Provenance

The provenance of Heinrich layers H1, H2, H4 and H5 within the IRD belt is very distinctive and hence can be mapped by any number of geochemical measurements, as well as magnetic susceptibility (Grousset et al., 1993; see [Figure H5](#)) and detrital carbonate content (Bond et al., 1992). The data that have been collected reveal a remarkably complete story of the provenance of the Heinrich layers (Hemming, 2004). Nd isotope compositions of bulk terrigenous detritus and Pb isotope compositions of individual feldspar grains reveal an Archean source area for the Heinrich layers. Furthermore, the Pb isotope compositions of individual feldspar grains and $^{40}\text{Ar}/^{39}\text{Ar}$ ages of individual hornblende grains indicate a profound Paleoproterozoic metamorphic overprint on the Archean terrain. The presence of detrital carbonate grains, organic geochemistry, clay mineralogy, and K/Ar and Rb/Sr ages of the fine fractions also reveal a substantial sedimentary contribution to the layers. The entire spectrum of provenance observations for the H1, H2, H4 and H5 layers is consistent with a derivation from near the Hudson Strait.

In the eastern North Atlantic, events H3 and H6 have compositions that are distinct from those of H1, H2, H4, and H5. Using Pb isotope compositions of composite feldspar samples, Gwiazda et al. (1996) found that H3 and H6 resemble ambient sediment in V28–82, suggesting a large European source

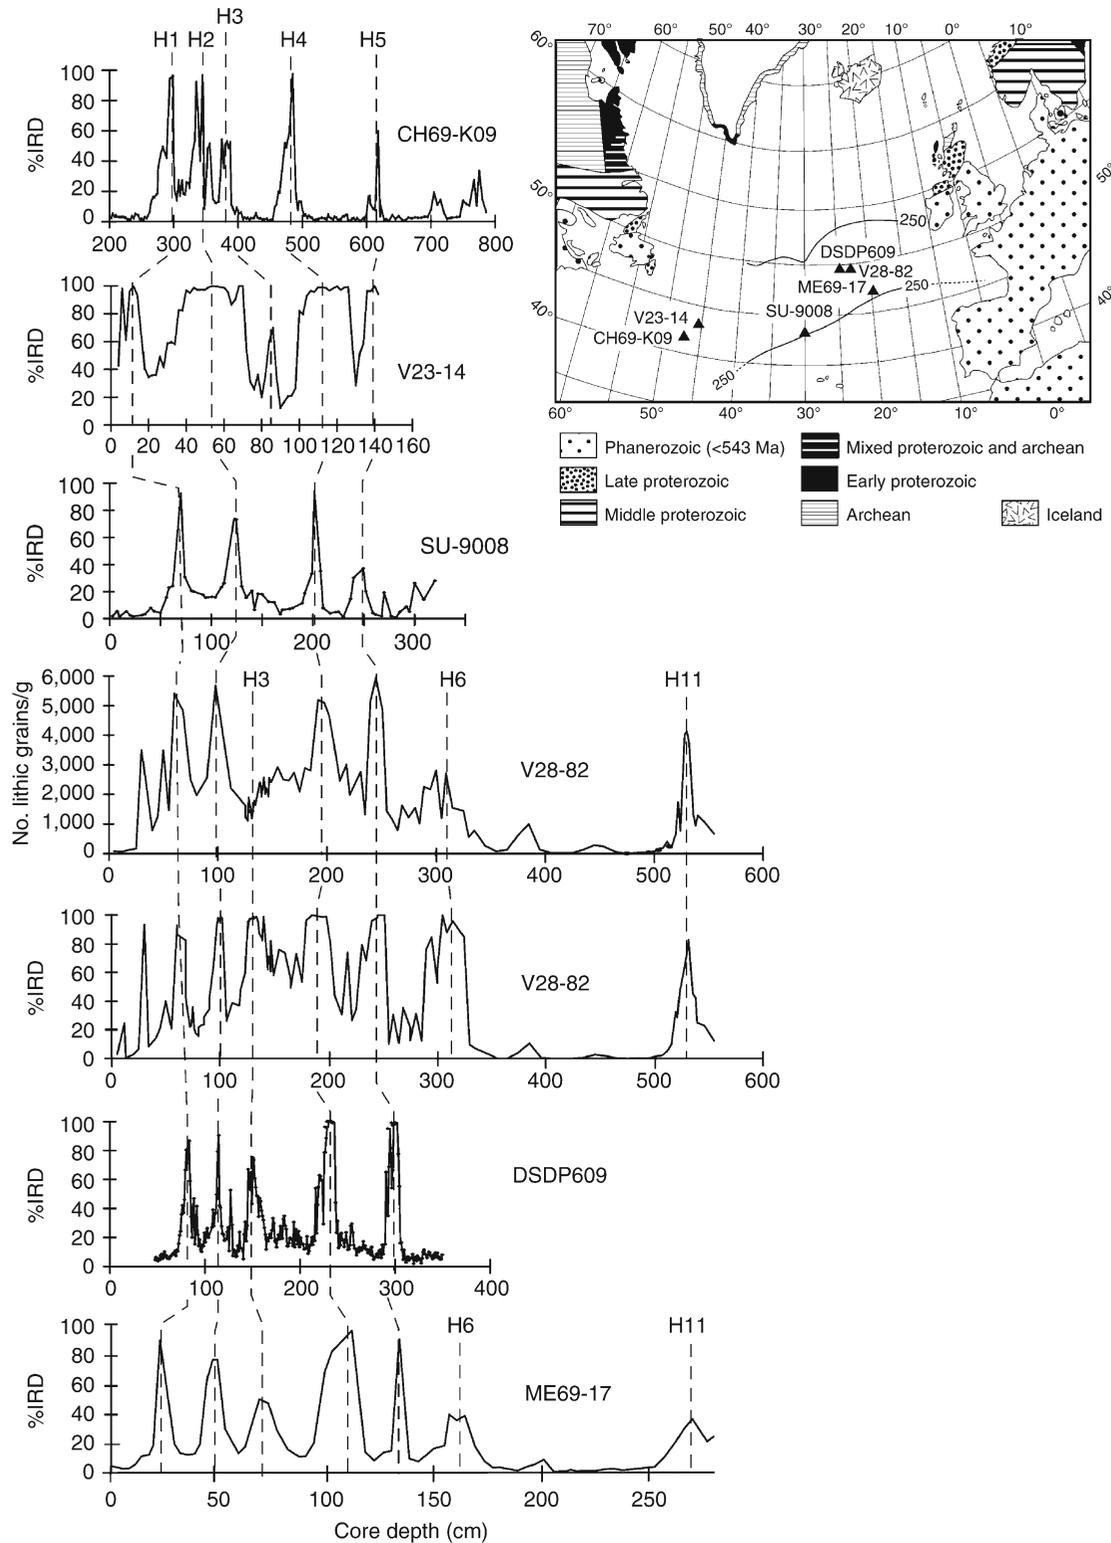

Figure H3 Ice rafted detritus data for North Atlantic sediment cores with Heinrich layers. Most of the data are % of lithic grains in the >150 μm fraction; however the data from ME69-17 (Heinrich, 1988) is % of lithic grains in the 180–3,000 μm fraction. Also shown is the record of number of lithic grains >150 μm per gram of dry sediment from core V28-82. Map shows the location of the cores. Data sources are: for CH69-K09 (Labeyrie et al., 1999), V23-14 (Hemming and Hajdas, 2003), SU-9008 (Grousset et al., 1993), V28-82 (Gwiazda et al., 1996; Hemming et al., 1998; McManus et al., 1998), DSDP609 (Bond et al., 1992; Broecker et al., 1992), ME69-17 (Heinrich, 1988).

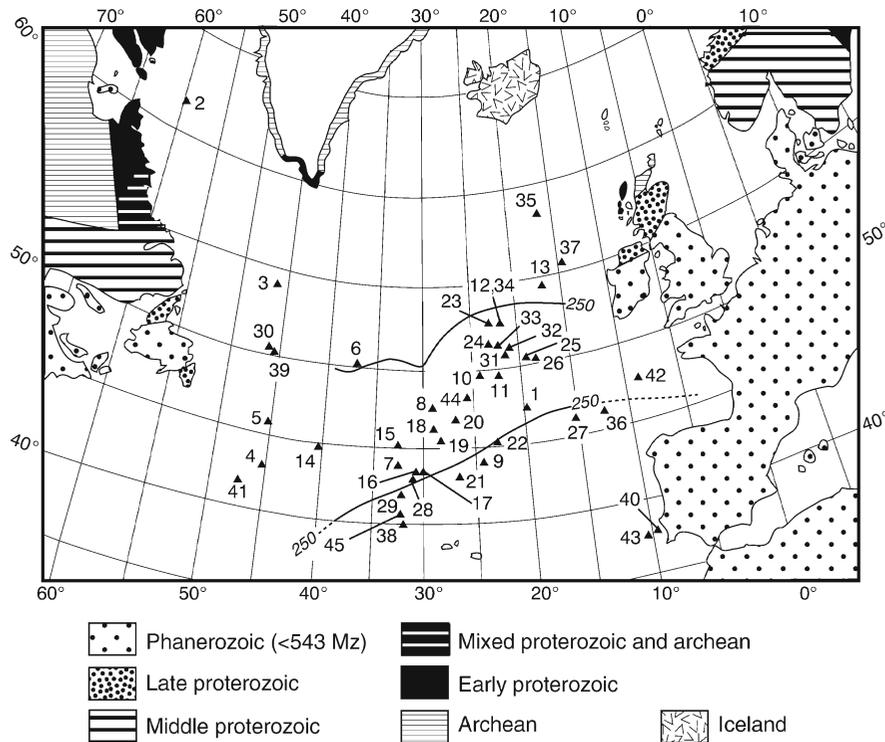

Figure H4 Map showing locations of cores with identified Heinrich layers. Simplified geological provinces are shown for reference. Map template and the $250 \text{ mg cm}^{-2} \text{ kyr}^{-1}$ flux lines from 25–13 kyr are from Ruddiman (1977); Ruddiman's "IRD belt" is shown for reference.

contribution, which agrees with the conclusion of Grousset et al. (1993). As mentioned above, H3 and H6 seem to be low foraminifera intervals rather than major ice-rafting events. These conclusions are consistent with other observations around the North Atlantic. Although Heinrich layer H3 appears to be a Hudson Strait event (Grousset et al., 1993; Bond and Lotti, 1995; Rashid et al., 2003), it does not spread Hudson Strait-derived IRD as far to the east as the other Heinrich events (Grousset et al., 1993). The map pattern of Sr isotope data from H3 shows a striking pattern of decrease in $^{87}\text{Sr}/^{86}\text{Sr}$ nearly perpendicular to the IRD belt (Hemming, 2004), consistent with a mixture of sediments from the Labrador Sea icebergs with those derived from icebergs from eastern Greenland, Iceland and Europe.

Chronology and duration of the Heinrich layers

Constraining the chronology and duration of the Heinrich layers is critical to understanding their origin as well as their role in global abrupt climate change. The duration of Heinrich layers has been estimated by the difference in ^{14}C ages across Heinrich layers, particularly H1 and H2 (Bond et al., 1992, 1993), as well as by measurements of sediment flux by the $^{230}\text{Th}_{\text{xs}}$ method (Francois and Bacon, 1994; Thomson et al., 1995; McManus et al., 1998).

The ages of Heinrich layers H1 and H2 are reasonably certain based on radiocarbon measurements, but estimations of their duration are compromised by the events themselves because they represent a large sediment flux increase (Manighetti et al., 1995). Within the IRD belt, the estimated age at the base of the layers is a maximum due to capping of the bioturbated layer by the Heinrich layer. The estimated age at the

top is a minimum due to bioturbation after the events. Additionally, the likelihood that Heinrich events are associated with major deep-ocean circulation changes (Vidal et al., 1997; Kissel et al., 1999; Elliot et al., 2001, 2002) and thus changes in the atmospheric radiocarbon content (Yokoyama et al., 2000; Waelbroeck et al., 2001) means that it is uncertain how to interpret the value of the radiocarbon measurements near these events. Data published by Bond et al. (1992, 1993) for core V23–81 give the best greatest density of data, but reveal age plateaus above both H2 and H1. Published estimates of Heinrich layer duration range from 208 to 2,280 years. Taking the best estimates, the average duration is 495 years and the standard deviation in this duration is 255 years (Hemming, 2004).

Precursor events

Understanding the origin of Heinrich layers relies on constraining the provenance of the layers themselves, and also in reconstructing the events leading up to their occurrence, the so-called precursor intervals (Bond and Lotti, 1995). Percentages of fresh basaltic glass and hematite-stained grains, counted at high resolution in several North Atlantic cores, vary on a 1- to 2-kyr interval, and the pacing of petrological changes in IRD appears to be similar to that of $\delta^{18}\text{O}$ in Greenland ice (inferred to be a proxy of air temperature changes) (Bond and Lotti, 1995; Bond et al., 1997, 1999). Bond and Lotti (1995) showed that peaks in Icelandic glass and hematite-stained grain abundances fall within the broad lithic peaks that encompass Heinrich layers, and that they precede detrital carbonate peaks for Heinrich layers H1, H2, H3, and H4 in cores DSDP609 and V23–81 (see also Bond et al., 1999). Grousset et al. (2001) showed a series of provenance changes that are consistent with

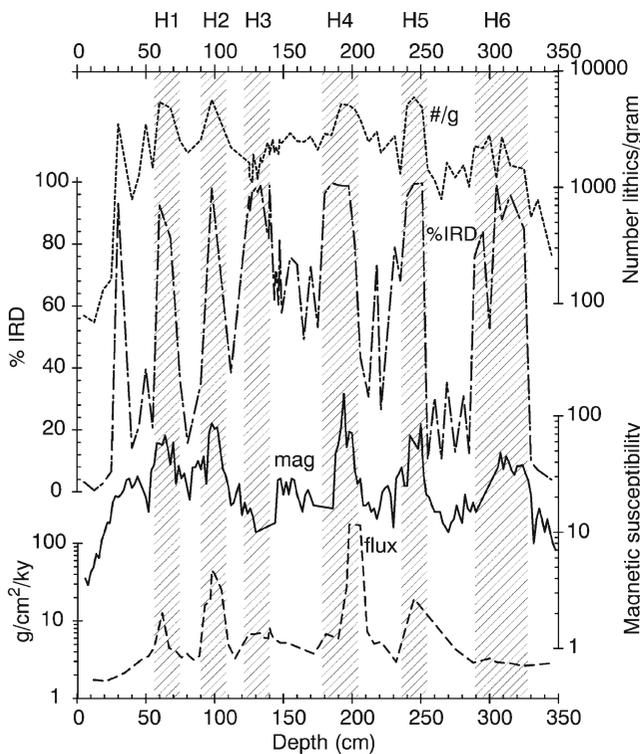

Figure H5 Different measures of IRD in core V28-82. Note that the Heinrich intervals defined by number of grains per gram do not appear to be precisely correlated with those defined by %IRD. Additionally, the intervals of high flux measured by ^{230}Th excess are smaller than those defined by counts. The intervals of high magnetic susceptibility are also smaller and appear to be offset from the flux peaks. These records reflect at least four independent samplings of the core, so partly the apparent offsets could be related to that. However, they are too large to be entirely explained in this way. Data sources are: %IRD and number of lithic grains per gram (Gwiazda et al., 1996; McManus et al., 1998; Hemming et al., 1998), flux (McManus et al., 1998), magnetic susceptibility (Greg Downing, unpublished data).

these observations. They found that during Heinrich layers H1 and H2 there appear to be sequential increases in volcanic grains, quartz grains, and carbonate grains at core SU9009 in the south-central part of the IRD belt. This observation of a precursor with greater lithic grains of non-Hudson Strait source suggested that the Laurentide Ice Sheet was not always responding to the same climate forcing as the Dansgaard-Oeschger (D-O) cycles, or was doing so later than other ice sheets. Furthermore, Vance and Archer (2002) have found that the provenance of precursory intervals to H4 and H2 are not similar based on radiogenic isotope studies of DSDP609 sediments.

One view of these precursors is that they simply represent the IRD signals of D-O cool phases in the North Atlantic (Bond et al., 1999; G. Bond, personal communication in 2002), and their appearance before the Hudson Strait-derived detritus means that the sea surface cooled prior to the input of Heinrich layers. Icelandic glass is an important component in Iceland Sea (Voelker et al., 1998) and Irminger Basin sediments (Elliot et al., 1998; van Kreveld et al., 2000), and East Greenland may be a significant source of hematite-stained grains (Bond et al., 1999; van Kreveld et al., 2000).

Although there is contention about whether Heinrich layers have correlatives in the Nordic seas (Fronval et al., 1995 and Elliot et al., 2002 vs. Dowdeswell et al., 1999), it is clear that the pattern is different. In the IRD belt, Heinrich layers are outstanding IRD events while events in between are modest although apparently correlative with Greenland cooling events (Bond et al., 1993, 1999; Bond and Lotti, 1995). In contrast, there is apparently an IRD event of equal magnitude for each of the Greenland cooling events, although there is a larger flux in general during the Last Glacial Maximum.

The key precursory events to Heinrich events may be preserved in Labrador Sea sediments. The recognition that the carbonate-rich intervals in the Labrador Sea marine sediment cores are approximately synchronous with Heinrich events (Bond et al., 1992; Andrews et al., 1994) helped to explain the source of the Heinrich ice armadas. However, in contrast to the case in the open ocean, where icebergs are the major sediment contributors, a large fraction of the sediment deposited near the Hudson Strait is brought by meltwater. Hesse and Khodabakhsh (1998) showed that the carbonate-rich layers near the mouth of Hudson Strait differ in sedimentological character from the Heinrich layers in the open ocean, and in particular are much finer-grained. They described a series of facies: nepheloid-layer deposits (or type I Heinrich layers), mud-turbidites (or type II Heinrich layers), laminae of IRD (or type III Heinrich layers), and fine suspended sediment and dropstones supplied by ice rafting (type IV Heinrich layers). These facies are generally arranged proximal to distal from the Hudson Strait, with type IV being the character of Heinrich layers in the IRD belt. Clarke et al. (1999) suggest that at Orphan Knoll site HU91-045-094 Heinrich events are separable into two distinct depositional processes. Turbidite sedimentation with high fine-grained carbonate concentrations is followed by a brief interval of increased IRD. The observations from the Labrador Sea suggest an interval where sediments were derived from subglacial meltwater prior to the launching of iceberg armadas to the North Atlantic.

Processes that may produce Heinrich layers

The timing of Heinrich events is in striking coincidence with the pattern of climate fluctuations documented from ice cores (Bond et al., 1993; Broecker, 1994). There is also good evidence for a global, or at least Northern Hemisphere wide, footprint (Broecker and Hemming, 2001; Hemming, 2004). Although the mechanism that drives the events remains a matter of debate, there is no doubt that they are spectacular examples of interactions among Earth's atmosphere, oceans and cryosphere. Most of the individual studies of sites outside the North Atlantic ice-rafting zone conclude that the Heinrich-correlated events are caused by changes in winds; stronger trade winds in the tropics, stronger winter monsoon winds in China (Porter and An, 1995; Wang et al., 2001) and the Arabian Sea, stronger northerly winds in the western Mediterranean. When compared to the ambient glacial conditions, there appears to be a general pattern of tendency for wetter (milder?) conditions along the western North Atlantic margin during Heinrich events, and perhaps along the eastern South Atlantic margin. In contrast, more extreme cold/dry glacial conditions prevailed during Heinrich intervals on the eastern North Atlantic margin and western Mediterranean. The pattern of differences between Heinrich events and ambient glacials, as well as the geographic distribution of sites that are sensitive to Heinrich events versus D-O events, may provide important clues as to the driving forces of these abrupt climate

changes. The coincidence in timing with the D-O pattern and the broad pattern of Northern Hemisphere correlations imply an important climate connection to Heinrich events. The layers themselves, however, reflect anomalous glaciological processes, and proposed mechanisms for their origin are discussed below.

Three broad categories of proposed mechanisms for Heinrich layers are reviewed by Hemming (2004): (a) catastrophic purging of the Laurentide Ice Sheet (MacAyeal, 1993) or episodic activity of an ice stream in the Hudson Strait (Marshall and Clarke, 1997), (b) jökulhlaups (Johnson and Lauritzen, 1995), and (c) ice shelf breakup (Hulbe, 1997; Hulbe et al., 2004). All appear to be capable of producing the first order features of the Heinrich layers, including the large injection of fresh water into the North Atlantic Current (with volume depending on duration) and the large volume of sediment deposited rapidly in these events.

Hemming (2004) concluded that glaciological instability (episodic purging) is the most likely explanation for the Heinrich layers unless it can be demonstrated that these events are much shorter than the estimated 500 year duration (essentially instantaneous). Although it is conceivable that the Heinrich layers represent instantaneous deposition as required by the ice shelf and jökulhlaup scenarios, the data appear to be more consistent with at least hundreds of year duration for the layers. Further examination of hydrographic changes in the North Atlantic may provide additional constraints on the ice-derived water volume by documenting the mixed layer thickness. Additionally, further examination of detailed sedimentology and hydrography proxies in the Labrador Sea provides constructive ways to decide among the proposed possibilities.

Summary

Heinrich layers are spectacular IRD deposits in the North Atlantic that resulted from massive discharges of icebergs from the Laurentide Ice Sheet through the Hudson Strait. They are clearly linked to dramatic climate shifts in the Northern Hemisphere. Detailed studies of the interval containing H1 through H4 in the IRD belt have demonstrated a strong connection between the timing of Heinrich layers and the pace of climate variability in the North Atlantic. More work is needed in the Southern Hemisphere in order to evaluate whether or not an inter-hemispheric correlation truly exists at the times of Heinrich events.

Much effort has gone into characterizing the Heinrich events in the North Atlantic and in identifying potentially correlative climate events globally, and from this effort a picture is emerging about the causes and effects related to them. They occurred during extreme cold periods in the North Atlantic, followed abruptly by dramatic warming trends. A large influx of ice-derived water into the North Atlantic accompanied these events, and it appears that a major reorganization of deep ocean circulation was produced. What remains to be better understood is whether the correlations were global or only Northern Hemisphere-wide, and what was the ultimate driver of these dramatic events.

HISTORY OF PALEOCLIMATOLOGY

The roots of paleoclimatology

This narrative will treat sequentially (i) the discovery phase of the evidence (which still continues to this day) and (ii) the causative and experimental phase. Short biographies of major paleoclimatologists are presented in a companion piece.

Earliest observations

The elemental concept of climate change probably evolved in documentary form in ancient Egypt (Nile Valley), Mesopotamia, the Indus Valley and in China, where exceptional river floods or extended droughts were experienced. Decadal to century-long variations in the amplitudes of the Nile floods were more or less paralleled by the fortunes of successive dynasties. Times of drought and famine were socially more serious than episodic experiences of excessive (summer) floods. Early chapters of the Judeo-Christian Bible, notably *Genesis*, recounted the tale of the forty-day rain, resulting in the “flood of Noah,” and the subsequent recovery. Other oriental cultures contained comparable traditional sagas. It can therefore be a reasonable speculation that the concept or idea of periodic climate change was not only firmly established in human folklore, but also justified by periodic reinforcement provided by anomalous climatic events (as discussed below); see especially Ryan and Pitman (1999).

During the last 10,000 years or so, climatic events have affected human history on various scales, evidence for which is now being uncovered with increasing frequency. The role of external events, large or small, as causative factors in human history, thus became a central feature in Aristotelian thinking, and this approach tended to dominate “natural history” for the next two millennia (Schramm, 1963). For example, the development of huge pro-glacial lakes across North America during the retreat of the Laurentian Ice Sheet was accompanied by iso-static crustal rebound that eventually tilted the lakes seawards, resulting in great floods of freshwater that spread out and eventually diluted adjacent ocean surfaces, causing paleoclimatic crises with global repercussions. This may have contributed to universal flood mythology.

Another single-event phenomenon was the drowning of the Euxinic freshwater lakes in the Black Sea region when the postglacial sea-level rise surpassed the threshold sill of the Bosphorus (Zenkovitch in Fairbridge, 1966, p.146). Recent

oceanographic exploration here has disclosed abundant evidence of the former littoral, its fauna and human inhabitants (Ryan and Pitman, 1999).

From a historical point of view, the rejection of catastrophic hypotheses illustrates the innate conservatism of geologists raised on a philosophy of Lyellian uniformitarianism (see discussion, below). The eventual acceptance of such “outrageous” hypotheses has gradually led to a modified philosophy of neocatastrophism.

Dawn of reason

Even prior to the time of Lyell (1797–1875), gradual build-up of an anti-catastrophic and anti-miracle camp had begun. By the eighteenth century, observations could often be supplemented by chemistry and geological fieldwork, and the latter presented the endless paradoxes of paleoclimatology (although this term did not emerge until the twentieth century). At first, the observers were like the hunter-gatherers of anthropology. They simply explored. They started recording their observations on maps. Specialized concepts like petrology, stratigraphy, structure, mineralogy and paleontology emerged only in the early nineteenth century. The observers of the eighteenth to early nineteenth centuries were in two categories: (i) the gentlemen-traveler, i.e., personages with “private funds” who explored the world out of curiosity; and (ii) the commercially funded people who were “mission-oriented,” searching specifically for resources such as coal or metallic minerals such as gold, silver, iron, copper, zinc and lead; or engineer-trained, who were planning canals or water-supplies. Those observers who asked questions about the climatic conditions indicated by this or that proxy at the time of its formation had both leisure and literacy. An early discussion of scientific questions was by Emanuel Swedenborg (1688–1772), the Swedish scientist and theologian, who attributed elevated shorelines to progressive desiccation of the world ocean following the Biblical flood (see further, below).

Oddly enough, the people asking questions were frequently members of the clergy, who were not only literate but whose duties called for considerable traveling. Thus, Nicolaus Steno (Stensius; 1638–1686), the “father of stratigraphy,” although trained in the flat terrain of Denmark, spent most of his (theological) career in northern Italy, where he found time to accurately observe and record the stratification and structures of rock formations.

The scientific approach

The earth-science historian Schwarzbach (1963, 1974) recognized Robert Hooke (1635–1703), the English physicist, as the first scientist in paleoclimatology. He observed giant turtles and oversized ammonites in the Portlandian (uppermost Jurassic) of Dorset in England and concluded that they indicated a once warmer climate. This he believed could only be explained by a shift in the Earth’s axis.

Another imaginative pioneer was George L. Leclerc, Conte de Buffon (1707–1788), a celebrated French natural scientist. In his book “*Epoques de la Nature*” (1778), Buffon described the gradual cooling of a once-molten Earth, a cooling that began at the poles. Formerly warm temperatures at high latitudes were demonstrated by discoveries of large mammal remains, such as elephants and rhinoceroses, in these regions; such creatures are only found in warm climates today.

Then came Thomas Jefferson (1743–1826), third president of the United States, who had also served as ambassador to France and had become acquainted with Buffon. In his book “*Notes on the State of Virginia*” (1785), Jefferson discussed the discovery of fossil mammoth bones in what he regarded as anomalistically high latitudes. He believed this could possibly be explained by a change in the angle of the Earth’s ecliptic, and thus the tilt of the spin axis that controls the annual distribution of the seasons. At present, the Southern Hemisphere summer coincides with the Earth’s closest approach to the Sun and the Northern Hemisphere summer comes when they are farthest apart. About 9,000 years ago, the northern summer came when the Earth’s orbit was closest to the sun, so that mid-latitude mean summer temperatures were 2–3 °C warmer than today. The question of the mammoths in North America could alternatively be explained by a change in the creatures’ preferred habitat, a choice also considered (and favored) by Jefferson.

The classic “gentleman-scientist-traveler” was Alexander von Humboldt (1769–1859), who became the most famous German earth scientist of the nineteenth century, notably for his work in South America. He also lived for nearly 20 years in Paris and thus had the good fortune to gain access to its scientific libraries and to contemporary naturalists and thinkers like Buffon. To begin with, in 1799, however, he succumbed to A. G. Werner’s “Neptunian” concept of water-laid granites and basalts, a false idea, albeit contributing to a once warmer Earth. Later, after observing active volcanoes, he was probably the first to recognize the potential influence of ash and dust clouds on cooling of the climate (1823).

Idea of climate cycles

The classic concept of climatic cycles is probably that attributed to Joseph who was a member of the Israelite community in the Egypt of the New Kingdom, perhaps around the fourteenth century BC. Joseph (in the scriptures) warned of 7 years of bounty followed by 7 years of lean conditions. The message was clear: climates fluctuate, so, take care and plan ahead! Egyptological data include evidence of high-water marks (carbonate crusts) on temple columns, alternating with signs of erosional dissection in Nile terraces, which point to times when the flow was sluggish. Papyrus descriptions can now be confirmed by geological surveys (Fairbridge, 1962).

Systematic measurement of Nile flood cycles was initiated during the Moslem era (AD. 610), with many centuries of accurate data. Both short and long cycles have been identified (Hassan, 1981), which reflect monsoonal rainfall, mainly in the Ethiopian headwaters of the Blue Nile. Spectrum analysis (Currie, 1995) discloses both solar (11 years) and lunar (18.6 years) periodicities.

The first discussion of elevated shorelines (around the Baltic) appears to have been by Emanuel Swedenborg (1688–1772), mentioned above, who attributed them to traces of former levels accumulated or eroded during the progressive desiccation of the world ocean after the Biblical flood. An experimental approach was that of Carl Linneus (1707–1778), a Swedish professor from Uppsala, jointly with Anders Celsius, the professor of physics. Linneus was best known for his systematic biologic classification (having introduced the structured nomenclature of biology with species, genus, and so on). Together they made a remarkable contribution to climatic history when they disproved the “Desiccation Theory,” which had been widespread in the eighteenth century. The theory was formulated by the Bishop of Åbo (now Turku, in Finland) and based on the gradual emergence of the

coasts of Scandinavia, which he and fellow-theologians interpreted as conclusive evidence for the Bible story of the Noachian Flood and its subsequent recession. Linneus and Celsius devised a practical experiment to test the Biblical Desiccation Theory. Having heard that southern Sweden was emerging more slowly than the northern part of the country, they decided on a summer vacation on horseback and chiseled a series of water-level marks along the coast. Each site was revisited annually for 10 years, after which they announced their results. In the north around the Gulf of Bothnia, the coast appeared to be rising at 6–8 mm a year, while in the south, the Baltic shore was progressively sinking; in places it was even negative (the water marks were submerged). A desiccation of the world ocean would be uniform, but relative motion must reflect motion of the Earth's crust. This was probably the first practical experiment in both crustal change and paleoclimatology. (However, they did not perceive the connection to isostatic rebound due to removal of the former ice load [Ed]).

Anders Celsius (1701–1744), the Swedish physicist and astronomer at Uppsala at the same time as Linneus, was distinguished for his early observations of the aurora borealis (1716–1732). Besides helping to measure the arc of the meridian in Lapland (with colleagues from the French Academy of Science, in 1736), he became known for developing the centigrade scale, later known as the “Celsius scale” for thermometers. Accurately calibrated instruments were distributed to the physics departments of all major universities. For the first time, temperatures could be measured quantitatively.

In connection with the Linneus-Celsius experiments should be mentioned the experience of Baron Christian Leopold von Buch (1774–1853), a famous German geologist who had been a fellow student with von Humboldt at the Freiberg Mining Academy in Saxony. He made extensive trips by boat around northern Norway, as well as in the Baltic. Von Buch confirmed that the coast was indeed rising at Åbo, as was most of Scandinavia. Northern Norway, exposed to severe storm waves of the North Atlantic, is subject to spectacular coast erosion. The crustal uplift in northern Norway, however, created a succession of emerged benches in the form of a staircase. These dramatic landforms are repeated along the coast for more than 1,000 km. In 1810, Von Buch attributed the uplifting not to cyclical climate factors but to pulsatory magmatic causes, such as he had seen operating in the Canary Islands and other volcanic regions. (The glacioisostatic explanation for the uplift had to wait for over one hundred years: see below.)

Reusch, in 1894, coined the term “strandflat,” for the wide shore platforms. However, storm waves were not responsible because shore erosion is also found on the inner sides of fjords. To explain them, Nansen (1922) proposed a two-stage process: (i) frost action at or above sea level, followed by (ii) freezing and transport of the debris by floating ice. First observations in Quebec by Lyell helped his drift theory (see below). Traces of “fossil” strandflats and ice-transported boulders are seen on the Channel coasts of England and France, and as far south as northwest Spain (Fairbridge, 1977).

Could cyclical processes be triggered extraterrestrially? The idea that the Sun might have something to do with climatic events was to tread on delicate ground. When Galileo Galilei (1564–1642) first observed sunspots, it implied to some theologians an imperfection in the face of God's creation, the Sun, and that was anathema. Astronomy led nevertheless to the idea of predictable cycles. When Sir Edmond Halley (1656–1742) successfully anticipated the return of his eponymous comet in

1758 (from earlier orbits in 1531, 1607, and 1682), the case was established. The comet returned again in 1835, 1910 and 1986. He also laid the foundations for the new science of geomagnetism, which eventually helped to link endogenetic forces with paleo-climatology. Later, Sir William Herschel (1738–1822), when astronomer-royal of England, hinted that not only did the sunspots fluctuate in a cyclical manner, but that they might also relate to some climatic fluctuations that could affect the price of wheat.

Systematic observations of sunspots were begun in 1826 by an amateur astronomer, S. H. Schwabe, of Dessau, Germany, who announced a roughly 10-year cycle in 1843. At that time, Sir Edward Sabine had been monitoring geomagnetic fluctuations in Canada and found a similar variation, even hinting at “a common cause.” This was also suggested independently in 1852, by R. Wolf and A. Gautier, in Switzerland and France, respectively, and by R. C. Carrington in 1860, in England.

A century of controversy about Sun-climate relations has followed. An abundant literature accumulated over the decades, summarized in “*Sunspot Cycles*” (Schove, 1983). Today, the concept of a solar forcing cycle is beginning to be recognized, but the “how” and “why” are still elusive (e.g., Bond et al., 2001; Shindell et al., 2001; Rind, 2002). Systematic measurement of temperature opened the door (very gradually) to the idea of climatic cycles. This practical step was made possible by Celsius in the early eighteenth century, and two centuries later came the first analysis of an instrumental temperature time series (which had been assembled by the Dutch meteorologist Labrijn during World War II) that clearly displayed climate cycles (Fairbridge, 1968, p.210).

Labrijn's time series disclosed temperature cycles corresponding to the 22-year solar magnetic reversals and radiation fluctuations. These observations applied only to the North Atlantic-European area covered by the temperature recordings initiated by Celsius, but they opened the way to some twentieth century thinking.

The existence of that 22-year cycle was later confirmed by Schuurmans (in Flohn and Fantechi, 1984). The cycle was further strengthened when small errors caused by the urban heating effect were skillfully removed in a 250-year study of Stockholm temperatures by Anders Moberg (1995). The statistical procedure that made Labrijn's study so impressive used the mean summer months (June, July, August) minus the mean winter months (December, January, February) (3-month values) to create an oceanicity/continentality record.

One clue to solar-climatic relationships lies in the Moon. The role of the Moon in weather cycles has long been established in folklore, for better or worse. In science, George Schübler a professor of physics at the University of Tübingen, Germany, presented a paper in 1836 containing statistical analysis of his 60 years of systematic measurements of rainfall, which disclosed the 18.6 years lunar nodal cycle (see: “Earth-Moon system – dynamics” in Shirley and Fairbridge, 1997). Also worth mentioning is a fifteenth century agronomy text published in Italy that pointed out the advantage in seeding time because of the rainfall indications of the 18.6 years cycle. Sir Arthur Schuster of Manchester (U.K.), known for his invention of the time-series periodogram, published on the lunar and solar periodicities in earthquakes (1897) and on the influence of planets on sunspot formation (1911). In the late twentieth century, R. G. Currie disclosed lunar cycles in practically all geophysical and climatic time series, not least the nearly 1,400 years' record of the Nile floods (Currie, 1995).

William Gilbert's (1544–1603) pioneering discoveries in geomagnetism eventually led to an understanding of the aurora borealis and later the aurora australis as expressions of the Earth's magnetic field in the face of an initially mysterious solar force. A comprehensive review of the history of this subject was done by Siscoe (1980), establishing their correlations with sunspot cycles, but he set aside specific linkage with the solar wind and the geomagnetic field.

Scientific observations of the aurora and the geomagnetic field were begun in Scandinavia in the nineteenth century. Because of the high latitude, the common folk of Norway and Sweden had been observing these phenomena for many centuries. Country pastors recorded many sightings and these were analyzed by two distinguished scientists Nils Ekholm and Svante Arrhenius (a meteorologist and a geochemist) in a publication of the Royal Swedish Academy of Science. They identified both the 11-year solar cycle and the 18.6-year lunar cycle, as well as their climatic associations (Ekholm and Arrhenius, 1898). Today, a century later, this seminal paper is never cited and these relationships are still very little understood.

Popularization of paleoclimatology

Popularization of scientific thought became the fashion in early nineteenth century Europe and North America. Hugh Miller (1802–1856) made fossil discoveries that became a basis for paleogeographic and paleoclimatic reconstructions in his writings. They proved to be immensely exciting for his non-technical audiences.

A Swiss naturalist and professor of botany in Zürich, Oswald Heer (1809–1883) was the first to discover evidence (fossil leaves and fruit) of a warm climate during an interglacial interval in the Alps. Heer's epoch-making book "*The Primeval World of Switzerland*" (2 vols., 1865, transl. 1876) was very widely read and helped establish him as one of the founders of paleoclimatology and of paleogeography. By assuming that fossilized plants could be used as analogues for modern ones, the present-day habitats (in terms of temperature and precipitation) could be used for calculating proxy temperatures and rainfall. Bearing in mind that during the early Cenozoic the Tethys seaway was open to the Indian Ocean and Pacific, Heer's calculation of a mean warming of 7° F (3.5 °C) at that time was "probably the best approximation" (Brooks, 1949). Intervals of the warm paleoclimates in the Cenozoic would appear to have been achieved by three synergetic global paleogeographic factors: (i) open Tethyan seaway worldwide; (ii) limited orographic blocking; (iii) restricted Antarctic mountain glaciers (Fairbridge, 1961).

Uniformitarianism and actualism

The Scottish "gentleman-farmer" James Hutton (1726–1797) was the first to examine climate as a global phenomenon, although this work was largely eclipsed by his revolutionary role in geology as a whole. His original "*Theory of the Earth*" (a paper to the Royal Society of Edinburgh, 1785) endeavored to set out the natural laws by which the dynamics of Earth history could be explained. To explain erosion of the Earth's surface, he introduced the idea of climate and the atmosphere, and the year before (1784) he outlined his "*Theory of Rain*." This included a global review of climate, recognizing that atmospheric humidity was the key to rainfall, and that precipitation must occur when a warm air mass encounters a cooler one. An invaluable summary of his ideas was published by John

Playfair in 1803 (see also below). Hutton contributed fundamentally to the eighteenth century concept that eventually came to be called "uniformitarianism." Lyell (1830) reasoned that the "laws of nature" were immutable and permanent, which permits one "to reason by analogy." The standard aphorism is: "the Present is the Key to the Past." Whereas Nicolaus Steno (1631–1687) discovered the idea of sequence, or time-ordering, it was Hutton, after his famous discovery of a stratigraphic unconformity, who realized that geological processes should not be seen as a continuum but as subject to periodic upsets or revolutions. Thus, the concept of a *cycle* of events or processes emerged, to be further consolidated by Lyell in his stratigraphic sequences. It was not, however, until the late twentieth and early twenty first centuries that those sequences became locked into a paleoclimatologic framework, when Milutin Milankovitch (1879–1958) and Frederick Zeuner (1905–1963) developed, respectively, astronomic forcing potentials, with their stratigraphic representation.

A slightly different concept of uniformitarianism and terminology had already emerged in Russia and eastern Europe, the word "actualism" being coined by M. V. Lomonosov (1711–1765), Russia's "Father of Science." As generally conceived, actualism was practical methodology. It was therefore an investigative tool based on laws derived from quantitative models and would justify predictions as well as past events. In contrast, uniformitarianism was more a philosophy of "geohistory," subject to many potential dangers of interpretation (Albritton, 1975). Today, the actualistic approach is preferred.

In northern Germany the late eighteenth century was marked by frequent observations of exotic boulders (mainly granite or ancient limestones), called "Findlinge" (foundlings). Both country people and geologists recognized they did not belong in the local suite of outcrops. In folklore, they were generally attributed to relics of the Biblical Flood. In 1802, John Playfair (1748–1819), the Scottish geologist and follower of James Hutton, appreciated that these blocks or boulders were similar to others in the peripheral valleys of the Alps, where local scientists attributed them to glaciers that were formerly more extensive.

The glacial theory

The "glacial theory" was to become one of the scientific world's preoccupations during the first half of the nineteenth century. Good summaries are to be found in Flint (1971), Schwarzbach (1963, 1974) and Imbrie and Imbrie (1979, 1986).

The glacial theory received a significant spurt when, in 1817, the Swiss Natural Science Society announced a competition for members to demonstrate the former extension of the Alpine glaciers. This was rewarded in 1822 by a key lecture delivered by the Swiss engineer, Ignatz Venetz (although it was not published until 1833). The theme was taken up enthusiastically by geologist Louis Agassiz (1805–1873) who eventually came to teach at Harvard University.

Scandinavia was also a potential source of erratic blocks, but the glaciers there were smaller and less known than those of Switzerland. Nevertheless, in 1824 Jens Esmark of Denmark (1762–1829) proposed a former glacial source for northern Europe's widespread erratics.

At this point in history, the "establishment" struck back, through the powerful and colorful pen of the Reverend Dean William Buckland (1784–1856), first professor of geology at Oxford, and president of the Geological Society of London in

1824 and in 1840. Bearing in mind that his income depended in large measure on his religious observances, it should be no surprise that the Noachian Flood should feature in his public utterances. Thus, his first major work in 1823 was entitled "*Reliquiae Diluvianae, or Observations on the Organic Remains, contained in Caves, Fissures and Diluvial Gravel, attesting the Action of a Universal Deluge.*" Buckland coined the term "diluvium" (i.e., flood formation) for deposits of the Pleistocene ice age and this label came into widespread use in Europe, retained even into the twentieth century, long after the Biblical Flood story was quietly abandoned. Buckland's enthusiasm and extrovert nature brought him some criticism; nevertheless, he firmly established the concept of stratigraphic paleontology, the contrasting sequences of which constitute the very core of paleoclimatology.

From drift ice to glaciation

The glacial theory was the first of those remarkable revolutions in thought that directly concerns paleoclimatology. From the question of erratic boulders to continental glaciation calls for a great leap in scale, but it was scarcely more than a decade before this intellectual leap was achieved. The key was field demonstration. On Alpine excursions in 1836, Ignatz Venetz and then Jean de Charpentier persuaded Louis Agassiz of the former expansion of the mountain glaciers over the surrounding lowland terrain, and in 1837 Agassiz presented his general theory of a "Great Ice Age" to the Swiss Society of Natural Sciences in Neuchâtel. His regular correspondence with geologists in Britain led to Alpine excursions by Buckland (in 1838) and exchange trips by Agassiz (first, in 1840) to England, Scotland and Wales. Charles Lyell was shown the evidence, and eventually there was consensus. Almost the whole of the British Isles must have been glaciated according to T. F. Jamieson (1829–1913). The first general survey of the subject in Britain was in 1874 by James Geikie (1839–1915), who had been professor of geology at the University of Edinburgh. North America also provided important clues (Flint, 1971).

Lyell, curiously enough, was not an instant convert. He made two trips to North America, including one to the St. Lawrence valley and Bay of Fundy in Canada. Here he observed glacial boulders embedded in floating ice, and in the first edition of his "*Principles of Geology*" (1830) he attributed all erratics to drifting ice. Indeed, for a long time (over a century) all superficial deposits of evidently glacial origin were classified in both Britain and the United States as "drift." This was more a habit than belief. It was only in the later editions of Lyell that "drift" became divorced from floating ice. In the United States, it served as a synonym for glacial deposits in general and a "driftless area" is still recognized in the upper Midwest (Flint, 1971, p. 478).

In Germany, the reception of the glacial theory was also not instantaneous (Schwarzbach, 1974). Nevertheless, the German word "Eiszeit" (ice age) was the first such expression used by Karl Schimper in 1837, though it was quickly adopted worldwide. Von Buch, professor of geology in Berlin, had an enormous influence but considered the erratics to be transported by mudflows. In a letter of 1850 (Schwarzbach, 1974, p.5), he refers to the glacial theory as "a strange aberration of the human mind." Eventually, in Germany, the concept became universally accepted after a visit to Berlin in 1875 by the Swedish geologist Otto Torell (1828–1900).

In Scotland, Charles MacLaren, in 1842, reasoned that if this huge amount of ice had been derived by evaporation from the ocean, then sea level at the glacial maximum must have

been much lower than today. Unfortunately he overestimated the former ice volume and calculated the fall of sea level at 800 feet, which later proved to be somewhat exaggerated (by a factor of about 2). The principle, however, was important, and a globally significant phenomenon was now established, although it was more than 100 years before it was incorporated in general geological reasoning. Not only were vast climatic changes possible, but they also affected sea level and the relative size of continents and oceans from which climatic feedback processes were inevitable (Valentine and Moores, 1970).

Pre-Quaternary ice ages

Before the end of the nineteenth century, other, even more extensive glaciations were discovered to have occurred prior to the Quaternary "Great Ice Age." First to be found was the Permo-Carboniferous Ice Age (in multiple phases). Evidence for these glaciations was widely greeted with incredulity, partly because their situations were often close to the equator and, as more and more sites were added, it was seen that they were (improbably) spanning the width of an entire hemisphere (Du Toit, 1937).

Possibly one of the most courageous acts that can be imagined was when a very youthful new arrival to the Geological Survey of India, W. T. Blanford, in 1856, announced that he had just discovered indisputable evidence of a former ice age in the Permo-Carboniferous sediments of the Deccan (between 17° and 24° N), at a distance of only a little over 2,000 km from the equator. At that time, fixed continents, fixed planetary orbits and fixed ideas were rather rigidly established. Nevertheless, cynics may be astonished to learn that Blanford later became Director of the Survey, his extraordinary discovery being later confirmed elsewhere in India, as well as in all parts of the Southern Hemisphere. In fact, this glacial formation, to be known as the Talchir Tillite, over 100 m thick in places, became a key factor in the concept of a former giant continent, called (in 1883) "Gondwanaland" by Suess (1831–1914), parts of which today straddle the equator.

Permo-Carboniferous glacial deposits and striated pavements were then discovered all across Gondwanaland (Frakes, 1979). They were reported in Australia (eventually in all seven states); in Africa, from the extreme south to north of the Congo; and Arabia (Crowell, 1999). They were also discovered in South America (from Brazil to Patagonia and the Falkland Islands), and finally in Antarctica. Historically, these discoveries generated many interesting and some altogether exotic hypotheses. The most significant of these was the "Theory of Continental Drift" of Alfred Wegener (1926; translated 1966) which proved to be the forerunner of the modern plate-tectonic paradigm (summarized by Emiliani, 1992, p. 234–253). In this way, with the aid of marine geology and geophysics, a solution was found for what at first sight was an insoluble problem in paleoclimatology.

Further great ice age intervals were subsequently discovered in earlier geologic periods. One of the largest of these was that of the late Ordovician, which eventually was found to have extended from Brazil through West Africa and completely across the Sahara to Ethiopia and Saudi Arabia. Interestingly it was only discovered in the 1970s, initially by French oil geologists. Its presence was anticipated through paleontological indicators and based on paleomagnetic data (Fairbridge, 1971, 1973).

Discovered earlier was a late Proterozoic ice age, known as the Varangian due to the site of its first discovery on the

Varanger Fjord in the Finnmark district of northernmost Norway. Its present latitude, about 100 km north of the Arctic Circle, presents no problem in climatology (Schwarzbach, 1974; Frakes, 1979). Eventually an “Eocambrian” glaciation was also discovered in South America, West Africa, in South Australia and elsewhere, leading to the concept of a “Snowball Earth” at one stage. Plate-tectonic reconstructions were needed, however, in order to apply “actualistic” models.

Still earlier Precambrian tillites, which are more difficult to date, have been traced back in time (For example, the Gowganda Tillite in Canada at about 2.8 billion years BP). The problem of correct identification rises as one goes back in time and, when in doubt, the terms “pebbly mudstone” and “diamictite” have been used.

Causality: climatic changes

Visher (1986) wrote: “Geology as a predictive science may find its roots in the naturalism of the eighteenth century. The need for a naturalistic philosophy was developed due to the discovery of the predictability of the motion of bodies useful in discovering the array of order throughout the solar system.” Progress called for inductive reasoning, and, in addition, “bold hypotheses” were needed. In 1830, Lyell had already written: “Geology is the science which investigates the successive changes that have taken place in the organic and inorganic kingdoms of nature; it inquires into the causes of these changes, and the influence which they have exerted in modifying the surface and external structure of our planet.”

These generalized principles can now be applied to paleoclimatology, provided that its highly interdisciplinary nature is clearly understood: Astronomy, meteorology, geophysics, biology, geochemistry, sedimentology and stratigraphy are all involved.

One of the lengthy treatments of paleoclimates in general was by Eugène Dubois (1858–1940), who discovered the “Java (Trinil) Man” (while working in the Dutch East Indies). Dubois (1893) believed that an evolving Sun was a factor in paleoclimatology, but the time-scale was a difficulty. Evidence of remarkable climatic fluctuations that completely changed the physical geography of central Asia and its human environments on scales of 10^4 years or less was found in central Asia (Huntington and Visher, 1922).

Early works on paleoclimatology include “*Climate Through the Ages*” (Brooks, 1949, 1970). Brooks (1949, p. 382–386) conveniently tabulated a series of potential forcing agencies, with numerous references. Schwarzbach (1974) and Frakes (1979) have greatly expanded this database. The actual term “*Palaeoklimatologie*” (in German) was used in a book-length text by a paleobotanist, F. Kerner-Marilaun (1930).

Cosmic variables

In the late twentieth century, increasing knowledge of outer space afforded, for example, by the Hubble Telescope, has greatly expanded our concepts of the galaxies, and particularly of our own, the Milky Way galaxy. A major climate-modulating agent that has been proposed is intergalactic dust, as well as gas clouds. The earliest suggestion of the latter appears to be by Calverwell in 1895. Cosmic dust in outer space was also favored by Noelke (1908). Two Cambridge astronomers, Hoyle and Lyttleton (1919), speculating on the potential for interstellar “matter” to modify climate, have both been severely criticized for their unconventional (but often stimulating) ideas.

Particles in the galactic arms

Twentieth century studies of the Milky Way galaxy have shown that there is a high concentration of particulate matter embedded in the two spiral arms. Further, their distal parts display a regular undulation through which the Solar system must pass in its revolution around the galaxy. This periodicity is around $30 (\pm 3)$ Myr, which provides a potential forcing function for extinction/evolution spurts (Eldredge and Gould’s “punctuated” evolutionary model, 1972), for which Rampino and Haggerty (1996) proposed the term “Shiva Hypothesis”.

Solar radiation

Two categories of radiation (or energy emission) from the Sun are especially relevant for climate and paleoclimate studies. More than 99% of that energy is in electromagnetic form, the spectrum ranging from gamma and X-rays through UV to visible and IR to radio waves. Only the UV to near IR spectrum is relevant for climate (Peixoto and Oort, 1992). It travels in a rectilinear sense at the speed of light ($2.9973 \times 10^8 \text{ m s}^{-1}$, or approximately 186,000 miles s^{-1}), and accordingly has its terrestrial impact maximized at the Earth’s equator and as far north and south as the two tropics, Cancer and Capricorn, decreasing polewards. Heat flow from inside the Earth, generated by nuclear reactions, is about 3.5 orders of magnitude less than the exogenetic source.

The second solar source is particulate emission traveling through the solar wind; a plasma flux, which travels at variable speeds but generally requires several days to reach this planet. The solar wind carries magnetized particles and consequently is deflected by the Earth’s magnetosphere and funneled into the lower atmosphere at the two magnetic poles. Passage through the atmosphere results in collisions with molecules of nitrogen, oxygen, and CO_2 , resulting in isotopic spalling (e.g., ^{14}C , etc.). The discovery of sunspots by Galileo Galilei (1564–1642) in 1610 opened the door to the concept of a small-scale variable in solar radiation. It just so happened that the weak sunspots of the “Maunder Minimum” during the Little Ice Age (approximately 1650–1730) immediately followed Galileo’s discovery, but stronger sunspots became visible at that time in China and Korea so that some continuity was maintained. From archaeological magnetic studies, it is now known that, at that time, the magnetic pole lay in the Eastern Hemisphere, north of Siberia, and thus much closer to China and Korea (Schove, 1983).

Orbital variations

Although precise calculations of orbital characteristics of Earth-Moon-Sun motions have only become possible in the computer age, useful hand calculations have been available for more than 300 years. Linkage with terrestrial climate was proposed by Adhémar (1842) and developed by James Croll (1875) and Sir Robert Ball in 1891. An excellent account of the nineteenth century debates can be found in Imbrie and Imbrie (1979).

With the twentieth century came the Yugoslav engineer-mathematician Milutin Milankovitch (1941, 1969). Earliest discussions with geological applications had been offered by Frederick Zeuner (1945, 1959), and these had a worldwide impact. The “Establishment” reaction was almost unanimously negative. Science historians will probably argue this question for a long time to come, but the present writer (R. W. F.), having been a close friend of Zeuner (and other major “players”), believes that this opposition was driven by multiple

factors: xenophobia, religious conservatism and professional narrowness, to name a few. The early history of the controversy is well treated by Imbrie and Imbrie (1979). Subsequent developments were noted at several international conferences (e.g., Berger et al., 1984, 1991, 1992).

The final face-to-face conference was held in 1984 at the Lamont-Doherty Geological Observatory of Columbia University in New York when all the leading experts gathered in one room, together with the surviving relatives of the Milankovitch family who were present as visitors (Berger et al., 1984). The evidence of (i) astronomy was precise; (ii) the chronology of deep-sea deposits with ^{18}O isotopic paleoclimatic proxies was incontrovertible; (iii) the deep-sea record was identical with the continental time-series developed from glacio-eolian loess deposits alternating with interglacial soil deposits with type sections in Moravia (Kukla, 1972) and China (see discussion, below), and (iv) dating the marine coastal deposits had disclosed a eustatic synchrony between them and the Milankovitch-predicted glacial/interglacial cycles as anticipated already by Maclaren (1842) and brought into the orbital perspective by Zeuner (1945/1959) and Fairbridge (1961).

Inasmuch as the three principal variables of the Milankovitch "canon" (effective terrestrial insolation results from changes in precession (18–23 kyr), obliquity (41 kyr), and eccentricity (100 kyr)), long-term extrapolation is difficult, but is assisted by power-spectrum analysis. Methods for the latter have been greatly refined (Berger, 1995). (See also *Astronomical theory of climate change*, and *SPECMAP*.) Insolation values have been calculated for the last 10 million years (Berger and Loutre, 1991, 1992; Berger et al., 1992).

Thanks to work mainly by petroleum geologists, the apparent recurrences of Milankovitch-type cycles are now known for further back than 500 million years (see *Pre-Quaternary Milankovitch cycles and climate variability*). As might be expected with a three-fold forcing mechanism, there have been periods when one or another of the cycles was dominant, and other intervals when antiphase blocking and paleogeographic smoothing weakened them practically to extinction.

Asteroid impact events

Small asteroid or bolide impacts are traceable from the evidence of craters in semi-arid terrain back in time for about 5–10 Myr, but are very difficult to trace in older sedimentary basins and in submarine settings, thus including much more than two-thirds of the Earth's surface (Shirley and Fairbridge, 1997).

Major asteroid events, on the other hand, are mainly deduced from secondary evidence, such as geophysical anomalies, debris rings and organic extinctions (Rampino and Haggerty, 1996; Rampino, 1998). The instantaneous result is a catastrophic heat surge, as evidenced by widespread charcoal fragments (Lewis and Anders, 1985). This, however, is brief but followed by acid rain and protracted global cooling. The 1906 Tunguska event in eastern Siberia was not really a major one but the destruction of forests was dramatic. Paleontological data suggest an impact event is followed by a climatic deterioration of 10^5 – 10^6 years, initiated by a relatively short-term particle loading of the stratosphere, but triggering positive feedback of some variety, from plate excitation, tectonic uplifts and rain-shadow desiccation to lowered tree-lines.

The massive extinction at the K/T boundary event was documented by Gramletter in 1965, two decades *before* the discoveries by Alvarez (1986). If the asteroid fell in the sea, some

1,250 billion tons of water (following Alvarez) would have loaded the atmosphere, and would not only have effectively quenched the initial forest fires, but its toxicity (sulphuric, nitric and hydrochloric acids) must have been inimical to most forms of life. The survivors were mostly sheltered by burrows on land, deep lakes or oceanic depths. Stenothermal (ecologically limited) forms of life perished. Eurythermal ones had much better chances of survival. The initial tsunami waves reached more than 1,000 km to central Texas from Chicxulub in Yucatan (Bourgeois, et al., 1985), so that marine littoral biotas would not have time to adapt or migrate.

Following any major impact event, there is now a general consensus that a "nuclear winter" would ensue. Besides the climatic effect, the impact area (larger than the Gulf of Mexico) would be a biological wasteland, a biotic vacuum into which new populations would be slow to penetrate. Thus, the climatic relations associated with soil development would be significantly delayed.

The impact model for the K/T event has not been universally accepted and a well-reasoned volcanic alternative (Officer and Page, 1996) has its adherents. In contrast, the Eocene-Oligocene boundary event (~34 Myr) also saw major extinctions and good evidence for an asteroid collision (~35 Myr ago, at the mouth of Chesapeake Bay, USA; Poag, 1997), but in this case an orogenic and tectono-eustatic model may also offer a reasonable explanation (Mörner, 1984). All these factors are possibly interconnected.

Endogenic terrestrial heating

Heat flow from the Earth's interior was evident since the early days of coal mining in the eighteenth century. Confirmed by deep mining for gold and other metals in the nineteenth century, it became a topic of geophysical interest in the twentieth century. Sir Edward Bullard of Cambridge (U.K.) devised "heat probes" for use at sea. A source of internal heating of the planet Earth would be provided by radioactive decay. During initial planetesimal infall, short-term (brief half-life) radioactive elements would generate considerable heat, but it is only the long-lived isotopes that would generate heat sources surpassing the age of the planet. Systematic heat-flow measurements around the globe disclose energy sources adequate to mobilize convective circulation and thereby drive plate tectonics (see below).

Plate tectonics and redistribution of continents and oceans

In the nineteenth century, there was a general assumption that continents and oceans occupied more or less permanent positions in the Earth's crust, although marine transgressions and regressions were universally recognized and orogeny was generally an accepted concept, albeit in an episodic sense. A brief historical review is provided by Gohau (1990).

With the early twentieth century came Alfred Wegener (1880–1930) and the theory of continental drift (Wegener, 1926, 1966). It was received rather favorably in Australia, South Africa, South America and India (e.g., Du Toit, 1937), but much less so in the Northern Hemisphere, where the evidence was not as striking.

Coastal matching had already been noted for Africa and South America by Francis Bacon (1561–1626) in spite of the rather poor maps of Elizabethan times. Critical factors were the paleoclimatic indicators, discovered in the nineteenth century. Pea-sized seeds of the Permian *Glossopteris* flora could not be

carried throughout Gondwanaland by wind. Richly fossiliferous (plant) remains in coal seams were interstratified with indubitably glacial deposits on each of the Gondwana continents. Wegener's drift theory, critics claimed, however, was (i) impossible in terms of geophysics, but (ii) more importantly, it was contrary to religious concepts and conservative philosophy.

After World War II, new geophysical instruments together with worldwide marine geological surveys and the Deep-Sea Drilling Program led to total rethinking. Ocean paleomagnetic anomalies were the key to understanding the dynamic history of the oceans. Sea-floor spreading opened oceanic seaways (Dietz, 1961, 1977; Pitman and Heirtzler, 1966), and subduction-driven orogenic structures closed them (Isacks et al., 1968). Permanence (or "fixism") was OUT and mobilism was IN. This "Theory of Plate Tectonics" then became the geological paradigm of the late twentieth century. A historical review is provided by Marvin (1973).

While plate boundaries are determined by seismic belts today and by structural or petrological indicators in the past, they do not determine paleogeographic boundaries, nor do they relate to climatic systems. Specifically it is the former shorelines that are of particular interest in terms of paleoclimatology. Nevertheless, the plates are essential for continental reconstruction, and thence for paleoceanographic reconstruction, but the latter requires a eustatic treatment, as, for example, in the Mesozoic trans-America and trans-Africa seaways (unrelated to plate boundaries).

For the Mesozoic-Cenozoic eras, there were two critical water bodies that profoundly affected and controlled global paleoclimatology: (i) the gigantic proto-Pacific "Panthalassa" of Wegener (1929) and (ii) "Tethys," which was formally established by Edvard Suess (1885–1909; translated 1904–1924) long before plate tectonic reconstructions. Over about 250 million years, the Panthalassa progressively shrank in size as the two Americas shifted westward while the eastern Pacific was subducted. At the same time, the west-central and southwest Pacific became segmented into back-arc basins and island arcs. "Tethys" was linked equatorially to Panthalassa. The Tethyan link was always equatorial, with oceanic circulation going east to west. The climatic consequence was a global warming system of extraordinary effectiveness and continuity. As long as it remained in place, no terrestrial ice age could develop. This global oceanic circulation acted like a clean radiator for an automobile in maintaining a constant global temperature for the "climate machine."

As Africa, India and Australia drifted northward, they helped to create the continuous Southern Ocean, creating a second global circulation that dominates Southern Hemisphere climate systems today (Fairbridge, 1982). This feature has developed in stages over the last 200 million years or so. In contrast to Tethys, the Southern Ocean has always been in the higher (southern) latitudes, with its circulation west to east, i.e., in the Prevailing Westerlies.

Plate migrations in the Cenozoic gradually constricted the formerly open Tethys. The present Mediterranean is all that remains of the once mighty Tethys (Emiliani, 1992). Eventually South America closed in on the Caribbean and North America plates. A volcanic belt sealed the Panama Isthmus (Kennett, 1982). Tethys ceased to exist (apart from the Mediterranean) as a world-encircling "radiator," and the global climate machine went into a cooling mode, part of the "paleogeographic preparation" (Schwarzbach, 1974) that was inevitably the forerunner of the Quaternary ice age (see also *Cenozoic climate change*).

Plate tectonic controls for this ice-age preparation were three in number (and in importance): (i) partial blockage of warm E-W equatorial ocean currents (Fairbridge, 1973); (ii) presence of a pole-oriented land mass (Antarctica; Schwarzbach, 1963); and (iii) orographic growth (in central Asia, Europe and North America; Raymo and Ruddiman, 1992; Raymo, 1994).

Two further climatic systems relate to the plate-tectonic dictates: (i) relative to crustal rifting of continents and sea-floor spreading and (ii) relative to subduction zones, orogeny and volcanism (see below).

Orographic response to plate tectonics, and eustasy

Examples of Quaternary and present-day continental rifts are seen in East Africa, with a transition to oceanic setting in the Red Sea and Gulf of Aden. Climatically, the Red-Sea type linear basins that were periodically closed generated either euxinic or evaporating troughs, as well as sites for future hydrocarbon concentration. In Brazil (see Bigarella, in Fairbridge, 1975), the uplifted rift shoulders generate a rainforest belt as far south as Santa Catarina, but on the opposite side of the Atlantic, in Namibia, the SE trade wind creates a desert; and in Angola, a savanna.

Rifting of continents and its effects on the vertical state of the Earth's crust can be measured to some degree by dating the trace of ancient shorelines. This introduces the complex problem of "eustasy" or universal shift of mean sea level, which approximates the geoid (Fairbridge, 1961). This is only an approximation because the actual mean sea level can vary considerably in both space and time. Mentioned already is the effect of glaciation on global sea level (e.g., *glacial eustasy*). However, the field evidence for a former shoreline, as represented by an ancient beach deposit, an erosion bench, the surface of a now-dead coral reef or other geomorphic features, can reflect a range of distinctive causative processes. Actual sea level represents the homogeneous sum of all those processes, but the role of each varies from place to place and time to time.

Edvard Suess, professor of geology at the University of Vienna, invented the expression "eustatic fluctuations" of sea level (1885–1909; 1904–1924). He saw that there were repeated, large-scale fluctuations of world sea level throughout geological time. Oddly enough, however, he did not associate these with glaciation, magmatism or tectonism, but with sedimentation. Thus, he reasoned, the gradual filling of ocean basins would be achieved by erosion and sediment-transport from the uplifted land masses. *Ergo*, sea level would rise. Although the expression he created was excellent, his version proved to be the least important of varied causes. These fall into three categories:

1. *Tectono-eustasy* (operating by structural deformation of ocean basins, as during pulsations of plate tectonics, with an "Archimedean effect"; Pitman, 1978);
2. *Glacio-eustasy* (operating by change in the hydrologic state, water being transported from ocean to land and being converted to glacier ice, and vice versa);
3. *Sedimento-eustasy* (operating by sediment-infilling of ocean basins; the corollary of land erosion; mainly unidirectional, the sedimental cycles alternating with tectonic uplift followed by erosion cycles).

Mountain uplift and terrestrial cooling

Paleogeographic evidence shows that during the last 65 million years (since the end of the Cretaceous) there has been a

progressive (but fluctuating) fall in mean global surface temperatures. Subduction at active convergent plate margins has led to intermittent surges of orogenic uplift, including high plateau formation, e.g., Tibet, Iran, Anatolia, Bolivia and Colorado. High elevations have led to increased snowfall on the mountains, but drier conditions in rain-shadow plateaus. Both continentality and global albedo have risen, leading also to progressive global cooling. Brooks (1949, p.385) lists numerous references to such processes, and the uplift of Tibet has produced a flood of publications (Raymo and Ruddiman, 1992). (See also *Mountain uplift and climate change*.)

Oceanic circulation

At present, there is a general global circulation in the ocean, first recognized by Stommel (1958), following his studies of the Gulf Stream. It was seen as operating in the manner of a conveyor belt, now referred to as the "Conveyor" (Broecker, 1991). The essential conception recognizes a cold-water sink that becomes a cold, dense deepwater flow that heads south from near Greenland to the Southern Ocean where it turns eastward and is strengthened by cold, high density waters from below the Antarctic peripheral sea-ice. Tongues of this deep-water stream reach northwards into the Indian Ocean and western Pacific. At the surface, equatorial easterlies lead to upwelling. A counter flow of warm water leads back through the East Indies to the Indian Ocean, around the Cape of Good Hope, and joins the Benguela Current up the coast of southwest Africa, thence across the equator westwards to join the Gulf Stream. Paleomonsoons mark Holocene fluctuations in the tropics (Maley, 1997), but the cold cycles of the Pleistocene saw almost complete cessation of monsoonal systems (see also *Monsoons, Quaternary*).

A critical submarine ridge extends from the Faroe Islands to Iceland and operates as a modulator of the conveyor due to periodic eustatic shallowing. On a large scale, this may operate as a major on-off switch for amplifying glacial/interglacial climatic cycles.

Geological activity along other submarine ridges has probably played analogous roles from time to time in the remote past. For example, Brooks (1949, p.386) cites E. Hull who in 1897 suggested an "Antillean continent" that could once have caused a major deflection of the Gulf Stream. This entire region has undergone fundamental reorganizations since the Cretaceous, eventually leading to the blocking of Tethys and the repeated opening and closing of the Panama Strait. The final closure in the late Pliocene permitted two-way migrations by land animals and blocked the marine connections (Stewart, in Fairbridge, 1975, p. 418,).

With reference to the global warming of Cretaceous times, T. C. Chamberlin (1897) suggested that at a critical point, increased evaporation in the low latitudes could reverse the present circulation. The global salinity sink would then be equatorial. Upwelling in polar regions would keep them permanently warm. Studies of $\delta^{18}\text{O}$ records in high latitude Cretaceous and Cenozoic fossils and recent drilling show that this was indeed true.

Sea-ice and glacier fluctuation

The presence of sea-ice in winter is said to be the origin of the naming of Iceland, which was settled by Scandinavian (Viking) migrants after the eighth century, about the time of Charlemagne and the Holy Roman Empire. Climatically, it was a

period of remarkable warmth: the "Little Climatic Optimum" or "Medieval Warm Period" (Lamb, 1977). A rich flora at that time flourished in Spitsbergen (now largely ice-bound). It lasted until about AD. 1300 which marked the beginning of a fluctuating series of cold intervals, the "Little Ice Age," which persisted until about AD. 1725, or even 1850 according to some opinions. The Vikings could not have been more fortunate in their colonization voyages, because there is evidence that at that time the westerly storm tracks in summer tended to head over Greenland and Spitzbergen. Accordingly, there were frequently light easterlies to fill their sails. For a short time, ca. AD. 1000, they had an outpost at Anse-les-Meadows in Newfoundland, the first European settlement in the New World. Its fireplaces have been radiocarbon-dated. With the Little Ice Age, conditions turned against them. Despite warm cycles, the general trend was from bad to worse. The South Greenland colony gradually perished, and the last Viking died around AD. 1400 (McGovern, 2000).

Sea ice on the north coast of Iceland develops occasionally today in winters when a tongue of the Gulf Stream weakens. Major and protracted incursions were recorded during the Little Ice Age (Schell, in Fairbridge, 1967; Grove, 1988). Greatest severity, however, was seen during the seventeenth, eighteenth and nineteenth centuries. Lamb (1977) regarded sea ice, through its albedo, as a major factor in high-latitude cooling.

Today, Iceland's biggest (ice-cap) glacier, Vatnajökull, covers about 8,300 km², and there are six smaller ones. The first systematic study of the mass balance on Vatnajökull was on the joint Swedish-Icelandic expedition, led by Hans Ahlmann, a Stockholm professor, and Jon Eythorsson. There had been some confusion earlier about the response of glaciers to climatic forcing (temperature vs. precipitation), but Ahlmann (1938) was able to show that, in this case at least, climatic cooling was the dominant control. The Ewing-Donn theory of ice ages (Ewing and Donn, 1956, 1958), on the other hand, claimed that precipitation was the key. They proposed instead that during interglacial warmings of the world ocean, the Arctic Ocean was largely ice-free, with more moisture evaporating and returning as snow; thus, all glaciers would expand and advance. However, the Arctic Ocean does not appear to have been totally ice-free for several million years (see *Arctic sea ice*). In the second half of the twentieth century, there has been a retreat of both sea ice and mountain glaciers (Kerr, 2006).

Changes in atmospheric composition

Since earliest Precambrian times, geological evidence reveals episodic and secular changes in the Earth's atmosphere (see also separate entries). These changes have been forced by various agencies, which have been subject to progressive modification. Not all of these factors are well understood, but one quite indisputable fact emerges from the geologic record: the continuous existence of water (H₂O) in a fluid state. From this it follows that Earth-Moon-Sun interactions and planetary orbits must have been maintained in a dynamic balance on multi-billion year time scales (Shirley and Fairbridge, 1997); further, it follows that secular or cyclical variations in solar radiation must be balanced by powerful feedback mechanisms that have maintained a quasi-stable climate ($18 \pm 5^\circ\text{C}$) and prevented the Earth's mean temperature from ever suffering either a runaway heating (e.g., to a Venusian state) or a runaway icehouse condition (e.g., a Martian state), although arguments for a "snowball" state have been presented (see *Snowball Earth hypothesis*).

Secular changes over geologic time are demonstrated by the sedimentological-stratigraphic-paleontologic record and its successive biogeochemical revolutions. These are summarized (Fairbridge, in Oliver and Fairbridge, 1987, p. 301):

1. First Life, in CH₄ or CO₂ environment (ca. 4.0 billion years)
2. Mid-Precambrian oxygen threshold (ca. 2.5 billion years)
3. Eocambrian/Cambrian CaCO₃-exoskeletal life (ca. 540 million years)
4. Late Paleozoic “Great Coal Age” carbon storage (ca. 350–290 million years)
5. Cretaceous-Paleocene pelagic carbonate storage (ca. 150–50 million years)

Secondary, largely cyclical changes have amplified or decelerated the great secular trends. Periodicities of the cyclical changes range from fluctuations in the galactic arms at about 30 ± 2 million years (Rampino and Haggerty, 1996) to the Milankovitch orbital parameters, as noted earlier.

Besides biogeochemical processes that mainly depend on climatically controlled environments, there are also asteroid impacts, and volcanological and tectonic processes that are largely non-cyclical, or only marginally so. Volcanoes, depending on their magmatic characteristics, emit H₂O vapor, CO₂, SO₂ and CH₄. Climatically important is the fact that H₂O, CO₂ and CH₄ are “greenhouse” gases; that is, they tend to be environmentally warming, in contrast with the volcanic aerosol SO₂, which is a cooling agent.

Methane (CH₄) is the most effective greenhouse gas. In nature, it is produced by a wide range of organisms, from termites and ungulate cattle to swamp bacteria. These sources in general lean towards a tropical climatic bias, but subarctic tundra swamps are also significant.

Greenhouse gases not only affect climate but also global hydrology (see Herschy and Fairbridge, 1998) and eustatic fluctuations of sea level (Fairbridge, 1961). The two are linked, for example, during a major cold cycle when sea level is low and biotic (metabolic) activity is globally reduced. During glaciations, low temperatures generally reduce metabolic rates, water is scarce and deserts are widespread; atmospheric H₂O, CO₂ and CH₄ levels are all reduced. Also related to the hydrology-eustasy link are the soil biotas. World soils are commonly ignored by both geologists and climatologists but their atmospheric role is of major importance. As mentioned above, Erhart’s “biostatic” condition is a long-term, warm, stable, high-eustatic state, with stable CO₂ (Fairbridge and Finkl, 1980; Erhart, 1956). This is contrasted by Erhart’s “rhexistatic” conditions that are marked by sharp cooling events, with eustatic fall (often by 100 m or more) leading to extensive erosion, resulting in transfers of iron oxides to sedimentary storage. Natural deforestation due to glacial advance and desertification shifts CO₂ to the atmosphere, so the pendulum swings abruptly into a warming mode once more.

In the twenty first century, considerable attention is being paid to the question of “greenhouse warming.” This condition has been brought about by anthropogenic activity, principally expressed by increasing levels of CO₂, SO₂, and CH₄, mainly consequent upon deforestation and the burning of fossil hydrocarbons (coal, oil and natural gas). This activity began with transition of *Homo sapiens* from the Stone Age to the era of metals, starting about 4000 BC. with charcoal-based smelting (Ruddiman, 2005). Deforestation also expanded with the need for increased pasturage and cereal crop planting (Lamb, 1977). The last naturally warm climatic cycle, or *Medieval*

Warm Period (q.v.) was roughly AD. 800–1300, from the time of Charlemagne to the beginning of the *Little Ice Age* (q.v.). Evidence for late twentieth century warming is accumulating. However, but is difficult to distinguish natural climate variability from evidence of anthropogenic modification of atmospheric gases. How much is natural fluctuation? Recent evidence, however, supports an anthropogenic role (e.g., see *Encyclopedia of World Climatology*).

The Moon, luni-solar tides and related solar, planetary and terrestrial cycles

The Earth’s only satellite, the Moon has a uniquely large mass ratio (1:81) and the two behave almost as twin planets, revolving about a common center of mass located approximately 4,800 km from the geo-center. The Moon’s orbital plane is inclined at an angle of $5^{\circ}10'$ to the Earth’s orbital plane (ecliptic), and the point where they cross is called the *Node*. The Moon’s elliptical orbit at *perigee* radius is about 365,000 km and at *apogee* about 409,000 km, on average (Shirley and Fairbridge, 1997). This leads to cyclical changes in both tides and climate-related periodicities (Currie, 1995). The principal climate effect in the 18.6-year nodal cycle, observed in both rainfall and temperature time series.

The tide-raising force of the Moon, on average, is 2.17 times that of the Sun, and the resultant is a luni-solar tide, which generates an oceanic “tidal wave” (not related to tsunamis) that circles the globe every day, though modified by land barriers. Over the period of nearly a fortnight (27 days, 7 h, 43 min), the range varies from “spring” to “neap” tide (at 90°), depending on the relative alignment of Sun and Moon. Amplification of the range occurs at *perihelion* (early January around the year AD. 2000) when the Earth in the Northern Hemisphere is closest to the Sun. In the Southern Hemisphere, it is in July (the axial precession effect). Tide is also higher at *perigee* (close lunar approach) and more so at *syzygy* (approximate alignment of all three bodies). Very close line-ups occur at 558.4-year intervals (30×18.6 years) and at 93.067-year intervals (5×18.6 years). These multiples of the 18.6-year nodal cycle are seen in long climatic proxies (Currie, 1995) as well as its short-term harmonics, which link with El Niños (Fairbridge, 1990).

Otto Pettersson (1912, 1930), the Swedish oceanographer, found that the 18.6-year nodal cycle generated an internal wave in the North Sea at the boundary of the rising offshore saline waters and the partly fresh outflow from the Baltic Sea. As it approached the coast across the progressively shallowing North Sea, the wave also becomes larger and steeper. At a tidal station on the Gulmar Fjord it can approach 25 m and set up dangerous currents. Extremes are reached at 93.067 years, a five-cycle repeat at the same season, and likewise 15 317.75 h (which has a ratio of 17:28 for the principal lunar and solar cycles). Pettersson discovered that rising super-tides brought a flood of young herrings that flourished and brought considerable profits to the fishermen of the Hanseatic League. He was able to trace their fish trade back to the twentieth century, with this proxy, peaking always at ca. 93 years and longer intervals.

The year 1912 brought the highest predicted astronomical tide of the twentieth century. In Greenland, super-tides cause floating glacier-snout calving and so in 1912 an exceptional stream of icebergs came directly in the course of the ill-fated *Titanic* (Wood, 2001). Warming waters plus the buoyancy effect triggers major iceberg launching and NOT cooling cycles as sometimes assumed. Long-term lunar cycles may

also be involved in “Heinrich events” that mark the last 80,000 years or so in the North Atlantic. A “staircase” of 185 isostatically emerged beachridges on the Hudson Bay at about 45-year periodicity suggest storm cycles (warm phases create open-water, ice-free conditions) of synergetic luni-solar forcing (Fairbridge and Hillaire-Marcel, 1977), with peaks at 317 years. Comparable but less-complete sequences occur elsewhere in the Arctic and in northern Norway (Fletcher et al., 1993).

The lunar nodal (or nodical) cycle of 18.6 year marks variations of the Moon’s declination (Wood, 2001). This results in the Moon’s zenith position shifting over $28^{\circ}45'$ or 1,568 km N or S in a 9.3 year interval, returning at about the same season in the 317-year luni-solar period. As the zenith position shifts north or south it has the effect of amplifying or decreasing normal meridional tidal current velocities and their heat transport. The effect is most apparent in the great meridional currents like the Gulf Stream, which disclose a $>1^{\circ}\text{C}$ rise or fall in related long-term surface temperatures. The Russian oceanographer Maksimov (Lamb, 1977) found that it also affected the length of the sea-ice in the Barents Sea and Russian Arctic. It could therefore affect global albedo.

It seems probable that the Moon may also play a climatic role in the equatorial belt. Particularly significant is the bottleneck created by the East Indies with their narrow straits and shallow seas, partially blocking the return flow of the “Conveyor” system as well as the east to west tidal “wave” as it moves from the Pacific to the Indian Ocean. This archipelago occupies a unique place on the planet; the many volcanic cones concentrate the rising warm-humid air, feeding it in diurnal pulses to the stratosphere. The latter is subject to modulation by incoming solar radiation, the mean pulse being the QBO (“quasibiennial oscillation”) of solar emissions at 2.172 year, which is also a distinctive terrestrial climate cycle (Schove, 1983). Five QBO cycles ($5 \times \text{QBO} = 10.86$ year) is close to the sunspot period. A 13.03-year period ($6 \times \text{QBO}$) coincides very closely with the lunar perihelion return and thus with the Earth’s tides. Solar emissions are thus linked chronologically both to terrestrial climate and tidal system. According to Lamb (1977), the QBO (2.172 year) is the most universal climate cycle above the annual one. It is also the most omnipresent solar emission period.

As suspected by Pettersson (op.cit.), the Moon is so large and close to the Earth that it greatly modulates the Earth’s orbit, which in turn shows linkages to the periodicities of other planetary orbits (Fairbridge and Sanders, 1987) and to the Sun’s 19.8593-year motion around the systemic barycenter. This cycle is locked into the beat frequency of the two largest planets, Jupiter and Saturn. Multiples of all the planetary beats are whole integer fractions of the longer cycles and multiples of the Sun’s inner spin rate (n : 0.0678785 year). They are linked by a simple formula, $BF = n + 2n^2$, where BF is the particular beat frequency. The beat frequency of the U-J-V planets (Uranus-Jupiter-Venus) is interesting because it seems to correspond to clustering of El Niño periods, thus $69.5076 (0.0678785)^{-1} = 1,024$ [$\sqrt{1,024} = 32$]. This U-J-V period ($\times 590.00$) is almost an exact fraction of the Milankovitch 41,009.5 ecliptic cycle. It is also exactly one third of 208.52 years, the ^{14}C tree-ring flux (Stuiver and Brazunas, 1989). The inner planets (mean beat frequency 46.3388 years) can be included with Saturn-Jupiter (19.8593 years) thus: $278.03 (0.0678785)^{-1} = 4,096$ [$\sqrt{4,096} = 64$]. This value corresponds to 25×11.1212 years, the mean sunspot cycle.

Consequences

Volcanic and desert dusts

Major volcanic eruptions of the historical era, such as Tambora (1815) and Krakatoa (1883), have been associated with several years of global cooling (Lamb, 1977; see also: *Volcanic eruptions and climate change*).

The atmospheric effects of the Krakatoa eruption and its dust clouds were explored by the Sarasin brothers in 1901, and a general theory presented by Humphreys in 1913. The database was greatly strengthened by a worldwide catalog of more than 1,000 years of geological and historical records (Sigurdsson et al., 2000, p. 249–269). Bryson (1997) suggested that large temperature and precipitation fluctuations, especially in the mid-Holocene, reflected planetary-scale volcanic-dust triggering. From Indian environmental indicators (mainly lake pollen), he concluded that cooling trends were marked by strengthening of the circum-polar vortex and southward shift of the jet stream. This shift is particularly clear in the Mediterranean and northern India, which are then visited by plentiful winter rains. In contrast, when the warm phases shift the winter jet north of the Himalayas, there are (often catastrophic) droughts. In the monsoon belt, however, the summer rains are strengthened. A NATO-sponsored conference in Turkey (Dalfes et al., 1997) considered these questions, notably in connection with the classical collapse of the advanced civilizations there in the third millennium BC.

Lee-desert dusts were first documented by Charles Darwin on the voyage of H.M.S. *Beagle* in 1832 off the coast of West Africa. Distinctive traces of microfossils from Lake Chad have now been tracked westwards as far as the Caribbean, Florida and even New York City. Caribbean deep-sea cores (Emiliani, 1966) and Antarctic ice cores (Petit et al., 1999; EPICA, 2004) showed that, during the last seven glacial cycles, the dust-load rose as water temperatures fell.

During the last glacial stage of the Quaternary ice age, which reached its maximum about 18,000–25,000 years ago, the lower sea levels led to increased continentality, and colder ocean temperatures to decreased evaporation. There was widespread aridity that extended from present-day Mediterranean belts and in places reached to the equator (Fairbridge, 1964). In Africa, dune belts crossed the Congo, both from the Sahara and the Kalahari. Long-distance dust transport from these vast deserts was universal (Jelbring, 1998), as shown by deep-sea sediment cores worldwide, but even more dramatically in the ice cores of Greenland and Antarctica. Stronger meridional atmospheric circulation was calculated by Lamb and Woodroffe (1970) for glacial-stage paleogeography, with weakened westerly systems.

Loess and paleosols

Loess is a German agricultural term, with the same root as the English word “loose,” for a friable soil (see also *Loess deposits*). Loess is a climatically-specific wind-blown silt, actualistically seen today in the lower Yukon delta area, where strong winds affect a tree-less area of braided stream channels and dry alluvial tracts. Although extremely restricted in extent today, during the maximum and waning stages of the glacial stages, loess distribution was almost worldwide. Classical loess is a slightly calcareous, siliclastic silt that extends across western and eastern Europe into southern Russia, Mongolia and northern China. In the Southern Hemisphere, limited areas occur in Patagonia and New Zealand (South Island). It was

first positively attributed to eolian activity by Baron von Richthofen (1877–1885), but it has long remained controversial. During warm cycles, loess weathering produces a distinctive red paleosol.

The loess/paleosol cycles in Moravia (eastern part of Czech Republic) are exposed in a spectacular sequence tens of meters thick in a brick-clay quarry at Cerveny Vlchy (appropriately: the “red hills”) near Brno. George Kukla collected carefully oriented samples for paleomagnetic measurement, which provided the chronologic key (see *Dating, magnetostratigraphy*). The upper part of the sequence was “normal,” oriented to the current North magnetic pole; the lower part was “reversed,” thus oriented to the south. (The last paleomagnetic reversal occurred 780 kyr ago). Later, Kukla compared his terrestrial climatic sequence with the $\delta^{18}\text{O}$ paleotemperature oscillations in the deep-sea sediment cores at Lamont Doherty Earth Observatory, Columbia University. An identical number of climate cycles down to the Bruhnes-Matuyama boundary was found in both sequences (Kukla, 1972). This was one of the greater paleoclimatic discoveries of the century. It demonstrated conclusively that climate oscillations in the mid-ocean are synchronous with those in the mid-continent; furthermore, in the latter, the temperature oscillations can be quantified with proxy data. Using the Kukla-devised model, the vast loess deposits of northern China have been systematically surveyed, disclosing not only a perfect correlation with the deep-sea and central European sequence, but still earlier stages, including the early Pleistocene and even Pliocene (Gauss magnetic epoch).

Eolization and eolianite

The expression “eolization” (see also *Eolianite*) was invented by the French sedimentologist André Cailleux. Many sands and sandstones of the Paris Basin were eolian or primarily marine, but during negative eustatic oscillations and exposure to wind action during long periods of desiccation they became redistributed, thus, “eolization.” In warm coastal belts where comminuted molluscan shells, fragmented corals and carbonate foraminifera commonly constitute the predominant beach sands, even short phases of lowered sea level favor the build-up of carbonate shore dunes. Climatic oscillations during the Holocene repeatedly led to eustatic withdrawal by up to 1 m or so, which led to massive coast-parallel dunes, in places exceeding 20 m in height. Winds with sustained high wind velocities could create sporadic “blowouts” at gaps in the shore-parallel dune belt, thus feeding linear dunes that extend inland, up to 1 km or more. Such high velocities were favored from time to time in particular regions where the normal westerly airflow would be amplified by the sea-breeze effect characteristic of the margins of the subtropical anticyclones. Rainfall during the cool interval led to partial solution of the carbonate dune sand to consolidate it into a dune rock or *eolianite*. Ice-age winds were undoubtedly stronger than the prevailing winds in the same localities today (Jelbring, 1998).

The essential synergy between carbonate sand supply, sustained westerlies and subtropical sea breeze was provided during the Quaternary period at times corresponding to the frequent negative sea-level oscillations with amplified wind velocities (especially winter seasons in cold intervals of 1–3 centuries) but also where abundant supplies of carbonate sand were available, implying relatively warm ocean waters. Ideal sites for such highly specific paleoclimatic indicators were

oceanic islands and continental shores between 25 and 35° N and S, for example in the Bahamas, Bermuda, Morocco and North Africa to Egypt, Palestine, Israel and Lebanon, South Africa (Cape Province), Madagascar, India (Gujarat), western Australia, South Australia, Victoria, and Hawaii.

At the time of the Napoleonic wars, a certain British naval officer, Lt. Nelson (not the admiral), noticed the curious dune features converted to a hard rock (eolianite) in Bermuda, which provides an excellent, easily sawn building stone (Sayles, 1931). In SW Australia, in 1791, another British naval officer, Capt. George Vancouver, had also commented on them (Fairbridge and Teichert, 1948), as did Charles Darwin on the voyage of H.M.S. *Beagle*, who remarked on how the dune rock can be seen disappearing below modern sea level. Later, Charles Darwin also noticed eolianite on the islands of Ascension and St. Helena. He reasoned that because there were essentially no beaches on those islands today, the dune sands must have been blown up on the higher slopes during periods when sea level was lower, and winds were stronger. That reasoning was, of course, prior to the glacial theory and the mechanism of glacioeustasy (Fairbridge, 1961).

Eolization and eolianites are thus two of the most incontrovertible paleoclimate indicators. Eolization calls for extreme aridity and sustained high winds where there is a plentiful supply of sand, pebbles or rock fragments (as in some modern deserts, e.g., Sahara, Gobi, Atacama, Namibia and the “dry-valley” areas of Antarctica). Eolianites are even more specific, being restricted to “Mediterranean” latitudes 25–35° N and S, that is, to littoral belts where warm offshore waters favor a rich carbonate-shelly fauna.

Lake levels and fluvial indicators

Lakes and lake-levels constitute a persuasive basis for past-climate appraisal. They may act as a measurable rain-gauge but this must be interpreted with caution because of the evaporation-precipitation balance and other factors. A systematic treatment of lake level chronology has been presented by Street and Grove (1976, 1979), with Africa and Australia as the most coherent grouping (Rognon and Williams, 1977). North American “pluvial” conditions were essentially independent (Bradley, 1985; Nicholson and Flohn, 1980; see also *Lake level fluctuations*).

Input and overflow of lakes may be quite significant. The role of fluvial input may be quite simple in a small area but in the case of a major river like the Amazon, the Nile or the Mississippi, a complex analysis is essential.

Historically, the Nile is by far the best documented, starting with Herodotus about 450 BC., who as librarian in Alexandria was undoubtedly familiar with the delta and the pyramids. The upper course was poorly known but Eratosthenes had drawn a reasonable map of the Blue Nile, though the White Nile’s course was still uncertain. The principal annual flood (mid-summer) was recognized as coming from the Blue Nile, while the weaker, winter-season flood was from the White Nile. The former is fed by the monsoonal rains in Ethiopia, which decrease when the atmospheric pressure in Cairo is high and vice versa, according to measurements by Sir Henry Lyons published in 1905 (cited by Brooks, 1926/1949). Brooks observed that the same relationship exists throughout most of the Asian monsoon belt as far east as Hong Kong. The White Nile floods, however, appear to reflect the general equatorial circulation. The dynastic history and “prehistory” of the Nile

is unique among rivers in that it has provided investigators with a rather secure system of dates based on both archaeology (Wendorf and Schild, 1976) and radiocarbon-dated sedimentology and geomorphology (Fairbridge, 1962; Williams and Faure, 1980).

Precise measurements of the Nile floods were apparently made since the time of the Ptolemy pharaohs, for the good reason that Egypt's wealth depended on the agriculture maintained by the Nile flood, but they were only systematically recorded until the Islamic era. We now have complete records from AD. 641 to 1480 but they were only sporadic from then until 1830. Brooks (op.cit., p. 331) cites a general monograph on the subject by Prince Omar Tousoun, which describes pre-Islamic Nile floods simply as "weak," "good" or "strong" for various periods since the fifth century BC. Modern power spectrum analyses have disclosed the 11–22-year sunspot cycle and the 18.6-year lunar cycle in the accurately recorded data (Currie, 1995; El Fandy et al., 1994) but long-term changes are also apparent. The same periodicities were obtained from historical flood records from China (Currie and Fairbridge, 1985). Sporadic material provides dates for the floods of the Yangtzi and Hwang-Ho (Yellow River).

No long-term precise records of other major rivers are available, but many written accounts exist for the great European rivers (Rhine, Danube, etc.). Within the last century or so the hydrometrics of all major rivers have been measured but this interval has coincided with the worldwide explosion of dam construction for hydro-electric, flood-control, irrigation and urban uses; thus, the data have been strongly influenced by anthropogenic effects. For a general treatment, *The Encyclopedia of Hydrology and Water Resources* (Herschy and Fairbridge, 1998) may be helpful.

HISTORY OF PALEOCLIMATOLOGY – BIOGRAPHIES

Abbot, Charles Greeley (1872–1973)

Abbot was an American astrophysicist who was active for many years in studies relating solar emissions to terrestrial climates. Born in Wilton, N. H., he was long involved with the Smithsonian Institution in Washington, D.C., first as director of the astrophysical

observatory (1907), and later as secretary of the institution (1928–1944). Abbot completed the infrared spectrum and organized studies of the so-called “solar constant.” Following one cycle of the 11 year sunspot period after another, he demonstrated remarkable solar variability together with difficult-to-explain climatic fluctuations. He obtained patents for his instruments for measuring solar activity and energy.

Adhémar, Joseph (1797–1862)

The French mathematician, J. Adhémar, is believed to have been the first to recognize the fundamental role of the *Precession of the Equinoxes* in ice ages and paleoclimatology, in a book published in 1842. Only 5 years after the announcement of the former ice age by Agassiz, Adhémar came up with his new concept: precession must have a climatic effect. He argued that because of the inclination of the Earth’s spin axis, there would be a reverse of the seasons receiving maximum solar radiation every hemicycle of the precession. At the present time, the Southern Hemisphere receives maximum radiation in the southern summer. Due to the eccentricity of the Earth’s orbit around the Sun, winters in the Southern Hemisphere are longer than those in the Northern Hemisphere. The precession is about 26,000 years but inasmuch as the eccentricity major axis is likewise moving counter-clockwise, the effective period is about 21,000 years. An important forcing paleoclimatic mechanism was thus provided, although additional orbital forcings were needed to generate the glacial/interglacial oscillations of ice ages (see Croll, 1875; Milankovitch, 1941).

Agassiz, Louis Jean Rodolphe (1807–1873)

Agassiz was a Swiss paleontologist and Quaternary glaciologist who was the first prominent geologist to adopt the “Glacial Theory,” pioneered in 1824 by Jens Esmark in Denmark, and by I. Venetz and Jean de Charpentier in Switzerland (1830s). The theory evolved in steps from being an explanation for the transport of erratic blocks down-valley from Alpine-type glaciers, to the concept of a formerly much greater ice-cap, and eventually to the recognition of ice sheets of near-continental dimensions in northern Europe and North America (Carozzi, 1966). His most famous work was *Études sur les Glaciers* (1840). He even suggested that the interior of Greenland was covered by ice, a very daring hypothesis in the mid-nineteenth century. Eventually, Fridtjof Nansen, the Norwegian explorer-scientist-humanitarian, crossed (and proved the existence of) the Greenland ice cap in 1888. Agassiz was so carried away by the ice sheet idea that in 1837 he proposed a giant glacial cover for most of the Northern Hemisphere.

In 1846, Agassiz emigrated to the United States and became professor of zoology and geology at Harvard University (1847). He traveled extensively in the southern states, Canada and Brazil. At an early stage in his career, he spent a year in Paris, studying under Cuvier. Therefore, it is not surprising that he adopted the Cuvier model of organic evolution: repeated extinctions and re-creations, being strongly opposed to the Darwinian model (Carozzi, 1973; Lurie, 1966).

Arrhenius, Svante August (1859–1927)

A Nobel prize-winner in chemistry (1903), Arrhenius is important in the field of paleoclimatology for his research into CO₂, which led to modern work on the greenhouse/icehouse concepts (1959), supporting the theory of J. Tyndall (1863) that enhanced infrared reflection from the Earth’s surface warms

the lower atmosphere in proportion to the CO₂ and H₂O vapor trapped there (1896).

Arrhenius, who served as Rector of the University of Stockholm (1887–1902) and later as the Director of the Nobel Institute for Physical Chemistry, was also interested in cosmology and was aware of the role of magnetized solar emissions in the fluctuations of the Earth's geomagnetic field (pioneer observations were being made in Norway at that time). Jointly with the meteorologist, Nils Ekholm, he analyzed the periodicities of aurora observations (which were often recorded by country pastors, and traced back for up to 800 years) and their geomagnetic correlations, discovering both the 22 year solar cycle and the 18.6 year lunar cycle.

Blanford, William Thomas (1832–1905)

Blanford's major contribution to paleoclimatology was that he discovered, mapped and announced the presence of Permian-Carboniferous glacial striations and deposits in the Deccan of India. This was the first discovery of "exotic" paleoclimatic evidence from the subtropics and was destined to become the nucleus of the Suess concept of Gondwanaland, the continental drift theory of Wegener, and finally the plate tectonics theory of the late twentieth century.

Blanford graduated from the Royal School of Mines in London and served on the Geological Survey of India (1855–1882), being the author of a major work on the Gondwana (Permian-Mesozoic) formations. He also made surveys in Burma, Sikkim and Iran. Vertebrate paleontology being among his many interests, he became vice president of the Zoological Society, F.R.S. and Fellow of the Geological Society (Anon, 1905; Bonney, 1907; Holland, 1905).

Bond, Gerard Clark (1940–2005)

Bond was one of the first researchers who identified that the "Heinrich events" documented in sediment cores in the northwest Atlantic Ocean indicated abrupt climatic fluctuations, using the deep-sea cores of the Lamont-Doherty Earth Observatory of Columbia University. Those sediment cores are marked by whitish layers that reflect limestone debris carried by glaciers melting in eastern Canada and swept out to sea by icebergs. For this work, he received the Maurice Ewing Medal from the American Geophysical Society in 2003. Later, he recognized that climate changes over the last 10,000 years were driven by variations in solar radiation, which fluctuates inversely with cosmic rays and whose flux is clearly recorded in the ¹⁴C measurements obtained from tree rings and thus chronologically fixed in time.

Chamberlin, Thomas Chrowder (1843–1928)

One of America's greatest earth scientists, educators and Quaternary glaciation specialists, Chamberlin initially taught at Beloit College, Wisconsin (1872–1882), serving also as director of the state geological survey and later with the U.S. Geological Survey. President of the University of Wisconsin (1887–1892), he moved on to the University of Chicago (1892–1919) when he founded the prestigious *Journal of Geology* (Willis, 1929).

In paleoclimatology, his leading role was in helping to identify and name the primary four-fold division of Laurentian glaciations and their interglacial paleosols (Alden, 1929). An expedition to Greenland in 1894 gave Chamberlin the idea of an ice-sheet anticyclone, which had only limited validity. With his astronomical colleague, F. R. Moulton, he developed the "Planetesimal Hypothesis" for the evolution of the Solar System.

Chambers, Robert (1802–1871)

Chambers was a self-taught Scottish geologist who developed early ideas about isostasy and made a comprehensive study of sea level and its climatic message, writing the first book on the subject (1844), which contains a general review that spans the British Isles, Scandinavia and North America. Field work in Scotland and Norway prompted several papers on the glacial striations and deposits (in 1851) that provided "an important service" towards the acceptance of Agassiz's glacial theory (Geikie, 1905) (Milhauser, 1959).

Charpentier, Jean de (1786–1855)

Born in Germany, Charpentier spent most of his life in Silesia, but worked professionally in Switzerland, France and Spain, becoming the first to postulate that the entire Alpine chain was once covered by a thick ice cap, from which radiated many ice streams as valley glaciers. He wrote earlier on the geology and tectonics of the Pyrenees, but from the paleoclimatic point of view his major work was *Sur les glaciers et sur les terrains erratiques du bassin du Rhône* (1841), which described the field work and outlined his general theory.

Charpentier contested the early catastrophist view of Agassiz, which visualized a giant Northern Hemisphere ice sheet, and argued persuasively for the more modern mountain chain ice cap. He also wrote on non-marine mollusca (Lugeon, 1920; Teller, 1983).

Croll, James (1821–1890)

Croll was a Scottish geologist who served with the H. M. Geological Survey (1867–1881) and made a fundamental contribution to the orbital theory of paleoclimatology and ice ages (Imbrie and Imbrie, 1979) that incorporated the Earth's axial precession (but not the other orbital elements; those had to await the twentieth century work of Milankovitch, 1941). He published several full-length books on the nature of ancient climates and ice ages. Furthermore, he examined the oceanic circulation of the past and the physics of glacier flow (Irons, 1897). In climate studies, he established a "retardation" principle, whereby the melting of the glacial ice would be retarded with respect to climatic warming by the latent heat of the melting. (Eustatic "retardation" or lag was later shown diagrammatically in Fairbridge, 1961, and subsequently by stable isotope and trace gas analysis of polar ice cores – see Shackleton (2000)).

Daly, Reginald Aldworth (1871–1957)

A remarkably versatile Canadian geologist and geomorphologist, Daly originally worked with the Canadian Geological Survey (1901–1907) (Birch, 1960). He then moved to M.I.T. (until 1912) and finally transferred to Harvard (until 1942). As a petrologist, he went to American Samoa in the South Pacific but, observing emerged coral reefs and shore platforms there, he focused on the question of ice ages and eustasy. He proposed a "Glacial Control Theory" for coral reef growth. His book on the ice ages is certainly the best in the early to mid-twentieth century; it was still in reprint three decades later. His "marginal bulge hypothesis," which postulated a positive peripheral crustal response to the ice loading in the interior, has stimulated innumerable calculations concerning the strength of the Earth's crust and rates of adjustment, and in relation to hydroisostasy. It also introduced the idea of a "zero isobase" that shifts progressively inland during the glacial retreat (Fairbridge, 1968, p. 885).

DeGeer (Baron) Gerhard Jacob (1858–1943)

The leader in Swedish Quaternary science, deGeer formed his first ideas about deglaciation on several expeditions to Spitzbergen between 1882 and 1910. He also elaborated on the theory of eskers that cross Sweden from north to south, and demonstrated how end moraines were built up during pauses in the glacial retreat. This was the first clear demonstration of cyclical dynamics in the paleoclimatic record.

DeGeer served as professor of geology at the University of Stockholm (1897–1924). His major contribution was a year-by-year chronology of the entire Holocene epoch based on the painstaking counting of annual varves measured in an overlapping sequence from one postglacial lake to another, as exposed in brick-clay pits from the south of Sweden to the north. The lake chronologies permitted the exact dating of the pauses in the glacial retreat, i.e., the cold climatic fluctuations in the otherwise warming secular trend. DeGeer's work was extended to North America and South America by his students Antevs (1944) and Caldenius (1948), respectively. His chronology was widely welcomed by archaeologists, but was less enthusiastically received by geologists, because of questions about interpretation and continuity. His surveys were repeated by the Swedish Geological Survey in 1970–1980, and found to be substantially correct. Radiocarbon dating (after isotopic corrections) confirmed the chronology.

Douglass, Andrew Ellicott (1867–1962)

Born in Vermont and educated at Trinity College, Hartford, Connecticut, Douglass was hired by Percival Lowell to select the best locality for a major telescope, choosing Flagstaff, with the objective of mapping the alleged Martian canals suspected by Lowell to reflect the activity of intelligent life on that planet. Inevitably, they disagreed, but Douglass remained in Arizona and became interested in tree rings, which he used to identify past solar cycles and predict future solar cycles. Appointed to the University of Arizona in Tucson in 1906, he initiated the science of dendrochronology, creating an unbroken record in Ponderosa pine tree rings extending back many thousand years. With this, he could date (to the year) the archeological record of early human activity in the American Southwest.

Douglass' main achievement was the technique of "cross-dating" whereby matching portions of tree ring patterns from different ruins could be overlapped, thus extending the chronological record. By overlapping tree ring records from many different sites in the region, a complete dendrochronology could be constructed. Douglass also realized that differing patterns of narrow versus wide growth rings reflected variations in climatic factors, thus laying the foundation of dendroclimatology (Webb, 1983). The Laboratory of Tree-Ring Research, which he instituted, is now a division of the College of Arts and Sciences at the University of Arizona.

Dubois, Eugène (1858–1940)

Sometimes confused with French and Swiss scientists with the same name, Eugène Dubois was in fact a Dutchman, who was working in the East Indies when (in 1891–1892) he discovered the "Java (Trinil or Solo) Man," an early primate that was identified as *Homo erectus* (More specimens were found in 1938 by Von Koenigswald).

Dubois has the distinction of writing the first book-length work on paleoclimatology. He recognized that the Sun as a heat-generating star would be expected to evolve through time,

and thus would influence terrestrial climates. However, he intuitively assumed it was cooling, whereas modern astronomy suggests it to be experiencing a slowing in warming. A critical question concerns Precambrian temperatures: were they warmer or colder than today? Current opinions favor the latter (Schwarzbach, 1974, p. 295).

Dunn, Edward John (1844–1937)

A stratigrapher and economic geologist, Dunn was preparing the first geological map of the Cape Colony in South Africa (publ. 1873), when he recognized a tillite, later named the "Dwyka Conglomerate," the first formally named Permo-Carboniferous glacial formation in South Africa (Molengraaff, 1898). Although some unquestionable tillites, varves, and erratics (up to 2 m across) had been found earlier in Natal (Zululand) by P. C. Sutherland (in 1868), they were not dated until Dunn's work suggested their contemporaneity.

Dunn was born in England, migrated to Australia, worked in South Africa and then returned to Australia to become director of the Geological Survey of Victoria (1904–1912). He published very little, except for government reports and a semi-popular book entitled *Pebbles* (1911) (DuToit, 1938).

Emiliani, Cesare (1922–1995)

Born in Bologna, Italy, Emiliani went to the United States in 1948 and obtained his Ph.D. from the University of Chicago in 1950. Moving to the University of Miami in 1957, he became one of the founders of the new science of paleoceanography. He was an early pioneer in the use of oxygen isotopes in marine fossils as a paleoclimate proxy, attributing variations in $^{18}\text{O}/^{16}\text{O}$ ratios to both changes in ocean temperature (60%) and glacial ice volume (40%). Based on sawtoothed patterns in oxygen isotope records from long ocean cores, he recognized many more than the traditionally-accepted four major Pleistocene glaciations. His dating of an ocean core spanning multiple climate cycles in calcareous ooze fundamentally contributed to the ultimate acceptance of the Milankovitch theory of climate change, as forced by changes in planetary orbits.

Emiliani was a natural born educator and produced many volumes on the earth sciences. In his last years, he was intrigued by the anomalous lack of a zero year in the classical calendar and explored the possibilities of selecting a new astronomically chosen zero year close to 10,000 yBP, such as would eliminate the AD/BC division of recent millennia (Hay and Zakevich, 1999).

Esmark, Jens (1762–1829)

The name Esmark (also spelled Esmarch) must always be associated with the Glacial Theory, although his paper of 1826 did not receive the recognition that came to Agassiz a decade or more later (Charlesworth, 1957).

Esmark was born and raised in Denmark, trained as a geologist and traveled widely. He became professor of mineralogy in Oslo. Esmark recognized that steep fjord-valley walls (U-shaped) were drowned relics of former glacial erosion. He had also seen the so-called "Findlinge" (foundlings) or glacial erratics all across northern Europe, and traced their lithological identities with specific source areas in Scandinavia. For example, the very distinctive Rapakivi granite came uniquely from only one area in Finland. A particular fossiliferous Ordovician limestone came only from the island of Gotland in the Baltic. Norwegian granites reached England and Scotland. Only a

continental-sized ice sheet could have been the mode of transport. Esmark believed the ice sheet responsible was at least 1,000 m thick.

Ewing, William Maurice (1906–1974)

Ewing was one of the founders of marine geophysics and first director of the Lamont Geological Observatory (now Lamont-Doherty Earth Observatory), Columbia University. Ewing's major contribution to the earth sciences was his leadership in worldwide oceanographic expeditions to map the sea floor, and his involvement with students and international associates that paved the way to the chronology of sea-floor spreading and the seismic location of tectonic plate boundaries (Wertembaker, 1974). Through his participation in the Deep-Sea Drilling Project (DSDP), the stratigraphic history of the last 150 million years was enriched with an absolute chronology including isotopically identified climatic fluctuations that were further characterized geomagnetically. The Ewing-Donn theory of ice ages was flawed, being based on a model of ice-sheet growth that depended mainly upon warming oceans (which increased the evaporation rate and hence Arctic snowfall (Bullard, 1975)).

Fairbridge, Rhodes W. (1914–2006)

Rhodes Fairbridge was ahead of his time in his early acceptance of Wegener's theory of continental drift, the role of orbital cycles in climate change (e.g., the Milankovitch theory), solar influence on climate, and recognition of general aridity during glacial periods. He was among the first to detect the twentieth century rise in global sea level in the 1960s. Fairbridge was active in many international scientific organizations, including INQUA and NATO-sponsored paleoclimate symposia. His numerous publications cover a broad range of subjects in paleoclimatology, Holocene sea level change and geomorphology, among others (Finkl, 1987; 2005).

Fairbridge was born in 1914 in Fairbridge Village, Western Australia, which established by his parents for disadvantaged and troubled youths. He studied at Queen's University (Kingston, Ontario) and Oxford University (England), and later received his Ph.D. from the University of Western Australia in 1944. During World War II, Fairbridge served in the Royal Australian Air Force in intelligence, and after the war he taught at the University of Western Australia between 1946 and 1953. In the early 1950s, his discovery of Permian tillites and Mesozoic plant fossils near the Irwin River, Western Australia that were Gondwanan age provided important evidence for Wegener's theory. In 1951, on the *Capricorn* expedition to the South Pacific with Roger Revelle, he investigated biogeochemical erosion of calcareous eolianites and coral reefs (Revelle and Fairbridge, 1957). Subsequent observations of emergent islands and shorelines in the Pacific and Indian Oceans pointed to the role of hydro-isostatic uplift. Correlation of data from many of the world's shorelines convinced Fairbridge that global sea level had fluctuated during the Holocene, in contrast to Francis Shepard's smooth sea level curve. (For a current view, see *Sea level change, post-glacial*).

Following a one-year teaching appointment (1953–1954) at the University of Illinois (Urbana), Fairbridge went to Columbia University in 1954, where he remained until his retirement in 1982. A keen interest in cyclical terrestrial phenomena is one of the recurrent themes in Fairbridge's long career. A 1961 symposium that he organized explored the effects of solar variability and other cyclic phenomena on

climate. Later, Fairbridge and Claude Hillaire-Marcel found a 45-year periodicity in raised beachridges at Hudson Bay, which they attributed to climate-related changes in sea level. With John Sanders, he investigated the role of planetary alignments on solar activity and Earth's climate. While the proposed linkages remain controversial, studies by G. Bond and others, for example, point to some solar influence (see *Sun-climate connections*). Furthermore, variations in the Earth's orbital parameters leading to changes in insolation are now accepted as an underlying cause of the Pleistocene ice ages (see *Astronomical theory of climate change*). After retirement, he continued working as Series Editor for the Earth Science Series Encyclopedias (of which this volume is one) at the nearby Goddard Institute for Space Studies until shortly before his death.

Flint, Richard Foster (1902–1976)

A long-time professor of geology at Yale University (New Haven, Connecticut), "Rocky" Flint played a leading role in the twentieth century development of a Quaternary stratigraphy in North America that was based upon meticulous field work, calling for close attention to the paleoclimatic forcing of the sequences of glacial deposits (tills of various sorts, "lodgment," etc.). Interglacial weathering profiles were recognized as warm climate products (Porter, 1978).

Through his key textbooks, Flint made an important contribution to the education of American geologists of the mid-twentieth century, for most of whom serious geological time ceased at the end of the Pliocene, although an "overburden" of Pleistocene was sometimes noted. Flint's first full-length textbook was *Glacial and Pleistocene Geology* (1957). The concept of the Holocene as a distinct geologic epoch was slow to penetrate and although first proposed at the International Geological Congress in 1885, it was long called "Recent."

Forbes, James David (1809–1868)

Best known for his work on the physics of glacier flow, Forbes was a professor at the University of Edinburgh (1833–1855) with many interests. He devised the first seismograph. In experiments on the physics of heat, he described the polarization of radiant infrared heat. He pioneered the field of geothermal heat flow with field measurements in mines at various depths and studied volcanology in the Auvergne. He traveled (and climbed) extensively in the Alps and Norway, examining the effects of glaciation on the geomorphology of the area and he applied these findings to the geomorphology of Scotland (Cunningham, 1990; Anon, 1869; 1871).

Forbes helped pioneer the mathematical modeling of paleoclimates, recognizing that they (a) are latitude dependent, and (b) vary according to local distribution of land and sea (Forbes, 1861). He saw that continentality lowers mean temperatures towards the poles, but raises them towards the equator (Brooks, 1949, p. 133).

Galileo Galilei (1564–1642)

The first use of the telescope in observing sunspots places Galileo in a special position concerning paleoclimatology and the dynamic universe, because this initiated studies of solar activity and established the concept that the Sun was subject to some "imperfections." This particular observation brought him into some disfavor with the theological Establishment. Galileo's epoch-making discoveries in celestial mechanics are

generally regarded among historians of science as marking the beginnings of the “Age of Enlightenment.” His adoption of the Copernican view of the Solar System brought him into trouble with the authorities, but also heralded the intellectual revolution of the age (Berry, 1898; Drake, 1972; Winkler and Van Helden, 1992).

Gauss, Carl Friedrich (1777–1855)

Born in Brunswick, Germany, in humble circumstances, Gauss was to become a celebrated astronomer and geophysicist and was director of the Göttingen Observatory for 47 years. He independently worked out the interplanetary ratios of the Titius-Bode Law. Largely concerned with geodesy, he became interested in sea level and its fluctuations, which played an important role in the history of the North German coast because of catastrophic dike-breaks and flooding during the amplified lunar forcing of the Little Ice Age (cf. Pettersson, O.). He met Alexander von Humboldt who interested him in geomagnetism, and by 1834 no less than 23 magnetic observing stations were set up. Jointly with Weber, their *Atlas des Erdmagnetismus* was published in 1840. The link between magnetic fluctuations and the solar cycle was to be discovered somewhat later by Sabine. One of the paleomagnetic epochs is named after him (Dunnington, 1955; May 1972).

Gilbert, William (1540–1603)

Thanks to his seminal work *De Magnete*, Gilbert established the basic attributes of geomagnetism, a study that has led to paleomagnetism, and in turn to the chronology of rock magnetism. Magnetostratigraphy has become a useful dating tool in paleoclimatology.

During the reign of Queen Elizabeth I, Gilbert was undoubtedly England’s most distinguished man of science. Widely traveled, he was a friend of Kepler and Galileo. Studying the regional nature of magnetism, Gilbert came to view the Earth as a giant bar magnet, a “lodestone” (a concept pioneered by Peregrinus in 1269). Increasing ship-use of the magnetic compass disclosed regional anomalies. Furthermore, but without using the word “gravity,” he anticipated Newton in postulating “*a mutual bodily affection between allied bodies, tending towards that union or junction.*”

Grabau Amadeus William (1870–1946)

Grabau was a professor of geology at Columbia University, but went to China in 1920 to become professor at the National University in Peking, chief paleontologist at the Geological Survey, and founder of the Geological Society of China (Sun, 1947).

His early work on the paleontology and stratigraphy of the American midwest and Appalachian belt convinced Grabau of the rhythmic nature of the geologic record, and he presented his “Pulsation Theory” at the International Geological Congress in Washington in 1933 (Grabau, 1936a, b). This was the most systematic approach at that time to the idea of long-term (>20 Myr) global cycles in paleoclimatology and paleogeography.

Grabau’s ideas of a general ordering of geologic processes are probably his lasting contribution. One concept of particular interest to paleoclimatology is quasi-actualist, that is to say based on historical records in part: the process of “marining” as displayed over the Yellow River (Huang-Ho) delta in northern China. This involves the simultaneous result of overwhelming discharge by a major river and an upward swing of mean sea level (eustatic), resulting in the general inundation of a delta and coastal plain on the order of >100,000 km².

These represent major paleoclimatic events that have occurred repeatedly in China (and also in the Mississippi, Nile and other major deltas).

An early adherent of Wegener’s theory of continental drift, Grabau prepared paleogeographic maps that reflected continental reconstructions based on paleontological reasoning. Grabau had observed that modern-day organisms, notably molluscan faunas, tend to suffer depauperization, reduction in size (within a species) and in population as one goes polewards. Vectors could thus be drawn for any period converging on the polar area. Particularly striking is his map (1940) of the Upper Ordovician, which illustrates a South Pole in the middle of the Sahara Desert. It was more than 30 years later that field evidence for glaciation was to be discovered there (Beuf et al., 1971; Fairbridge, 1973).

Granlund, Erik (1892–1938)

Swedish Quaternary geologist of the Svenska Geologiska Undersökning in Uppsala, Granlund made valuable discoveries in peat formation and pollen analysis (Lundquist, 1938). In an intensive study of Swedish peat bogs, he established that evidence existed for five dry intervals in the postglacial period, marked by oxidation and reddish colors. Using the varve-based chronology of deGeer (see above), their dates were approximately: 2,300, 1,200 and 600 BC and AD 400 and 1,200. The best developed is the 600 BC layer, which is the so-called “Grenzhorizont,” marking the boundary between the warm-wet climates of the subboreal stage and the cool-wet characteristics of the subatlantic stage. Rainfall comparisons are shown in Brooks (1949, p. 299).

Heer, Oswald (1809–1883)

One of the founders of paleogeography and paleoclimatology, Heer was a Swiss professor at the University of Zürich. He was particularly interested in the message of paleobotany in permitting the scientific reconstruction of past landscapes. His major work *Die Urwelt der Schweiz* (1865), later translated into English as *The Primeval World of Switzerland* (2 vols., translated 1876), played an important role in bringing the Earth’s ancient past into the forefront of literature (Grey, 1884).

Howchin, Reverend Walter (1845–1937)

A minister of the Church of England, Howchin emigrated to South Australia and took up church duties. Among his geological discoveries were striated pavements, erratics and glacial sediments associated with fossiliferous Permo-Carboniferous sediments, traces of which had been reported earlier (Alderman, 1967). These paleoclimatic discoveries were sensational in view of their distance from the Talchir glacials in India and the Dwyka of South Africa. They helped to consolidate the Suess concept of Gondwanaland, and thus became an integral link in the continental drift theory of Wegener, which later became incorporated into the current theory of plate tectonics.

Huntington, Ellsworth (1876–1947)

American geographer Ellsworth Huntington took part in expeditions to Turkistan (1903–1904) and western China (1905–1906). In 1907, he joined the faculty at Yale and in 1909 led their expedition to Palestine and Asia Minor. With the Carnegie Institution of Washington, he studied climate in the U.S., Mexico and Central America. In paleoclimatology, his name is associated with the history of the semi-arid lands of central

Asia. In geomorphology, he established an important concept, now known as the “Huntington Principle” (Fairbridge, 1970), that fluvial terraces tend to accumulate during semiarid regimes, whereas they become dissected during wetter cycles. A comprehensive rearrangement of ancient river systems was observed in central Asia, implying major changes in climatic regimes. He later became interested in solar activity and other paleoclimate changes.

Jamieson, Thomas Francis (1829–1913)

A Scottish geologist and agriculturalist at the University of Aberdeen (appointed 1862), Jamieson played a key role in the Quaternary geology and geomorphology of Scotland (Woodward, 1913). His great distinction was to have developed the concept of glacio-isostatic rebound (though he did not use that expression). He observed uplifted shorelines and coastal deposits and reasoned their origin as an isostatic crustal response to unloading of glacial ice, a critical concept in the study of ancient glaciations. Jamieson’s “classic” field evidence definitively negated the early idea of a marine ice-flow agency for glacial deposits. He was also convinced that the lowered evaporation rates during glacial times led to pluviation in closed basins like the Dead Sea, and the Caspian and Aral Seas. He coined the term “Pluvial Period” (More recent evidence points to generally more arid conditions and lower lake levels during glaciations, except where lakes are fed by glacial melt-water [Ed.]).

Kerner-Marilaun, Fritz (von) (1866–1944)

An Austrian paleobotanist, Fritz Kerner was the author of the first major textbook with the title: *Paläoklimatologie* (Borntraeger, 1930), although earlier studies of climate history had been made. Kerner went to some pains to stress the uncertainties of many would-be paleoclimatic proxies. Quoting his own words (translated, R. W. Fairbridge): “*There can be no shadow of doubt that an examining magistrate would declare such a family of evidence or testimony completely inadequate for the explanation of what is a very complicated case.*”

Kerner developed mathematical formulas for modeling paleotemperatures appropriate for specific latitudes and continentality in relation to geostrophic currents (Brooks, 1949, p. 41). He recognized the low equator-pole thermal gradient for non-glacial world climates (with an ice-free Arctic). These he called “acryogenic” (*akryogenen*), in contrast to glacial phases: “cryogenic” (*kryogenen*) (Brooks, 1949; Fairbridge, 1964; Schwarzbach, 1974, p. 269–267). Kerner recognized causal relationships between paleogeographic changes and oceanic circulation. He also suggested various proxy-sediments (e.g., bauxite and brown coal) for past climates.

King, Lester C. (1907–1989)

A New Zealander who spent most of his professional life in Africa, King was well-traveled and worked in seven continents. Primarily a geomorphologist, he viewed earth history globally, and accepted Wegener’s crustal mobilism well before plate tectonics became established. King’s great contribution to paleoclimatology was his identification of world-wide phases of terrestrial (non-marine) sedimentation, paleosol building, landforms, etc., that reflect synchronous global events, clearly relating to planetary climate change but with details unspecified. He noted that Phanerozoic time is marked by long intervals of warm humid climates leading to deeply weathered paleosols,

which alternate with short, sharp interruptions associated with tectonism (uplift or depression).

Milankovitch, Milutin (1879–1958)

Of Serbian origin, born in Dalj, Slavonia (in what is now Croatia), Milankovitch was destined to become one of the world’s central figures of late twentieth century paleoclimatology, although considered highly controversial in his own lifetime. His belief in the long-term climatic significance of the Earth-Moon orbital variables followed in the footsteps of Adhèmar, Croll, Ball and others, but he added the essential refinements of meticulous astronomic calculations, long before electronic calculators were invented. In a curious way, he was helped by two world wars (Imbrie and Imbrie, 1979, 1986). During long periods of captivity he was able to complete the mathematical foundations for his *Kanon der Erdbestrahlung* (1941; English translation, 1969), which disclosed the effective radiation or “insolation” at various latitudinal belts and at various time epochs.

Supported on climatic grounds by Köppen and Wegener (1924) and on geological grounds by Zeuner (1959), the Milankovitch theory was violently opposed or ignored by the scientific establishment until marine geologists were able to prove the same orbital chronology and paleotemperatures in deep-sea deposits (Broecker, 1968; Berger et al., 1984), which were confirmed in the chronology of loess and in paleosols on land (Kukla, 1970). Acceptance of the Milankovitch Theory opened the way to serious studies of cyclical processes and the role of external forcing in climate change.

Oeschger, Hans (1927–1998)

Oeschger founded the Division of Climate and Environmental Physics at the Physics Institute, University of Bern, and remained as Director until his retirement in 1992. Oeschger was an innovator and leader in the use of polar ice cores as important paleoclimate archives. He and his colleagues were the first to discover and measure large glacial to interglacial variations in atmospheric CO₂ concentrations in the air bubbles trapped in ice. Together with his colleagues, he detected a series of abrupt climate changes in the Greenland ice cores, now called “Dansgaard-Oeschger events.”

Pettersson, Otto (Sven Otto) (1848–1941)

Swedish professor of oceanography at Stockholm University, Otto Pettersson was one of a family of marine scientists with strong international ties. While associated with the Swedish Fisheries Commission, he observed that the rising tide at their laboratory and tide station on the Gulmarfjord, on Sweden’s west coast, would form an internal wave up to 25 m high at the boundary of the (cold, dense) offshore water and the out-flowing (somewhat fresher and less dense) Baltic water. At the peak of the 18.6 year nodal cycle, the tide produced a dramatic effect near the head of the fjord. Sweeping into the Baltic, it carried young herrings, providing a bounty for the fishermen. Herring statistics, reaching back to about the twelfth century in Hanseatic League archives, showed this luni-solar orbital cycle to increase harmonically at the same season: 18.6/93.067/186.134 year, with effects on regional climate as well. Pettersson’s tidal force theories were summarized in the *Geografiska Annaler* (1930, v. 18).

The oceanographic and climatic effects of the 18.6 year lunar nodal cycle are well known (Lamb, 1977), and the coexistence

of the sunspot cycle and the nodal cycle was recognized in auroral and geomagnetic records by Ekholm and Arrhenius (1898), and in the Nile floods and climate data by Currie (1995).

Ramsay, Wilhelm (1865–1928)

A Finnish mineralogist and Quaternary geologist, Ramsay was the proponent of the “Relief Theory” in paleoclimatology (Spencer, 1936). The role of uplift was neglected as a climate-forcing process until the late twentieth century when plate-tectonic studies drew attention to the progressive underthrusting of the Himalayas and general uplift of the Tibetan plateau, especially during the Quaternary. Simultaneous uplifts occurred in the Rocky Mountains, Andes and Alps.

Ramsay was also very interested in eustasy. However, his estimate of lowest Pleistocene sea level (1930) was 275 m, approximately double the present estimates. He investigated the meltwater filling of the Russian closed basins, at one stage forming a giant Aralo-Caspian lake. Ramsay also visualized a post-glacial downcutting of the Dardanelles and Bosphorus to drown the Black Sea, a concept recently embraced by Ryan and Pitman. In terms of the glacio-isostatic uplift of Fennoscandia (he appears to have invented the concept), he allows a considerable lag time by reducing the theoretical crustal response (see discussion by Daly, 1934, p. 71).

Reusch, Hans Henrik (1852–1922)

A Norwegian geologist, Reusch (1890) discovered the first unquestionably glacial deposits stratigraphically related to the lowest Cambrian, on the north shore of the Varanger Fjord in the Finnmark district of Norway (Kaiser, 1923). The tillite is diagenetically lithified, but not structurally deformed, and rests on beautifully striated and grooved bedrock of Proterozoic age. Its discovery triggered the recognition of comparable tillites elsewhere in the Caledonian belt, in Scotland, Spitsbergen, and elsewhere in the Arctic. Analogous formations were then found on every continent, which has led to the concept of “Snowball Earth.” Harland (1964) called it “the great Infra-Cambrian glaciation” (Schwarzbach, 1974), also known as the “Eocambrian glaciation,” or “Vendian” or “Upper Riphean” in Russia. Today, several Neoproterozoic glaciations between 750 and 542 Myr are recognized: the Sturtian (~750 to ~720 Myr) and the Marindan (~620 to 600 Myr).

Revelle, Roger Randall Dougan (1909–1991)

Roger Revelle, standing six feet and four inches tall, has been described as a “scientific giant,” both literally and figuratively. He was one of the first scientists to study marine geology and the role of ocean carbonates in global warming. He was also involved in many international scientific programs, showing concern over issues of population growth, adequate food and energy resources.

Born in Seattle in 1909, Revelle obtained his B.A. in geology from Pomona College in 1929 and Ph.D. in oceanography from the University of California, Berkeley in 1936. Shortly thereafter, he was appointed an instructor at the Scripps Institution of Oceanography in San Diego. By 1951, he had become director of Scripps. During his years as director, he attracted many prominent scientists and expanded the laboratory facilities and fleet, stimulating Pacific basin geophysical studies, which played a key role in the discoveries leading to plate tectonics.

One of his major contributions to climatology was the finding that excess atmospheric carbon dioxide, produced by

anthropogenic greenhouse gas emissions, was being absorbed by the ocean at a much slower rate than previously thought, thereby contributing to recent global warming (Revelle and Suess, 1957). He hired David Keeling to monitor atmospheric carbon dioxide levels, initially at Mauna Loa in Hawaii, and elsewhere. The “Keeling Curve,” showing rising carbon dioxide levels since 1957, has become a key piece of evidence in the ongoing debate over global warming.

Schimper, Karl Friedrich (1803–1867)

The first person to use the term “Ice Age” (“Eiszeit” in German, 1837), Schimper certainly deserves a place in paleoclimatology’s history (Volger, 1889). He was a naturalist and paleontologist, and was also interested in glacial geomorphology. After discussions in the field with Agassiz, he coined the term “Eiszeit,” which may have owed something to the German poet J. W. Goethe, who referred to an “epoch of great cold” in a romantic novel of 1829.

Selwyn, Alfred Richard Cecil (1824–1902)

Selwyn, an English geologist, was director of the Geological Survey of Victoria (1852–1869). Later, he held a similar position in Canada (1869–1894), contributing to the stratigraphy of Quebec and vertebrate footprints. He was the first to discover (in 1859) the Permo-Carboniferous glacial formations and elegant grooved and striated pavements in the Inman valley of South Australia, which were the first to be identified on the Australian continent (Whitaker, 1904).

Shackleton, Nicholas J. (1937–2006)

Nicholas Shackleton received his B.A. in 1961 and Ph.D. in 1967 at Cambridge University, where he remained during his professional career. Over many productive years, Shackleton made numerous contributions to paleoclimatology, primarily through his pioneering work using marine oxygen isotopes to unravel the climate record contained in ocean cores. Working closely with Neil Opdyke, who dated the sequence of paleomagnetic reversals, he developed a chronology of oxygen isotope variations, which led to the recognition of numerous Quaternary glacial to interglacial cycles on roughly 100,000-year timescales. Once a reasonably accurate timescale had been established, the observed climate cycles, including cycles at 23,000 years (precession) and 41,000 years (obliquity), could be linked to Earth’s orbital parameters, thus confirming the Milankovitch theory of the ice ages (Hays et al., 1976). The CLIMAP project (see *CLIMAP*) grew out of these early studies. The marine oxygen isotope curves derived from benthic foraminifera form the basis of the widely-used SPECMAP chronology (see *SPECMAP*). Shackleton was also one of the first researchers to apply carbon isotopes to paleoclimate studies, in particular using ¹³C values in benthic foraminifera as a marker for major changes in deepwater ocean circulation (Ruddiman, 2006).

In collaboration with John Chappell in 1986, Shackleton compared marine oxygen isotope oscillations with eustatic sea level variations recorded in emergent reef terraces on the Huon Peninsula, New Guinea, and assessed the role of variable deep-sea temperatures. A more recent comparison with Antarctic ice cores, however, also indicated that a substantial fraction of the foraminiferal oxygen signal stemmed from variations in deep-ocean temperature rather than ice volume (Shackleton, 2000). Furthermore, ice volume was found to lag behind fluctuations in orbital eccentricity and carbon dioxide, thus pointing to the role of feedbacks involving CO₂ (Shackleton, 2000).

Shackleton was the Director of the Godwin Institute of Quaternary Research at Cambridge University for many years, officially retiring in 2004, yet remaining active until shortly before his death. In recognition of his many scientific contributions, he received numerous honors and awards, including a knighthood in 1998 for his services to earth science, appointment as Fellow of the Royal Society (1985) and Foreign Member of the U.S. Academy of Sciences, the Crafoord Prize (1995), the Milankovitch Medal (1999), the Vetlesen Prize (2004), and Japan's Blue Planet Prize (2005).

Suess, Eduard (1831–1914)

Suess, professor of geology at the University of Vienna (1857–1908), saw the Earth's crust as undergoing long-term cycles of extension with subsidence, alternating with horizontal compression and uplift, a revolutionary idea at that time (Gohau, 1990). His *Antlitz der Erde* (in 5 parts, 1885–1909) was immediately translated into French and then into English (as *The Face of the Earth*, 1904–1924).

From his worldwide reviews of stratigraphy and paleontology, Suess became convinced about the worldwide rise and fall of the ocean level, and coined the expression “eustatic movements” (1888). Particularly in the rocks of the region between the Alpine belt and the Mediterranean, he perceived a regular and universal ebb and flow like a giant tide. He understood that the basins opened tectonically and closed by sedimentary infilling, but climatic forcing was not considered (Tietze; 1916).

His grandson was the celebrated geochemist Hans Suess at the Scripps Institution of Oceanography, La Jolla, a branch of the University of California. Hans was the first to demonstrate the cyclical fluctuations of ^{14}C in the wood of tree rings (a proxy for solar-wind energy flux) and found that the thickness of these tree rings coincided with climatic variables (Suess, 1981).

Swedenborg, Emanuel (1688–1772)

A Swedish scientist, philosopher and religious mystic, Swedenborg traveled widely and wrote extensively about all branches of science, but also noted the elevated beachlines that mark the boundaries of Scandinavia. However, following the beliefs of the day, he attributed them to pauses in the gradual desiccation of the world ocean after the Biblical flood of Noah. Nevertheless, he was credited with the earliest work on paleontology in Sweden, and attempted a systematic approach to mineralogy. In 1734, he outlined his nebular hypothesis for the universe, long before Kant. Swedenborg was one of the first to attempt some reconciliation between scientific developments and the literal interpretation of the Bible (Tufel, 1875–1877).

Urey, Harold C. (1893–1981)

Harold Urey was one of the most prominent and influential scientists of the twentieth century. His research contributed to nuclear physics, chemistry, and the earth sciences. His work on elemental isotopes led to the development of entirely new disciplines such as cosmochemistry, geochronology, stable isotope geochemistry and paleoclimatology. He also took a keen interest in the origins of the Solar System and of life on Earth.

Born in Walkerton, Indiana in 1893, Harold Urey received his B.A. in 1917 from the University of Montana and his Ph.D. in chemistry in 1923, from the University of California, Berkeley. He worked on atomic structure with Niels Bohr at the Institute

for Theoretical Physics in Copenhagen for several years. Upon his return to the United States, Urey became associate professor in chemistry at John Hopkins University, and later taught chemistry at Columbia University between 1929 and 1936. His research in nuclear systems and isotopic variations resulted in the discovery of deuterium – “heavy” hydrogen, with mass 2. This discovery earned Urey the Nobel Prize in 1934.

Contributing to the Manhattan Project during World War II, Urey designed methods for separating and enriching ^{235}U , the fissionable isotope of uranium needed for making an atomic bomb. After the war, he became professor at the Institute for Nuclear Studies, Chicago University. During the course of his work with oxygen isotopes, Urey noticed a temperature dependence in the fractionation factor of $^{18}\text{O}/^{16}\text{O}$ between carbonates and water and realized that this could be used to measure paleotemperatures. Several papers published between 1948 and 1951 became the basis for stable isotope paleothermometry, which is so widely used in paleoclimatology today (Epstein et al., 1951; Urey et al., 1948, 1951).

After retirement in 1958, Urey became professor of chemistry-at-large at the newly-formed University of California in San Diego. He became interested in the origin of the Solar System and of life on Earth. In 1959, he and his then-graduate student Stanley Miller simulated early Earth conditions by passing an electric discharge into a flask containing a mixture of methane, ammonia, and water, and obtained a variety of amino acids, precursors of the proteins that are essential to living systems (Miller and Urey, 1959).

In addition to the Nobel Prize, Urey received numerous awards and honors, among which are the Medal of Merit from President Harry S. Truman, the National Medal of Science, and the 400th Anniversary of John Kepler Medal and Citation from the American Academy of Arts and Sciences.

Von Richthofen, Baron Ferdinand (1833–1905)

Often considered as one of the founders of the science of geomorphology, Baron (Freiherr) von Richthofen was born in what was German Silesia (now Poland); he studied in Breslau (now Wroclaw) and later Berlin. Von Richthofen's many interests eventually earned him a university chair in Leipzig (1883) and then in Berlin (1886) (Ravenstein, 1905; Beckinsdale, 1975).

He joined the Austrian geological survey, his work taking him to China, Southeast Asia and California. In the 200 m high cliffs of the Chinese loess plateau, he first recognized non-actualistic phenomena, i.e., sediments that could not possibly be explained by modern-day processes (Tiessen, 1907). Von Richthofen correctly interpreted the loess as an eolian deposit of silt to dust-sized particles that had accumulated during glacial cycles. He viewed the upper part as a paleosol, modified by weathering and soil-forming processes that suggested mild interglacial climates. The loess sections of the world are now known to constitute unique records of continental climatic oscillations that have been dated to show contemporaneity with (a) glacier oscillations in ice sheets such as Greenland and Antarctica; and (b) deep-sea sediments with similar oscillations characterized by micropaleontology and $\delta^{18}\text{O}$ temperature data. Von Richthofen's eolian loess thus forms the third leg of our ice age chronology (Hettner, 1906).

Some confusion arose during the twentieth century when water-laid loess was discovered in central and eastern Europe. At one stage, this was the “official” Soviet interpretation. Von Richthofen in fact had remarked on loess dust that in places

had fallen into lakes or had been reworked to become a fluvial deposit. While cliffs along the Danube clearly display lenses of water-lain loess, the uniquely periglacial hyperaridity of loess episodes has been abundantly confirmed.

Another of his important paleoclimatic discoveries was in the Dolomite Alps (then part of Austrian Tyrol). He viewed each mountain block as an original coral reef of Triassic age, evidently a subtropical facies in cool latitudes today. The original limestone had been altered to dolomite (named for Deodet de Dolomieu, 1750–1801).

Zeuner, Frederick Everard (1905–1963)

Paleoclimatologist, prehistorian, geologist and all-round naturalist, Zeuner was one of the “greats” of the early twentieth century. Trained at the universities in Berlin, Tübingen and Breslau, he became a lecturer at Freiburg im Breisgau in 1931, where he worked with Walter Soergel on the fluvial evidence for the Milankovitch orbital hypothesis. At that time, the very idea of extraterrestrial forcing was very tentative, and violently opposed by many authorities. Although the astronomic basis was fairly sound, the geological record was pitifully bereft of a quantitative chronology. Nevertheless, Zeuner took the astronomic record as a basis for that chronology.

Fleeing persecution in Germany in 1934, Zeuner found sanctuary in London, at the British Museum of Natural History, where he worked on fossil insects, the paleoclimatic value of which was already recognized. Zeuner then became honorary lecturer, later professor, and finally director of the London Institute of Archaeology. He elaborated on the orbital theory and found it to be compatible with the geological record of glaciations, paleosols, eustatic sea levels, and other paleoclimatic indicators and proxies. Two of his books, *The Pleistocene Period* (1945, 1959) and *Dating the Past* (1946) had a worldwide impact.

The chronology problem had been partially solved by the Swedish varve-dating system of Baron deGeer, which had been integrated with Holocene sea-level fluctuations. The last 10,000 years were seen to span a precession hemicycle (Fairbridge, 1961, 1981). Radiocarbon dating subsequently expanded the chronology to over 40,000 year, taking the record back two precession cycles.

HOLOCENE CLIMATES

Introduction and definition

The Holocene – or “wholly recent” – epoch is the youngest phase of Earth history, which began when the last glaciation ended, and for this reason it is sometimes also known as the post-glacial period. In reality, the Holocene is one of many interglacials that have punctuated the late Cenozoic ice age. The term was introduced by Gervais in 1869 and was accepted as part of valid geological nomenclature by the International Geological Congress in 1885. A summary account of Holocene environmental history is provided by Roberts (1998). A commission of the International Union for Quaternary Research (INQUA) has been devoted to the study of the Holocene, and it is also a major focus of the PAGES (Past Global Changes) program. Since 1991, the journal *The Holocene* has been dedicated exclusively to Holocene research.

There are three principal schools of thought about how the Holocene should be formally defined. Because the Holocene still “lives,” debate has focused on defining its onset, namely the Pleistocene-Holocene boundary. The first school of thought (Watson and Wright, 1980) believes that the beginning of Holocene is easily recognized in individual records of deglaciation or biotic change (e.g., in pollen diagrams), but that because these changes are not exactly the same age everywhere, the Pleistocene-Holocene boundary should therefore be time-transgressive. A second school prefers the “type-section” approach commonly used in geology to define stratigraphic boundaries. Mörner (1976), for example, proposed that a sequence in southern Sweden might be the standard reference point for the Pleistocene-Holocene boundary. The third view, and one which is supported by INQUA, is that the Holocene is simply defined as beginning 10,000 radiocarbon (^{14}C) years ago.

^{14}C chronologies count AD 1950 as being the “present-day” and also underestimate true – or calendar – ages by several centuries for most of the Holocene. Cross-dating of pines from

the western United States and northwest Europe has revealed a systematic divergence between ^{14}C and tree-ring ages in samples more than 2,500 years old, with a discrepancy amounting to 600 years (or 12%) at 5,000 yBP. Moreover, the calibration curve is not a smooth line but contains a number of deviations that represent short-term variations in atmospheric ^{14}C production. This is significant in that some ^{14}C dates have more than one calendar age. Current estimates for the beginning of the Holocene put it at around 11,500 yBP in calendar years, based on counts of tree rings and annual ice layers (Alley et al., 1993; Gulliksen et al., 1998). It is now possible to calibrate ^{14}C dates for the whole of the Holocene (Stuiver and Reimer, 1993), and because it is better to use calendar rather than radiocarbon years as a time frame for past global changes, the former (i.e., cal. yBP) will be used in this entry.

Various attempts have been made to subdivide the Holocene, usually on the basis of inferred climatic changes. Blytt and Sernander, for instance, proposed a scheme of alternating cool-wet and warm-dry phases based on shifts in peat stratigraphy in northern Europe. However, with the systematic application of ^{14}C dating it has become clear that Holocene vegetation and climatic changes were more often than not time-transgressive, and as a result most researchers prefer to use age (e.g., 8,000 cal. yBP) rather than stage (e.g., Boreal-Atlantic transition) for defining past events.

Data sources

For the last few centuries of the Holocene, instrumental data are available and can be used to build up high-quality time-series for individual climate variables. However, because the climate system varies over timescales longer than can be observed directly, it is also necessary to turn to longer-lived human and natural archives. For intermediate time-scales, documentary sources can be used (Bradley and Jones, 1992), although these data were not always collected in a form ideal for the analysis to which we wish to subject them. The length of the “historical” time period also varies greatly in different parts of the world, extending back around 5,000 years in regions such as Egypt, but little more than a few decades in places like Papua-New Guinea. A third group of techniques operates over longer Holocene timescales. These are proxy-climate methods such as dendroclimatology and pollen analysis, which can sometimes be combined within a single sequence to create a multi-proxy approach.

In environments with little human disturbance, it is widely believed that organisms – terrestrial, aquatic or marine – will eventually achieve a state of equilibrium with the prevailing climate. Modern data on climate-species relationships can therefore be applied to paleoecological data from sediment cores to produce quantitative estimates of past temperatures or rainfall levels, using transfer functions or other multivariate statistical methods. Climatic calibration of modern and fossil pollen data has allowed maps to be produced showing temperature, precipitation or air mass distribution for different times during the Holocene over eastern North America (Webb et al., 1993). An alternative, complementary approach involves calibrating proxy-climate indicators, such as the stable isotope signature in cave speleothems, against local meteorological records for the last 50–100 years. If a statistically significant correlation can be found, the proxy-climate records can then be used to extend the time series back to before the beginning of recorded weather observations.

The last deglacial climatic transition

The Last Glacial Maximum occurred around 25,000–18,000 years ago, according to calibrated radiocarbon dating. At this time, temperatures on land were lowered by as much as 20 °C although ocean temperatures changed much less. Under the full glacial climate, ice sheets more than 4 km thick lay across northern Europe and North America, and smaller ice caps existed in the Alps, the southern Andes, and parts of East Asia. Climatic warming, and the consequent deglaciation of these continental regions, took place in a series of steps that appear to have been broadly synchronous over large parts of the globe, although there may have been some asynchrony between the Northern and Southern Hemispheres.

Deglaciation, which took about 9,000 years to complete in Europe and North America, was an unsteady process, and at various times towards the tail end of the Pleistocene ice sheets temporarily re-advanced. In at least some cases, this was the result of a temporary but sharp oscillation in climate, which represented a false start to the present interglacial. In the circum-North Atlantic region, this late Pleistocene thermal oscillation comprised a warming event often known as the Bølling-Allerød interstadial (~15,000–12,700 cal. yBP) followed by a cooling event called the Younger Dryas stadial (12,700–11,500 cal. yBP). Evidence from coleopteran (beetle) and chironomid (midge) fossils shows that summer temperatures warmed rapidly to reach – or even exceed – those of today soon after 15,000 cal. yBP.

Ice cores provide some of our most important paleoclimatic data for ice age climate, with Greenland possessing the most important record in the Northern Hemisphere. Ice has accumulated faster here than in Antarctica and it therefore offers a more detailed sequence of past climatic change, with an annual time resolution for the part covering the late Pleistocene and Holocene. The GRIP and GISP2 cores drilled at the summit of the Greenland ice sheet between 1988 and 1993 provide especially important climate records. They show the same late-glacial climatic oscillation as revealed in biotic records, and confirm that the warming steps were extremely rapid. The last of these, marking the transition from the Younger Dryas stadial to the Holocene interglacial proper, involved a temperature rise of 7 °C over no more than 50 years (Alley et al., 1993). These sudden jumps in climate may be linked to periodic on and off switching of the thermohaline “conveyor belt” circulation in the Atlantic Ocean (Bard and Broecker, 1992). The Younger Dryas climatic reversal, for example, was most probably the result of a partial shut-down of the Atlantic conveyor caused by large pulses of meltwater from adjacent Northern Hemisphere ice sheets.

The early Holocene climatic optimum

Because climatic change was especially rapid during the millennia either side of the Pleistocene-Holocene boundary, many Earth surface systems experienced lagged responses. Global (eustatic) sea levels, for example, lay at about –40 m at 11,000 cal. yBP and only reached modern elevations around 6,000–5,000 years ago (Edwards et al., 1993). Similarly, because soil formation and vegetation cover often lagged behind the climate, many landscapes experienced a phase of temporary geomorphic instability during the Pleistocene-Holocene transition, with high rates of erosion and sediment flux.

In many mid-latitude Northern Hemisphere regions, a thermal optimum can be identified between ~10,000 and ~6,000 cal. yBP from the extension of species such as the water chestnut and the pond tortoise north of their present European climatic limits.

The cause of these long-term climatic changes lies in astronomically-controlled variations in the Earth’s receipt of solar radiation (Figure H6). At the start of the Holocene, one of the three *Croll-Milankovitch* cycles – the precession of the equinoxes – lay at the opposite point on the cycle from where it lies today. Therefore, the Northern Hemisphere received nearly 8% more solar radiation during summer months than at present, and northern summers were considerably warmer in consequence.

Because climatic conditions exert a powerful influence over geomorphic processes, relict landforms can furnish indications about past climates. In the tropics and sub-tropics, two of the most climatically-sensitive geomorphic regimes are desert dunes and lakes. As a result of the close relationship between eolian processes and climatic aridity, fossil dunes have helped to provide an indication of the changing extent and location of the World’s arid zones (Goudie, 1983). Eolian landforms not only indicate times of climatic aridity but also reveal former wind strengths and directions. While dunes indicate periods of climatic aridity, high-level lakes reflect periods of positive water balance, and in the Holocene at least, these are associated with phases of wetter climate. Direct geomorphic evidence of former high levels derives from shoreline terraces and related landforms left above present-day lakes.

It was recognized in the early twentieth century that deserts were not always as arid as they are today. In addition to the evidence of high-level lakes, ancient rock paintings from the Sahara depict herds of savanna mammals, while pollen diagrams and rodent nests indicate much richer, often wooded, vegetation cover. Within the tropics, ¹⁴C dating has shown that the last “pluvial” (or wet) period started during the terminal Pleistocene and continued through the first half of the Holocene (14,000–5,500 cal. yBP). Water-balance calculations for these enlarged early Holocene lakes indicate that rainfall in East Africa, the Sahara, and northwest India increased by between 150 and 400 mm per year (Street-Perrott et al., 1991). This increase was caused by an enhanced monsoon circulation that brought summer rains further north than they occur today. The

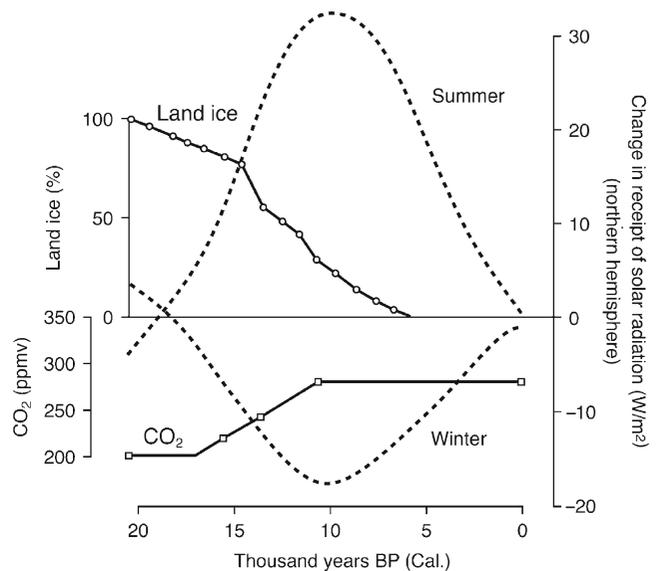

Figure H6 Changing receipt of solar radiation and other climatic controls in the Northern Hemisphere since the Last Glacial Maximum (modified after Kutzbach and Street-Perrott, 1985)

stronger monsoon was itself generated by the “thermal optimum,” which led to greater heating over the land – especially over south Asia – and caused low pressure, which sucked in the humid, monsoonal air masses from the south.

In mid-latitude regions such as the North American prairie, a different pattern of climate change occurred around this time. Pollen data show that the mid-western prairie-forest boundary moved eastwards until 8,000 cal. yBP, but subsequently shifted back in the opposite direction. As this boundary is today controlled by moisture availability, it is reasonable to use it as a proxy climatic indicator, recording climatic conditions between 8,000 and 4,500 cal. yBP that were drier than at present. Sediment cores from some of the many small lakes of the North American Great Plains also record this climatic phase. Diatom and geochemical analyses, for example, show high salinities during the first half of the Holocene, while before and after this phase the lake water was relatively fresh (Haskell et al., 1996).

This orbital forcing of the early Holocene climatic optimum appears to have been amplified by the biosphere itself. Modeling experiments have shown that vegetation had a significant effect on climatic conditions in key boundary areas, such as the edges of forest and desert biomes, by changing the surface albedo and moisture conditions. Along the boreal-tundra ecotone, for example, calculations suggest that the expanded forest caused an additional warming of about 4 °C in spring temperatures 6,000–7,000 years ago, over and above that caused directly by solar heating (Foley et al., 1994).

These longer-term climatic trends were interrupted on several occasions during the Holocene by abrupt events of shorter, centennial duration. In the tropics, they are recorded in abrupt lake-level falls, dated in Africa to ~12,000, 8,200 and 5,200 cal. yBP (Gasse, 2000). As with the rapid rises in temperature at the Pleistocene-Holocene transition, these hydrological changes occurred so rapidly that their true rate cannot be determined by ¹⁴C dating. The abrupt arid events are also recorded by the Greenland ice core record as sharp troughs in atmospheric methane, implying a reduction in tropical wetlands, which are a major source of this greenhouse gas (Figure H7).

Late Holocene climatic variability

Although less marked than during the early Holocene, the later Holocene nonetheless experienced some significant shifts in climate. Among these were the progressive cooling following the Holocene thermal optimum and the climatic desiccation of the northern sub-tropics after 6,000 cal. yBP that created the modern Saharan, Arabian and Thar deserts. The water levels of some low-latitude lakes fell abruptly at this time (Figure H7), suggesting rapid suppression of the monsoonal circulation system, which controls tropical rainfall (Street-Perrott et al., 1991; Gasse, 2000).

Superimposed on longer-term climatic trends linked to orbital insolation forcing were shorter-term secular variations from wet to dry, or cold to warm, recorded in the stratigraphy of peat bogs (Charman et al., 1999) or the advance and retreat of mountain glaciers. Whether these oscillations represent true, regular cycles is uncertain, as is the question of the causes of these climatic changes. Among the most likely controlling mechanisms for sub-Milankovitch climatic variations are changes in the radiation output of the Sun, linked to sunspot cycles, and the heat-shielding effect of volcanic eruptions with large dust emissions.

Volcanic aerosols can play an important role in disturbing the Earth’s climate, for example by creating a dust veil that reduces the transparency of the atmosphere. After major

Arrows show abrupt arid events interrupting longer-term climatic trends. Ages are in 1000 yBP (cal).

historically-recorded eruptions like that at Laki in Iceland in AD 1783, contemporary writers such as Benjamin Franklin recorded severe late frosts and peculiar hazes in regions far removed from the volcanoes themselves (Grattan and Brayshay, 1995). Some earlier Holocene eruptions were substantially larger than the Laki fissure eruption, and it has been suggested that they may have had a proportionately bigger climatic impact (Zielinski et al., 1994). For example, in about 1628 BC (3,578 cal. yBP), the Aegean island of Santorini (Thera) exploded catastrophically, forcing its Bronze Age population to flee or perish. Dendroclimatology studies have shown that the tree rings of Irish bog oaks were unusually narrow at this time, while bristlecone pine growth rings of the same age in California show signs of frost damage. These have been interpreted as the result of a cooler and/or wetter climate. However, in Turkey, which is warm and dry in summer, the same climatic change appears to have given rise to more, not less, favorable growing conditions and to broader tree rings (Kuniholm et al., 1996). While the evidence linking tree-rings, climate and volcanic eruptions is impressive, it also suggests that in most cases the climate perturbation was short-lived, typically a decade or less.

Increasing evidence is also being found to support a role for variations in solar radiation upon Holocene climates, typically based on the observation that cyclic fluctuations in climate proxies have periodicities close to those found in the record of solar activity (Bond et al., 2001). In some cases, well-dated climatic anomalies have been to correlate with a known forcing function, such as European temperature minima coinciding with the Maunder minimum in solar activity of AD 1650–1715 (Mauquoy et al., 2002).

In addition to these external mechanisms, variations in Holocene climate will also have been forced by cyclic

processes originating within the Earth system, such as the quasi-periodic ~1500-year long Bond cycles during which ice-berg “armadas” drifted southward into the North Atlantic, slowing down the oceanic thermohaline conveyor belt. A comparable but much higher-frequency auto-cyclic phenomenon is the well-known El Niño-Southern Oscillation (ENSO). Although ENSO-type events appear to have operated throughout the Holocene, there is evidence, especially from high-resolution stable isotope analysis of corals, that the current ENSO frequency spectrum was not established until mid-Holocene times (Gagan et al., 2000).

The period during the Holocene with the best-resolved and most reliably calibrated climate data is the last millennium, including both the Mediaeval Climate Anomaly (~AD 1000–1250) and Little Ice Age (~AD 1250–1850, particularly AD 1590–1850) during which major rivers like the Thames and the Tiber regularly froze over. Data come from proxy-climate records, notably tree rings, from historical observations and – for the last two centuries – from instrumental records. Following the initial work of Mann et al. (1999) a number of synthetic curves have been generated from available data sets for Northern Hemisphere temperature changes. Source of these have a “hockey-stick” shape, in which temperatures fell progressively to reach a minimum in the seventeenth century, before rising sharply during the last 150 years. It remains an unresolved question how much of the observed rise of ~1 °C since the mid-nineteenth century is due to anthropogenic increases in atmospheric greenhouse gases, and how much is due to natural variability. However, global temperatures are probably now higher than at any time during the last 1,000 years, and it is likely that most of the post-1980 warming is of human origin.

To judge by recent experience, drought-prone regions can be expected to have been at least as severely affected by any climatic fluctuations as mid- and high-latitude areas, not only because of temperature change, but also due to rainfall variability. During the last millennium, greater aridity appears to have marked the North American Great Plains at the time of the Little Ice Age to judge from lake salinity variations, while increased dust flux onto the ice caps of the Andes suggests a similar tendency towards drought during this time interval. By contrast, East African lakes were at low levels at the time of the Mediaeval Climate Anomaly and were often higher during the Little Ice Age (Verschuren et al., 2004).

Conclusion

It is clear that since the end of the last glacial stage, climatic stability over decadal to millennial timescales has been far from the norm. A Holocene perspective can help to disentangle the different factors that determined these variations in global climate. Secular climatic cycles are recorded by many paleoclimatic indicators, including peat bog profiles, salinity fluctuations in non-outlet lakes, and in cores from ice caps. Some of these archives, such as variations in tree ring widths, can be resolved to individual years, and this permits investigation of the potential causes of short-term changes to the climate.

A Holocene timescale is also valuable if we want to establish how typical current rates of climatic change are, compared to those of the recent geological past. During the last major global warming around 11,500 years ago, a gradual orbital forcing of climate was amplified by a series of positive feedback mechanisms to cause an abrupt switch from glacial to interglacial conditions within the span of a human lifetime. The current temperature rise is therefore not unprecedented, although the climate is heading

towards conditions warmer than at any time during the Holocene. Past climatic changes offer further warnings about the potential instability of climate and the consequent hazards of climate prediction. On at least three occasions within the last 10,000 years, the climate deteriorated abruptly, only to return to its previous state within a few centuries.

If it is climatically calibrated and homogenized, proxy data for the Holocene can also be compared against numerical (global circulation models) GCM experiments run with different boundary conditions (COHMAP, 1988). Such data versus model comparisons allow the sensitivity and reliability of GCMs to be tested, hence improving their ability to predict future climates. The climate during the early Holocene “thermal optimum,” in particular, has been used to test and calibrate numerical models of the atmosphere. On the other hand, the Holocene does not offer a direct analogue for a future greenhouse gas-warmed climate, because it was dominated by seasonal, rather than mean annual, changes in the Earth’s net receipt of solar radiation.

HOLOCENE TREELINE FLUCTUATIONS

Timberline and treeline

Treelines are climatically sensitive transitional zones between closed forests and alpine, polar, or dry grassland communities. In most cases, temperature and precipitation thresholds determine whether a site is treeless or not (Arno and Hammerly, 1993; Körner, 1999). However, many other factors, such as vegetation type, soil type, snow cover, topography, and wind can locally co-determine the boundary of tree growth. Independently from the biotic and abiotic causes that form this conspicuous vegetation limit, the spatial position of treeline depends on the definition of “tree.” The most commonly used criterion to define “tree” at treeline is a minimum height between 8 and 2 m (Arno and Hammerly, 1993; Körner, 1999). Some studies prefer to distinguish between timberline and treeline (e.g., using the height of trees as a diagnostic criterion: 8 m for timberline and 2 m for treeline). The width of the transitional zone separating closed forests from treeless plant communities is not uniform: polar treelines and drought-caused treelines can form very broad transition zones such as parklands with widely spaced trees (Arno and Hammerly, 1993). Conversely, mountain treelines have rather narrow transitional zones (i.e., 100–200 m of vertical extent). It has been suggested that this range overlaps with the altitudinal span between timberline and treeline as defined above (8 vs. 2 m of tree height, Tinner and Theurillat, 2003).

The climatic sensitivity of treelines has led to much effort on the reconstruction of past treeline positions in order to quantify Holocene climatic changes. The significance of the method for paleoclimatology lies mainly in two factors: (a) Treeline studies have local to regional spatial resolutions and therefore provide valuable information about climatic changes of mountainous or polar sites, and (b) If combined with independent environmental proxies (e.g., oxygen isotopes as climatic proxy), treeline studies can give insights into biosphere responses to rapid environmental changes.

Reconstructing treeline fluctuations

The reconstruction of treeline fluctuations can be performed using different approaches. Analysis of pollen, stomata, macrofossils, and megafossils (including tree rings) are the most important methods. In addition, charcoal, soil, and phytolith analysis may be applied to determine maximum treeline positions. The methods have different spatial resolutions. Since pollen is easily lifted, transported, and deposited by winds over long distances, pollen records have rather low spatial resolutions. Thus, it is difficult to reconstruct treeline fluctuations by using the pollen approach alone. Macrofossil and megafossil analyses are considered to be more reliable tools for reconstruction of timberline fluctuations (Birks, 2001; Tinner and Theurillat, 2003) since they have higher taxonomic and spatial resolutions (meters to decameters) than pollen studies (decimeter to kilometers). A disadvantage of macrofossil and megafossils is that, in contrast to pollen, they are not ubiquitous in Holocene deposits. Producing treeline reconstructions requires records from today’s treelines that reach back to the late glacial. Two preconditions are essential: (a) the chronology of the treeline records must be fixed to an absolute scale with sufficient ¹⁴C-dates of terrestrial fossils, and (b) the study sites should be situated near to the present-day treeline position.

To assess the magnitude of past climate changes, reconstructions of Holocene treeline fluctuations must be related to modern treeline positions. For estimations of past temperature changes it is assumed that today's occurrence of trees is in equilibrium with the climate of the past few decades. In regions affected by strong human impact (e.g., the Alps), single trees in remote areas may still indicate the potential altitudinal limit of forest and tree growth. Using today's lapse rates (under the assumption of Holocene stability), it is possible to convert past treeline fluctuations (m) into (summer) temperature changes ($^{\circ}\text{C}$) (Haas et al., 1998), although it must be considered that higher treelines in the past reflected warmer periods that were stable enough to allow subalpine forest to migrate up-slope (100–200 years of potential response lags). In an attempt to synthesize common patterns across two continents, we focus on a few well-documented but representative case studies from temperature-controlled mountain treelines in Europe and Northern America.

Holocene treeline dynamics

Since reconstructions of Holocene treeline fluctuations reflect past local dynamics, comparisons among the sites are needed

to assess larger-scale patterns that could be related to climatic changes. Comparisons among pollen and macrofossil stratigraphies in the Swiss and Italian Alps allowed the detection of phases of warm (dry) and cool (wet) phases (Wick and Tinner, 1997) that are in agreement with lake-level fluctuations in the alpine forelands (CE-1 to CE-8, Haas et al., 1998) and glacier oscillations (Figure H8). The analysis of pollen and macrofossils from lake and mire deposits along altitudinal transects permits the reconstruction of treeline fluctuations during the Holocene (Tinner and Theurillat, 2003). These reconstructions show that the positions of timberline and treeline fluctuated within a band of 100–180 m during the Holocene and that treeline was at its uppermost limit (ca. 180 m higher than today) during the period 10,000–6,000 cal. yBP (Figure H9). Severe diebacks of treeline vegetation occurred during cold (humid) periods (CE-1 to CE-8 as well as during the Little Ice Age; Figures H8 and H9). A severe treeline decline lasted from 8,200 to 7,500 cal. yBP (CE-3), with two minima at 8,000 and 7,600 cal. yr B.P. (Figure H8, sites Gouillé Rion and Lengi Egga). After 6,000–5,000 cal. yBP, timberline and treeline progressively declined by about 180 m and 300–400 m, respectively (Figure H9). The regression of densely forested areas

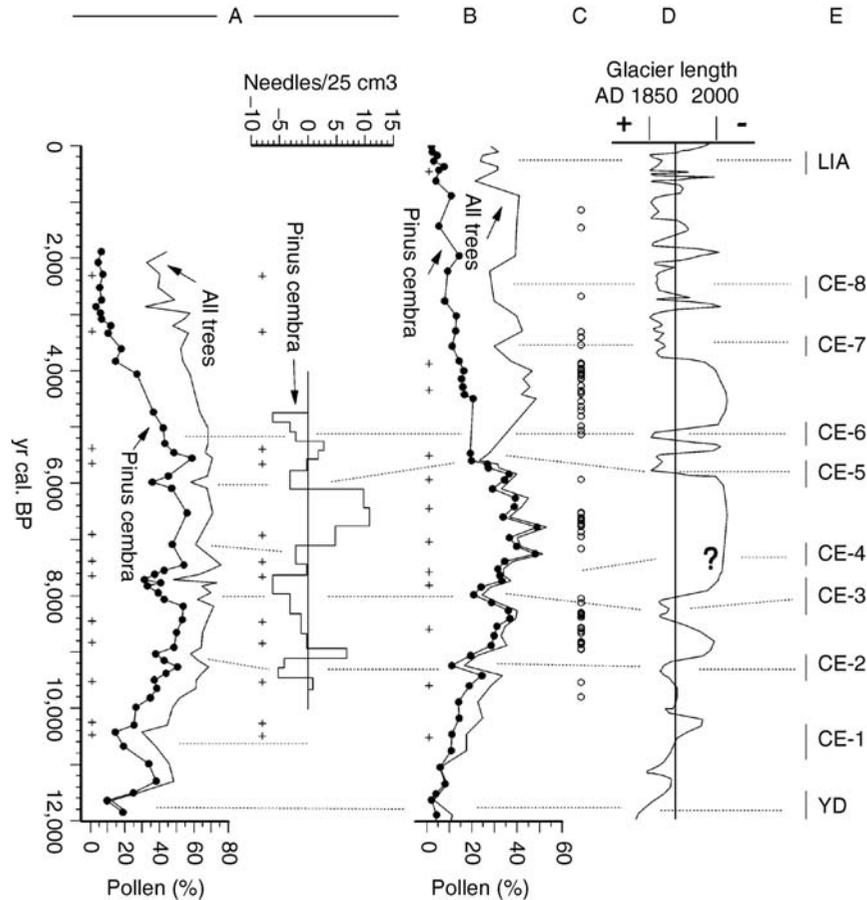

Figure H8 Comparison between pollen and macrofossil records of high-elevation sites and glacier fluctuations during the past 12,000 years; (a) pollen percentages and macrofossil concentrations at Gouillé Rion (Swiss Alps); (b) pollen percentages at Lengi Egga (Swiss Alps); (c) radiocarbon dates of wood and organic debris collected in front of Alpine glaciers (Hormes et al., 2001); (d) estimated length variation of Swiss glaciers (Maisch et al., 1999); (e) central European cold-humid phases (Haas et al., 1998). +in a and b show the chronological position of radiocarbon dates used for depth-age models.

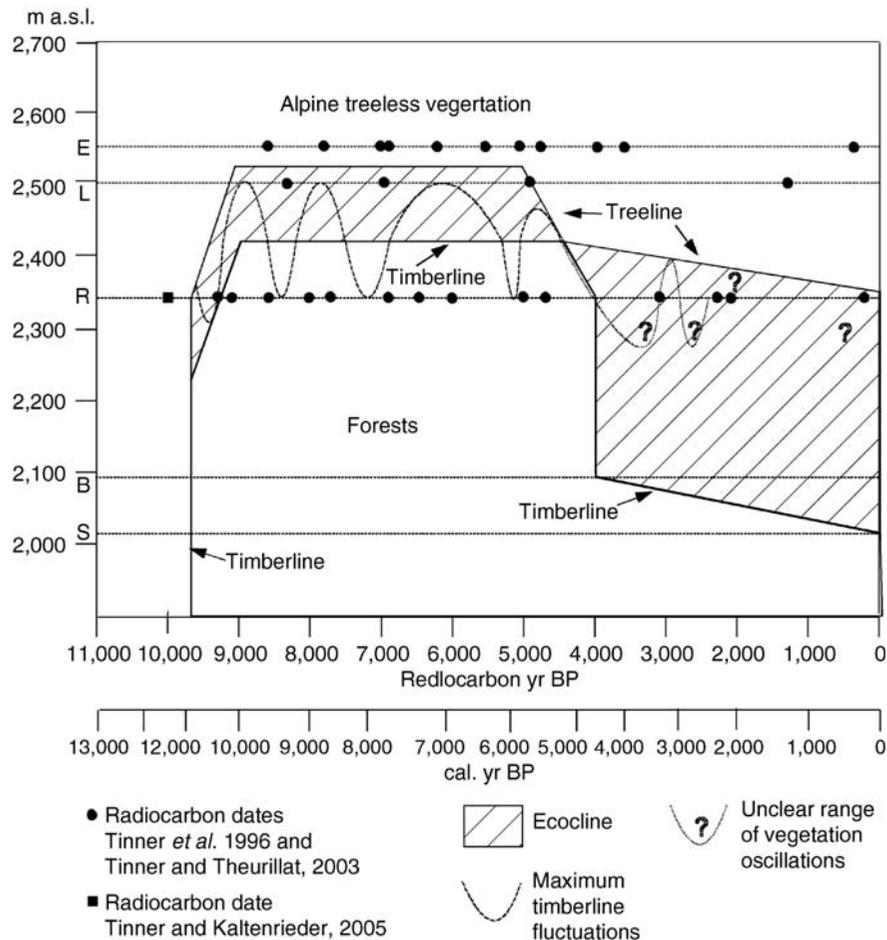

Figure H9 The approximate Holocene timberline and treeline elevation (m) in the Swiss central Alps based on radiocarbon-dated macrofossil and pollen sequences (modified from Tinner and Theurillat, 2003).

(timberline) in the Alps during the past 5,000 years was primarily caused by human impact, whereas the course of treeline gives a more realistic estimation of the climatic influence (Figure H9). Assuming constant lapse rates of $0.7^{\circ}\text{C}/100\text{ m}$, it is possible to estimate the range of Holocene temperature oscillations in the Alps to $0.8\text{--}1.2^{\circ}\text{C}$ between 10,500 and 4,000 cal. yBP, when average (summer) temperatures were about $0.8\text{--}1.2^{\circ}\text{C}$ higher than today. After 4,000 cal. yBP, summer temperatures successively declined to values comparable to those of the twentieth century (Figure H9).

The general course of Holocene treeline fluctuations in the Alps is similar to that reconstructed for Scandinavian sites. Megafossil, macrofossil, and pollen studies suggest that treeline was at its uppermost limit between 9,500(–9,000) and 6,500 (–6,000) cal. yBP in Norway and Sweden, about 200–400 m above today's treeline position (Kullman, 1995; Dahl and Nesje, 1996; Barnekow, 1999; Barnett et al., 2001). At some study sites, treelines declined temporarily between 8,300 and 8,000 cal. yBP (Dahl and Nesje, 1996; Barnekow, 1999; Barnett et al., 2001). Using today's lapse rates, it has been estimated that temperatures were $1.3\text{--}2.0^{\circ}\text{C}$ higher than today during the period of highest treeline positions.

A number of pollen profiles from western North America provide multi-millennial year records of alpine timberline fluctuations. These records were derived primarily from sediments deposited in high-elevation lakes and bogs, and, in most cases, limited dating control of the sedimentary records restricts their application to the reconstruction of only the general trends in treeline position throughout the Holocene. A more detailed picture of timberline fluctuations during the last 1,000 years has emerged from the study of tree rings taken from living trees or dead snags situated near the alpine timberline in the North American Cordillera. Most pollen records indicate that the alpine timberline was higher than present during the early to mid-Holocene and a general and widespread decline was underway by ca. 6,000–5,000 cal. yBP (Hebda, 1995). Pollen-based estimates of Holocene timberline position have been corroborated by several complementary proxies for estimating past environmental and climatic conditions. Taken together, these data suggest that mean growing season temperature in western North America was on the order of $1\text{--}4^{\circ}\text{C}$ warmer than present during the early-mid Holocene.

Perhaps the most direct and unequivocal evidence for past high stands of alpine timberline in western North America is

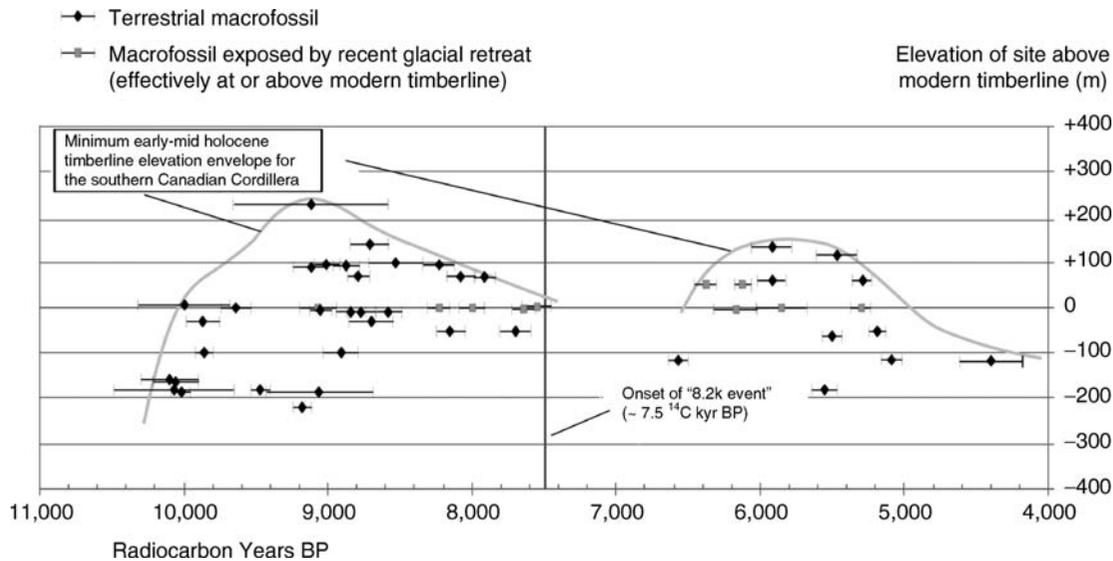

Figure H10 The approximate minimum early-mid Holocene treeline elevation in the southern Canadian Cordillera, based on radiocarbon-dated wood macrofossils recovered from high-elevation sites (modified from Reasoner et al., 2001).

radiocarbon-dated macrofossils that have been preserved in alpine environments. In some cases these data are derived from abundant conifer needles preserved in lacustrine sediments at sites that are currently above natural treeline (Reasoner and Hickman, 1989) and in others they are obtained from logs (megafossils) preserved in alpine bogs or soil profiles (Kearney and Luckman, 1983; Carrara, et al., 1991). Similarly, fossil wood dating to the early Holocene has been recovered from retreating termini of a number of glaciers in western Canada (Luckman, 1988), which indicates that early Holocene forests occupied areas now covered by ice. The recovery of wood ranging in age from ca. 10,000–5,000 cal. yBP from sites situated 100–200 m above the present timberline clearly indicates that subalpine forests reached at least this elevation during the early Holocene. Reasoner et al. (2001) compiled early-mid Holocene macrofossil information from across southwestern Canada and plotted this information relative to modern timberline. The results indicate two clear periods of higher-than-present timberline during the early Holocene: an early phase from the onset of the Holocene to approximately 8,200 cal. yBP (7,500 ^{14}C yBP) and a later phase between 7,300 and 5,700 cal. yBP (6,400 and 5,000 ^{14}C yBP, Figure H10). These data are in general agreement with European records (e.g., Figure H9) that indicate the timberline was higher than present during the early-mid Holocene and suggest the 8.2 event may have also impacted alpine treelines in western North America. Additional high-resolution records for the North American Cordillera are necessary to resolve this issue.

Several small-scale fluctuations of the alpine timberline have been documented during the last millennium, primarily from dendrochronological analyses of living trees near alpine timberline and in situ dead snags. For example, the abrupt synchronous termination of 92 tree-ring records related to the 1690's "cold snap" (Luckman, 1994) clearly indicates that significant changes to the position of the alpine timberline have occurred on decadal timescales and that these changes have been driven by natural variability of the regional climate (Figure H11).

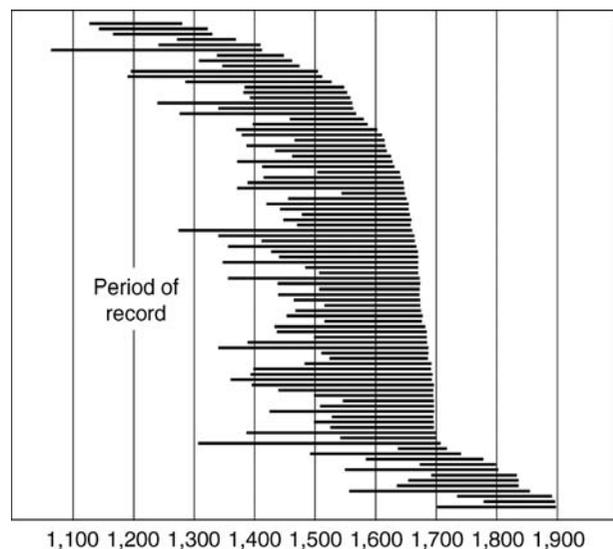

Figure H11 Length of record preserved in calendar-dated snags recovered from the Athabasca Glacier Site, Central Canadian Rockies. The standing and fallen snags occur at and above the present treeline or where these snags are considerably larger than trees presently growing at the site. One of the main Little Ice Age advances of the Athabasca Glacier has been dated at 1714 (modified from Luckman, 1994).

Linking the past to the future

It is clear that the position and composition of the timberline ecotone has been sensitive to Holocene climate change. The millennial-scale trends generally reflect gradual decline in Northern Hemisphere insolation from approximately 11% higher-than-present in the early Holocene. Superimposed on this long-term trend are higher-frequency fluctuations related to changes in oceanic circulation, volcanic activity, and solar

irradiance or a combination of these factors. It is also clear that anthropogenic climate forcing over the next 100 years is likely to rival or exceed the warmest conditions of the Holocene. Concerns about global warming involve adjustments, collapses, migrations, or extinctions of boreal and alpine life. Surprisingly, relatively few studies have addressed past responses of ecosystems such as treeline communities to climatic change. One of the reasons for avoiding this topic is that accurate studies require independent climatic proxies and very high temporal resolution (<10–20 years/sample). To assess how tree-lines could respond to global change, high resolution studies including macrofossil analysis are urgently needed.

HUMAN EVOLUTION AND CLIMATE CHANGE

Introduction

How, where, and why humans evolved are fundamental questions that capture our attention and spark curiosity. A number of recent hominin fossil discoveries as old as 6 Ma and advances in DNA research have now documented that humans evolved in Africa and then migrated to other parts of the world starting as early as 2.0 Ma. Hominins are living or fossil members of the family Hominidae. Evidence of their early exodus from Africa has raised other questions. Why did humans leave the safety of trees? What were the drivers that may have nudged hominins toward bipedalism and developed species that failed, while only one ultimately succeeded? Were the development of tools, the exodus from Africa, and the brain development that led to language, art and imagination a passive or direct response to some paleoenvironmental stresses?

During the last few decades, the need to understand the Earth's climate system and evaluate the potential threat of global warming has yielded a wealth of knowledge on climate and paleoclimate. This research has led to the exciting potential of GCMs (global climate models) – computer models that facilitate the analysis of present, past, and future climates. However, understanding the paleoenvironmental and paleoclimatic context of human evolution can only be accomplished using an interdisciplinary approach integrating geologic, biologic, and anthropologic data and the knowledge of global climate change.

The hominin fossil record reaches back in time to ~6 million years ago and stone tools to ~2.5 million years ago. The general framework of global climate during the Plio-Pleistocene is well documented from the oxygen isotope record from deep sea cores, but the details of paleoclimate on the continents is just now starting to emerge. There have been a few attempts to synthesize within regions and to place key sites within a broader temporal and spatial context, e.g., Turkana, northern Kenya (Brown and Feibel, 1991; Feibel et al., 1991), Ologesalie, southern Kenya (Behrensmeier et al., 2002) and Olduvai Gorge, northern Tanzania (Hay, 1976; Ashley and Hay, 2002). However, most geological studies of hominin-bearing deposits have typically focused on correlation and chronology of sites, with usually only local site-based descriptions accompanying each find. With the growing realization of the importance of tectonism, volcanism, and astronomic climate forcing during the Plio-Pleistocene, there is now an opportunity to integrate what is known about the paleoenvironment and paleocli-

mate from the geologic record and the evolutionary history from archaeological and paleo-anthropological records. A number of scientists have attempted to relate climate to hominin evolution, with some success (Brain, 1981; Behrensmeier, 1982; Boaz and Burckle, 1983; Foley, 1994; deMenocal, 1995; Potts, 1996b; Feibel, 1997), and a series of international workshops and conferences have been held to address the problem (Vrba et al., 1995; Bromage and Schrenk, 1999).

In order to examine the relationship between climate and human evolution, the following will:

1. Review the phylogeny (family evolutionary record) of the hominins
2. Describe the evolution of aspects of hominins that are distinctively “human”
3. Summarize briefly what is known about global climate during the period of hominin evolution

4. Examine possible links between climate change and human evolution

Hominin family tree

Despite the meager fossil record of hominins prior to appearance of modern humans (probably less than a few thousand individuals total) the main pattern of the hominin family tree is evident (Figure H12). Prior to about 4 million years ago, the record is so poor and the connections between fossils so uncertain that each hominin fossil has been given its own genus name: *Sahelanthropus tchadensis*, ~6–7 million years from Chad (Brunet et al., 2002); *Orrorin tugenensis*, ~6 million years from Kenya (Pickford and Senut, 2001; Senut et al., 2001); *Ardipithecus kadabba*, 5.77–5.54 million years from Ethiopia (Haile-Selassie et al., 2004); and *Ardipithecus ramidus*, 4.4 million years from Ethiopia (White et al., 1994). The fact

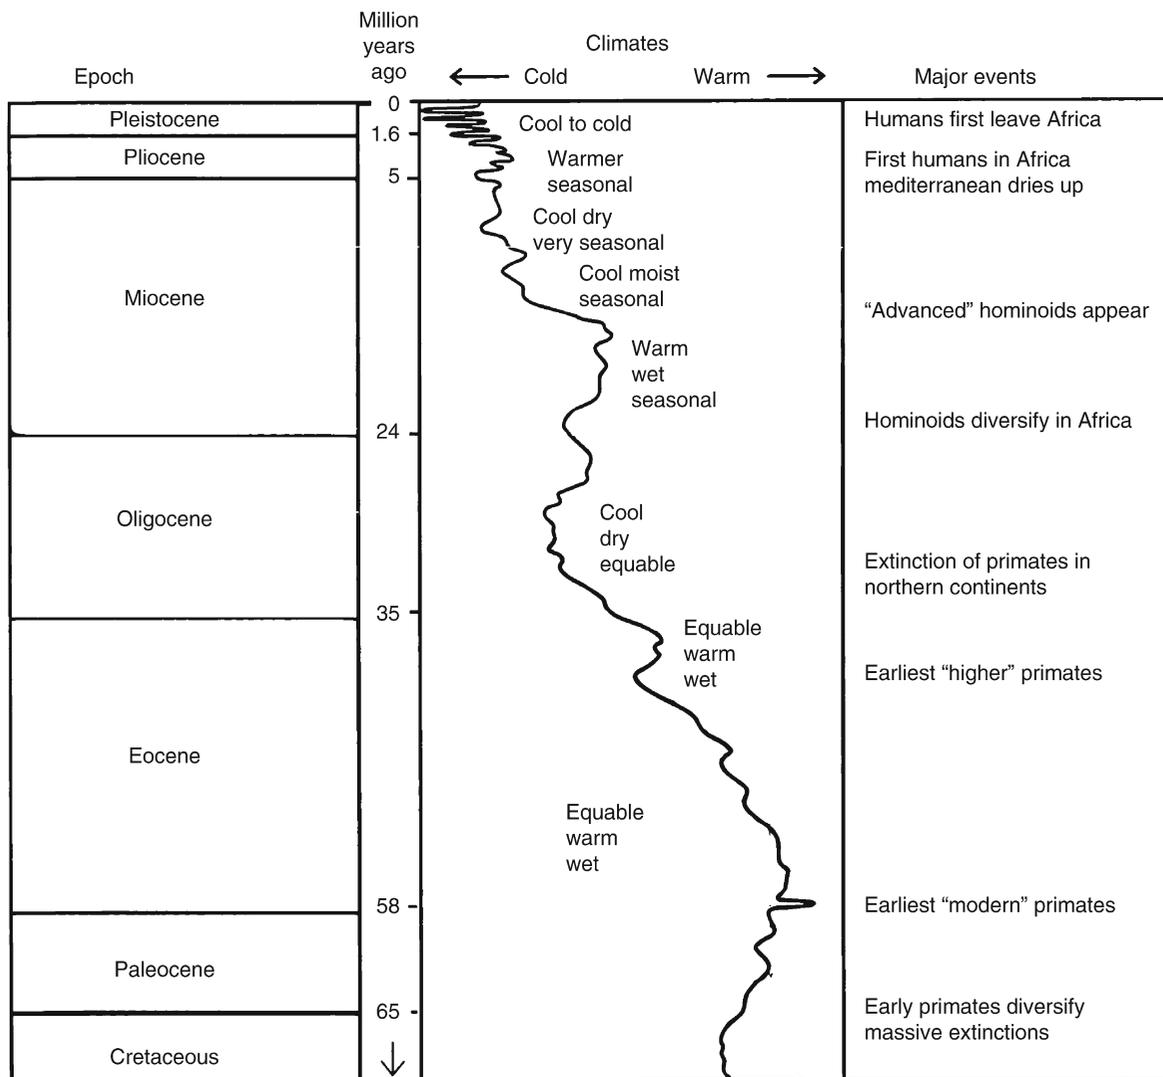

Figure H12 The graph traces the trend of climate during the Cenozoic era, showing a general cooling and culminating with the ice ages of the Pleistocene epoch. The relative temperatures are interpreted from the oxygen isotope record of foraminifers found in marine sediment records. Major events in primate evolution are indicated on the right (Tattersall, 1993) (modified from Partridge et al., 1995).

that hominins existed at least 6 Ma suggests that the divergence between apes and humans took place earlier, during the late Miocene, perhaps between 7 and 9 Ma.

The gracile australopithecines were the dominant hominin group from about 4–2.5 Ma and it is likely that several species existed at the same time; *A. africanus* and *A. afarensis* were important species. One of the earliest australopithecines, *Australopithecus anamensis*, dated at 4.2 Ma, was found in northern Kenya (Leakey et al., 1995) and the group lived in a large region stretching from South Africa to Ethiopia. Two hominin lineages diverged at about 2.5 Ma from the early more gracile australopithecines, leading to the robust australopithecines (e.g., *Paranthropus boisei*), who eventually went extinct, and the earliest members of the genus *Homo* that led to modern humans (Figure H12). There is some uncertainty, however, concerning the age of the earliest *Homo*. The genus may be as old as 2.4 Ma, but it was definitely present by 1.9 Ma, when the lineage had radiated to produce three species: *H. habilis*, *H. rudolfensis* and *H. erectus* (Wood, 1992). The genus *Homo* overlapped in both space and in time with the robust australopithecines, but eventually became the single survivor. Anatomically modern humans, *Homo sapiens*, are recognized from about 200,000 years ago.

Evolution of hominin traits

There are two key physical traits that can be tracked in the hominin fossil record: (a) bipedal locomotion (which appeared early on and characterizes all hominins), and (b) an increase in brain capacity relative to body size (associated with genus *Homo*). Average cranial capacity ranges from ~400 cm³ in australopithecines, ~650 cm³ in early *Homo* to ~1,400 cm³ in modern humans (*Homo sapiens*). The two characteristics were assumed to be linked somehow and early models of human evolution envisioned that hominins would leave the safety of trees, develop bipedalism, and then the increase in brain size would follow. However, the fossil evidence suggests that bipedalism and an increase in brain size were independent. The fossil evidence of one of the oldest hominins, *Orrorin tugenensis* (6 Ma), reveals it was a good tree climber, but it had already adapted to bipedalism when on the ground (Senut et al., 2001). A study of *A. africanus* fossils from South Africa dated between 2 and 3 Ma showed a bipedal creature that had a “primitive” body with a more “advanced” cranial capacity (ranging from 435 to 530 cm³) (McHenry and Berger, 1998). The primitive body consisted of a large chest and long upper limbs with a small pelvic girdle and short lower limbs. These

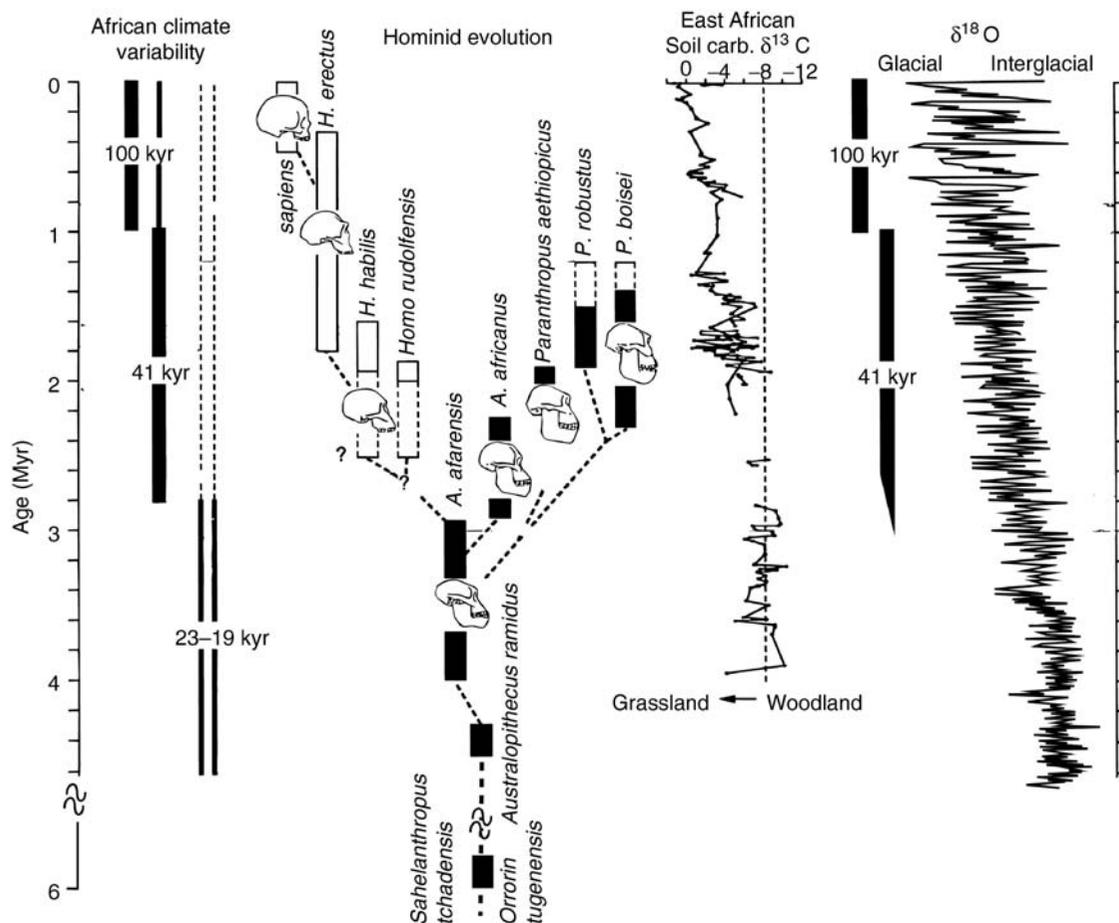

Figure H13 A comparison of the African climate variability represented by the dominance of Milankovitch cycles (*far right*); a graph of human phylogeny (Wood, 1992); vegetation record interpreted from the carbon isotopes in soils (Cerling and Hay, 1988; Cerling, 1992); global temperatures interpreted from oxygen isotopes from the marine record (Shackleton et al., 1990) (modified from deMenocal and Bloemendal, 1995).

characteristics suggest tree climbing was still important to some hominins despite the ability to walk on two legs and the possession of a larger brain.

The development of technology, abstract thought, language, and culture are thought to develop when the brain attains significant cranial capacity. As body size and sex affects cranial capacity, a direct correlation is not appropriate. Primitive stone tool making, the first evidence of technology, dates to 2.5 Ma (Semaw et al., 1997). These tools are assumed to be a product of *Homo*, but there is no direct evidence of this. The human abilities of language and complex cognitive thought leave no record, but it appears that these had evolved in hominins 200,000–300,000 years ago, based on dated archaeological sites containing grindstones, pigments, and stone blades (McBrearty and Brooks, 2000). By 100,000 years ago, there are records of long distance exchange, fish hooks, and mining, and by 50,000 years ago, beads and other art forms are found (McBrearty and Brooks, 2000).

Global climate change

The Earth's climate has varied significantly over its 4.6 billion year history. The climate system, a complex interaction of five components (oceans, land surface, ice, atmosphere, and vegetation) is forced by the tectonics, variations in strength of the Sun, and astronomic forcing, i.e., changes in the Earth's orbit (Ruddiman, 2001). The most continuous and complete record of climate change since the evolution of primates (<65 million years ago) occurs in marine sediments. Microfossils and minerals collected in long sediment cores from ocean basins around the world are analyzed for variations. Oxygen isotopes in foraminifers and diatoms (tiny marine organisms) and dust blown from continental deserts are used as proxies for climate change over time. The isotope variability reflects global temperature (ice volume) changes, whereas the dust signifies moisture changes (Hays et al., 1976; deMenocal, 1995). More fragmentary continental records that occur in lakes or in soils are used to provide additional climate information. For example, carbon isotopes in soil carbonates serve as a proxy for vegetation change and have been used to determine the proportion of forests, open woodland and savannah (Cerling, 1984; Cerling et al., 1993).

Both the marine and terrestrial records during the Cenozoic era (last 65 million years) point to general cooling and drying that ultimately led to the ice ages of the Pleistocene epoch (Figure H12). There were times of particularly abrupt cooling (14 and 2.8 Ma) that brought on increases in global ice volumes. At 14 Ma, the Antarctic glaciers increased in size and became permanent; 2.8 Ma marks the onset of Northern Hemisphere continental-scale glaciation. The general cooling of the Earth has been linked to plate tectonics that led to massive uplifts (i.e., mountain building in the Tibetan Plateau and western North America) and later (10–4 million years) the closing of the Isthmus of Panama, which changed oceanic circulation (Stanley, 1995; Ruddiman, 2001).

Although the long-term trend has been toward a cooler and drier climate, the record clearly shows oscillations on a variety of time scales and more importantly an increase in the magnitude of these climate swings, particularly in recent times (Figure H12). Many have been related to long-term variations in solar radiation caused by the relative position of the Earth with respect to the Sun (Milankovitch cycles), as well as short-term variations (solar radiance). Milankovitch cycles

include 100 ka cycles, which are due to eccentricity of the Earth's orbit; ~41 ka cycles, reflecting the tilt of the Earth (obliquity); and ~21 ka cycles, related to the precession of the equinoxes. The ice ages that dominated the Northern Hemisphere in the Pleistocene are related to both the 100 and 41 kyr Milankovitch cycles (Ruddiman, 2001).

Climate during the last 6 million years, when hominins evolved into modern humans, has been characterized by high variability. 6 million years ago, it was cooler and drier, but with more seasonal continental conditions and the periodic enhancement of the Indian monsoon system (Ruddiman, 2001). Monsoon strength is directly related to the 21 ka precession cycle that changes amount of solar radiation reaching the Earth. Lake levels rose and fell to the rhythm of this shortest Milankovitch cycle and wet-dry cycles dominated the tropics where human evolution took place. This climate variability would have had a significant impact on hominins and is likely to have been a key factor in human evolutionary response.

Evolution and climate

It is tempting to begin to make correlations between the dramatic evolutionary changes of hominins from tree dweller to modern humans capable of space travel and the climatically turbulent environment of Africa in which much of this evolution took place. Speciation events are commonly attributed to climate change, because without the catalyst of environmental change, most species and ecosystems would remain in equilibrium and unchanged (Vrba et al., 1995; Poirier and McKee, 1999). Linking a specific climate circumstance to a specific evolutionary change is problematic. Some question whether global climate signatures are felt at the environmental level important to human survival (Behresmeyer, 1982). Despite the fact that the hominin fossil record is meager and widely dispersed and the paleoclimate record, particularly on land, is scanty, there are some generalizations that can be made.

During the last 5–7 million years, general cooling and drying in Africa caused a decrease in forest and an increase in open woodland and savannah grasslands. Coincidentally, this is the time that hominins began to develop bipedal locomotion, although early fossil evidence indicates they retained their tree climbing skills for a considerable time. Approximately 2.5 million years ago, the World's climate system experienced increasing variability, continental glaciers developed in the Northern Hemisphere, and the tropics became drier (Figure H12). Coincidentally, the first appearance of the genus *Homo* occurred at about this time along with the first appearance of hominin "technology," i.e., stone tools. The discovery of primitive tools and hominins (*Homo*) in the Republic of Georgia at 1.75 Ma may record the migration out of Africa to seek a more stable environment (Gabunia et al., 2000). There are now indications that other animals in Africa showed an evolutionary response to the changing environment. In a study of grazing and browsing fauna in northern Kenya and Ethiopia, Behresmeyer et al. (1997) found that the cooling and drying climate gradually nudged the population toward more grassland-adapted species.

How does climate change trigger evolution? Climate may act more like a filter. Potts (1996a, b) proposed an ecological model termed "variability selection" to explain patterns of hominin evolution. He suggests that dramatic climate shifts favor animals that can readily adapt to new environments. He points out the

trend toward survival of the generalist, rather than the specialist. Those lineages capable of living in varied environments and adapting to change succeed. Whereas, those more specialized go extinct when they fail to adapt to new conditions. Humans have survived droughts and ice ages and live in every possible ecological niche from high altitudes (~4,500 m) to sea level and from arctic sea ice to tropical jungles.

Conclusions

Specific climatic events cannot be linked directly to a specific evolutionary response in the family Hominidae. However, there is a broad coincidence between aridification of Africa (and the associated expansion of open woodlands and grasslands) over the last 7 Ma and the development of bipedalism. Increasing climate variability at about 2.5 Ma is associated with the first record of genus *Homo*, the first appearance of stone tools (evidence of technological capabilities), the increase in cranial capacity, and eventually the migration of hominins out of Africa. The development of complex cognitive processes, language, art, etc. cannot be tied directly to climate, but may fall into the “variability selection” theory where dramatic climatic shifts favor animals that are truly generalists and can adapt to a wide range of environmental conditions (Potts, 1996a).

HYPsITHERMAL

Hypsithermal is derived from the Greek root *hypsos*, meaning “high.” In geology, the A.G.I. *Glossary* states that hypsithermal is “a term proposed by Deevey and Flint (1957) as a substitute for *climate optimum* and *thermal maximum*” (see also Charlesworth, 1957; Schwarzbach, 1963; Nilsson, 1983), in reference to a warm period during the early to middle Holocene.

The original concept of a postglacial “climatic optimum” first emerged in the nineteenth century among paleobotanists in northern Europe from evidence of hazel nuts and leaves discovered at anomalously high latitudes and later from pollen analyses (mostly in core samples). Three pollen zones were recognized as discrete subdivisions of this climatic optimum, following the original nineteenth century pollen-based plan of Blytt and Sernander (see Sernander, 1908): boreal (V, VI), Atlantic (VII) and subboreal (VIII) (now classified internationally as “biozones”).

The proof of an exceptionally warm phase in the early to middle Holocene is attributable to L. von Post, the Swedish “father” of modern pollen analysis. In 1946, he recognized three post-glacial climatic phases, stage II being warmer than present. Antevs (1953) named them *anathermal* (“warming”), *althethermal* (“high thermal”), and *medithermal* (“moderating”). However, the last two are linguistic hybrids and should be replaced respectively by *hypsithermal* and *katathermal* (Nilsson, 1983). Synonymous terms are *althethermal* (now obsolete), *megathermal* (likewise, see Judson, 1953, p. 59) and *xerothermal* (specifically hot, dry climates of the postglacial interval). None of the above is mentioned in the newest edition of *The Holocene* (Roberts, 1998). These terms have mostly been limited to North American authors and have now largely fallen into disuse.

A distinct climatic negative swing in the mid-hypsithermal at about 3850 BC (5,000 ¹⁴C yBP) was first recognized by Tage Nilsson in 1935 and attributed by many writers to the recent immigration of human settlers with associated forest clearing. However, the same negative swing has subsequently been established worldwide (e.g., the Rotmoos Neoglacial in the Alps), even in uninhabited areas, as well as in a negative swing of eustatic sea level (the “Bahama Low”). Thus, its natural (non-anthropogenic) forcing is now accepted (Nilsson, 1983). It marks the AT-2/SB-1 biozone boundary. This negative swing was marked by a dramatic fall in the elm pollen, the so-called “*ulmus decline*,” although after a few centuries it recovered somewhat and the Greenland ice cores show some warming

trends. Significantly, the negative “spike” is seen also in the solar modulated (¹⁴C flux record of tree rings Stuiver’s “S” type), and must therefore be forced by a major fluctuation in the Sun’s radiation (Stuiver and Braziunas, 1989).

The chronology of these intervals is confused by the difference between “absolute” ages (now based on varves, tree rings and ice cores) and the radiocarbon ages (which require calibration). The hypsithermal interval is traditionally given as 9,000–2,500 BP (by radiocarbon, from AD 1950), i.e., boreal to subboreal biozones. However, the oxygen-isotopic temperature records of the Greenland ice cores suggest a much younger limit. In Dansgaard et al. (1971), the “climatic optimum” lasts from only about 8,300–4,800 BP, thus a span of 3,500 sidereal years. It is therefore practically limited to the Atlantic biozone (AT-1 and AT-2).

Besides the pollen evidence, there are also clear traces of the “tree line” (the northern limit of tree growth at the edge of the treeless tundra, or in mountains at a critical elevation; Markgraf, 1974). A very stylized approximation of this boundary was presented by Firbas (1949), who also showed that it did not coincide with the effective radiation curve for these latitudes of Milankovitch. This roughly 10,000 yr lag or “retardation” factor is also observed in worldwide eustatic sea-level curves (Fairbridge, 1961, 1983; Lowe and Walker, 1997). Unfortunately, all regional sea-level curves are different because of isostatic and tectonic variables. Probably the nearest approach to a “standard” curve is that of Ters (1987) or Fairbanks (1989). The explanation of retardation lies both in the onset of ice-age glaciation and in its general retreat. Atmospheric cooling precedes the glacial advance (and sea-level fall), just as warming precedes post-glacial melting, although both are associated with secondary climatic fluctuations (notably the Allerød-Younger Dryas oscillation).

Climatic fluctuations within the hypsithermal interval became recognized rather widely in all parts of the world after the 1950s, following the development of radiocarbon dating. The incidents of neoglacial advance were seen first in the Alps (e.g., by Patzelt, 1974), and then extended progressively worldwide (Denton and Porter, 1970; Denton and Karlén, 1973; Röthlisberger, 1986). In her comprehensive volume on the Little Ice Age, Jean Grove (1988) drew attention to preceding Holocene cycles of climatic cooling during the alleged hypsithermal, marked in the Alps by the Venediger, Frossnitz (or Larstig), Rotmoos, Löbber and Goschener advances. In the more recent Scandinavian papers, even more frequent oscillations are documented (Karlén et al., 1995).

In North America, the Alaskan glaciers have also been found to fluctuate more or less synchronously with the European ones. In the semiarid Southwest, there were major lake-level fluctuations, but their interpretation has been complicated by seasonality contrasts, notably the incidence of winter rains during cold cycles, as opposed to summer, monsoonal rains during warm cycles.

Globally, the fluctuations of the hypsithermal are registered most dramatically by proxies other than neoglacial and their associated melt-water lakes. The best dated and most homogeneous of these are the ¹⁴C flux measurements from tree rings (Stuiver and Braziunas, 1989). When standardized and reduced to 10–20 years means, the results disclose an alternation of major intervals of more than 100 years duration. Each positive departure is matched by a negative one of equal dimensions. These are interpreted as being due to fluctuations in solar radiation, and thus affect terrestrial climates (Fairbridge and Sanders, 1987; Charvátová and Štěpánek, 1991; Windelius and

Carlborg, 1995). During the 10,500 year history of the Holocene, there have been approximately 20 of these major perturbations.

The amplitudes and lengths of these solar perturbations display a variance that decreases over the second half of the hypsithermal interval. This decrease is apparent in the glacier fluctuations, as well as in sea level, in fluvial discharge (reflecting flood/drought alternations), and in other proxies. This systematic behavior is mainly registered in the Northern Hemisphere proxies and may therefore reflect the gradual decrease in ecliptic angle that accompanies the Earth/Moon precession cycle, a major climatic forcing of the Milankovitch parameters. It is now approaching a minimum contrast between Northern and Southern Hemispheres.

To summarize, the “hypsithermal” is a semi-formal interval, defined climatically, in Holocene history, originally taken as between roughly 9,000–2,500 yBP (radiocarbon years), but now restricted to about 8,300–5,000 sidereal yBP. It corresponds to the “Atlantic” biozone, and appears to be related to the Northern Hemisphere phase of the Milankovitch precession when high continentality led to warmer summers and colder winters.

ICE CORES, ANTARCTICA AND GREENLAND

Introduction

Polar ice results from the progressive densification of snow deposited at the surface of the ice sheet. The transformation of snow into ice generally occurs within the first 100 meters and takes from decades to millennia, depending on temperature and accumulation rate, to be completed. During the first stage of densification, recrystallization of the snow grains occurs until the closest dense packing stage is reached at relative densities of about 0.55–0.6, corresponding to the snow-firn transition. Then plastic deformation becomes the dominant process and the pores progressively become isolated from the surface atmosphere. The end product of this huge natural sintering experiment is ice, an airtight material. Because of the extreme climatic conditions, the polar ice is generally kept at negative temperatures well below the freezing point, a marked difference to the ice of temperate mountain glaciers.

Ice cores are cylinders of ice with a diameter of ~10 cm. They are obtained by drilling through glaciers or ice sheets. This entry deals with ice cores recovered in the two ice sheets existing today at the surface of the Earth: in Antarctica and Greenland. Ice cores from mountain glaciers are handled in another section (see *Ice cores, mountain glaciers*). Ice cores range from shallow (from the surface to 100 m), to intermediate (down to about 1,000 m) and deep (>1,000 m), and are recovered using specific technologies, including thermal and electro-mechanical drilling systems. The main purposes of recovering ice cores in Antarctica or Greenland are to describe the past changes in atmospheric composition and climate of our planet, understand the past behavior of the ice sheets and the mechanisms controlling ice flow, and ultimately contribute to an improved understanding of the Earth system.

The main Antarctic and Greenland ice cores

Apart from several shallow drilling sites in the most coastal area and a few drillings through the ice shelves, a total of 14 drill cores have reached bedrock or a depth close to bedrock

in Antarctica and Greenland. Therefore, the current number of drill sites is still fairly limited in relation to the large dimensions of these ice sheets. [Table II](#) provides information on the ten deepest drilling operations; [Figures I1](#) and [I2](#) show their location in Antarctica and Greenland.

Two pioneering long ice cores, the Camp Century (Greenland) (Hansen and Langway Jr., 1966; Dansgaard et al., 1971) and the Byrd (West Antarctica) (Gow et al., 1968; Epstein et al., 1970) cores, drilled in the 1960s, provided the first continuous and already detailed record back to the last deglaciation and the last ice age.

Three deep Antarctic ice cores record several glacial-interglacial cycles: Vostok (4 cycles, back to 420 kyBP; Petit et al., 1999), Dome Fuji (DF) (3 cycles, 330 kyBP; Watanabe et al., 2003) and EPICA Dome C (EDC) (8 cycles, 740 kyBP; EPICA Community Members, 2004, [Figure I3](#)).

The Vostok drill site holds the world's record in terms of depth, as of 2007. The EDC core, although shorter by a few hundred meters, provides the longest record, approximately twice as old as the Vostok record. New measurements are performed to extend the EDC record back to 800,000 yBP. Furthermore, a new deep drilling at DF, completed in 2006, lies close to bedrock. It should provide the second longest record, covering ~700,000 years.

Three long Greenland ice cores, GRIP, GISP2 and NGRIP cover the last 100,000 years; i.e., most of the last glacial-interglacial cycle, but only the NGRIP core provides an undisturbed record back to the latest part of the penultimate interglacial (also called Eemian) (North Greenland Ice Core Project Members, 2004). A new drilling operation (called NEEM) is planned in Greenland to recover an ice core able to provide a complete record of the Eemian. In addition, a number of intermediate-type cores recovered from both ice sheets sample the Holocene (our current interglacial) and part of the last glacial period with good resolution.

Establishing an ice core chronology

Establishing the chronology of Antarctic and Greenland ice cores is essential for interpreting ice core records. The age of the ice corresponds to the time the snow is deposited at

Table 11 Major ice cores: sites, depth, length of record. Please, note that in most cases, we use the first publication that provides the basic information, rather than the most recent or most relevant ones

Site	Ice sheet	Year of recovery	Depth (m)	Temporal length of the record
Camp Century (Dansgaard et al., 1971)	Greenland	1966	1,387.4	Back to the last ice age
Byrd (Epstein et al., 1970; Gow et al., 1968)	West Antarctica	1968	2,164	Back to the last ice age
Dye 3 (Dansgaard et al., 1985)	Greenland	1981	2,037	Back to the last ice age
GRIP (GREENLAND-SUMMIT-ICE-CORES, 1997)	Greenland	1992	3,029	~105 ka
GISP 2 (GREENLAND-SUMMIT-ICE-CORES, 1997)	Greenland	1993	3,053	~105 ka
Vostok (Petit et al., 1999)	East Antarctica	1998	3,623	~420 ka
North GRIP (NORTH-GREENLAND-ICE-CORE-PROJECT-MEMBERS, 2004)	Greenland	2003	3,085	~120 ka
EPICA DC (EPICA-COMMUNITY-MEMBERS, 2004)	East Antarctica	2004	3,270	~800 ka
EPICA DML (EPICA-COMMUNITY-MEMBERS, 2006)	East Antarctica	2006	2,774	More than one glacial-interglacial cycle
Dome Fuji	East Antarctica	2006	3,029	The age at the bottom is estimated to be ~700 ka

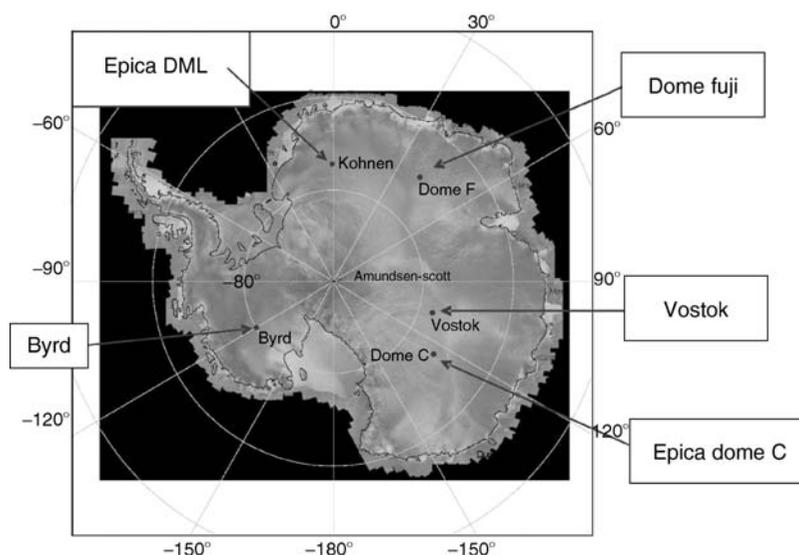

Figure 11 Index map showing the locations of ice cores from Antarctica that are listed in Table 11.

the surface of the ice sheet and its chronology can be established using different tools including layer counting, synchronization to the Earth orbital variations (orbital tuning approach), synchronization to other well dated archives, and glaciological modeling. On the other hand, during snow densification, interstitial air can exchange with the atmosphere at the surface through the firm porosity until it is trapped in the form of bubbles. Therefore, in any ice core, contemporaneous gas and ice signals are not recorded at the same depth and air occluded in air bubbles is younger than its surrounding ice.

Note that methods based on radioactive decay are not of use to date polar ice directly. In particular, ^{14}C dating of the CO_2 trapped in air bubbles is possible but limited in accuracy because of in situ production in the firm.

Counting preserved annual layers through the seasonal variations of different properties, like ice isotopic composition, aerosol chemical composition or dust content, works in sites with high accumulation rates and is especially appropriate for Greenland ice cores. For instance, the method has been used on the DYE-3, GRIP, GISP2 and NGRIP cores, and can be

especially accurate for Holocene ice (maximum counting error estimated to be up to 2%; Rasmussen et al., 2006). This layer counting method is, however, not applicable for low accumulation sites such as those of the East Antarctic Plateau. Orbital variations of the Earth impact the solar radiation received at the top of the atmosphere (generally called insolation), and in turn the Earth's climate. The orbital tuning approach consists of tuning ice core climatic records to those changes in insolation that can be accurately calculated for the past millions of years (Berger, 1978; Laskar et al., 2004). This approach has been used in the case of the long, 420-kyr Vostok record. Unfortunately, the phasing between insolation and the climatic response is generally poorly constrained and not likely to be constant due to the non-linearity of the climatic system, which is a major limitation of the orbital tuning approach. As a consequence, the chronological uncertainty of the orbital tuning approaches is about 5 kyr. Nevertheless, it has been recently suggested that ice core properties recording local insolation directly may overcome this limitation (Bender, 2002; Raynaud et al., 2007).

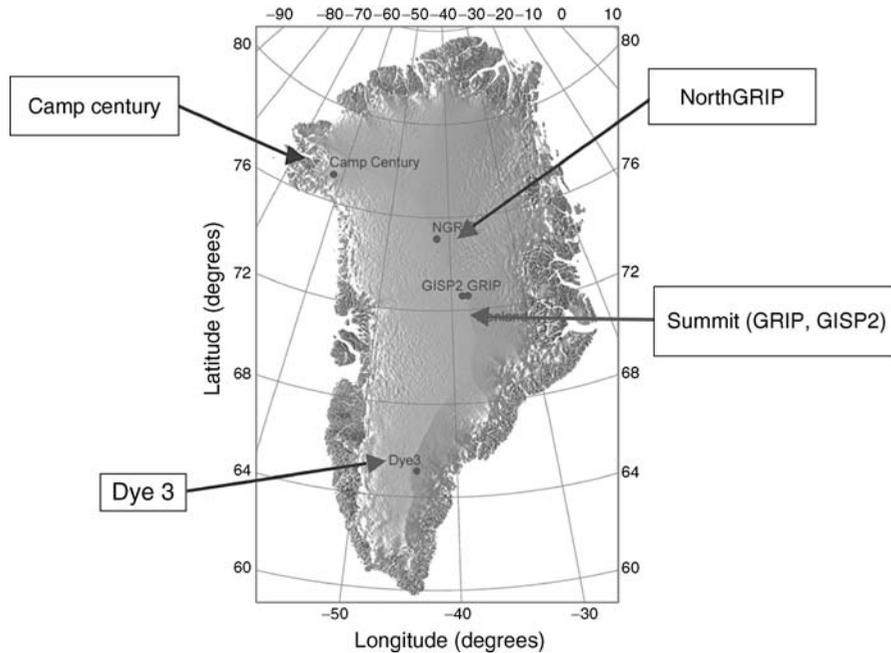

Figure 12 Index map showing the locations of ice cores from Greenland that are listed in Table 11.

Figure 13 Ice core protruding from the drill head from EPICA Dome C, Antarctica (photo courtesy of Eric Lefèvre, LGGE, Grenoble).

Ice cores can also be dated by synchronization with other well-dated archives. For example, back to the last glacial period, ice cores from Antarctica can be synchronized with the Greenland ice cores using the CH_4 records or the Be-10 records (Yiou et al., 1997; Blunier and Brook, 2001). A second example is the identification of well-dated volcanic eruptions in the ice cores.

In order to provide a method independent of the orbital tuning approach, glaciologists have proposed to date ice cores continuously using snow accumulation and ice flow models for calculating the annual layer thickness at each depth. In this case the main limitations include the uncertainties in our

knowledge of past accumulation changes, basal conditions (melting, sliding) and rheological conditions.

Finally, it has been recently proposed to use an inverse method, which associates the information of the different dating methods available on one core to obtain an optimal chronology. This inverse method has been applied on the Vostok (Parrenin et al., 2001; Parrenin et al., 2004), Dome Fuji (Watanabe et al., 2003) and EPICA Dome C (EPICA Community Members, 2004) cores. In the future, such an inverse method could be applied to several drilling sites simultaneously, obtaining a common and optimal chronology for those drilling sites.

The difference between the ages of gas bubbles and the surrounding ice can be computed with a firm model (see Goujon et al., 2003 and references therein). Under present-day conditions, this difference is on the order of a few centuries for high accumulation/high temperature sites and of several thousands of years in sites of the high Antarctic Plateau with low accumulation and temperature conditions (e.g., $\sim 3,000$ years at Vostok). Under glacial conditions it increases significantly due to colder climate, which is paralleled by lower accumulation rates, but the accuracy of the calculation under past conditions is limited due to uncertainty in past accumulation rates and temperatures.

Antarctic and Greenland ice core: an archive of the atmospheric composition and climate

The Antarctic and Greenland ice cores contain a wide spectrum of information on past changes in the environmental conditions of the Earth. Examples are given in Table 12.

Polar ice cores record both variations in climate and in atmospheric composition. They essentially provide a pure record of solid precipitation, atmospheric gases, dust and aerosols and are, in fact, a unique archive of past changes of our atmosphere. For their part, deep oceanic and continental sediments are recording oceanic, vegetation or soil changes.

Table 12 Climatic or environmental parameters and corresponding properties measured in ice. Note the diversity of the information contained in ice cores, which deals with the atmosphere, the cryosphere, the oceans and the continents

Climatic and environmental parameter	Ice properties
Temperature change at the surface of the ice sheet	Isotopic composition of the ice ($^{18}\text{O}/^{16}\text{O}$, D/H); Isotopic composition of the air trapped in ice (^{15}N , ^{40}Ar)
Variations of atmospheric greenhouse trace gases	Greenhouse trace gas concentrations in the air trapped in ice (CO_2 , CH_4 , N_2O)
Origin of the precipitation	Deuterium excess of ice
Atmospheric transport and circulation; Source (marine, continental, volcanic, anthropogenic) of dust and aerosols	Dust and aerosols in ice
Changes in continental ice volume and sea level; Changes in hydrological cycle and biological activity	Isotopic composition ($^{18}\text{O}/^{16}\text{O}$) of the atmospheric oxygen trapped in ice
Local insolation changes due to orbital cycles	O_2/N_2 of air trapped in ice; Air content of ice
Changes in surface elevation of the ice sheet	Air content of ice; Isotopic composition of ice
Changes in ice flow	Physical properties of ice
Solar activity and Earth's magnetic field intensity	Beryllium-10 (^{10}Be)

Continuous changes in temperature at the surface of the ice sheet are revealed by measuring the isotopic composition of the ice (deuterium or oxygen-18), and more sporadic abrupt temperature changes are accurately recorded by the isotopic composition of N_2 and Ar found in the air trapped in ice.

Polar ice cores also provide the most reliable paleo-archive of air composition, by directly recording atmospheric composition in the form of air bubbles when the firm becomes ice. They allow the reconstruction of the past evolution of important greenhouse gases (see section on carbon dioxide and methane, Quaternary variations). Thus, the Vostok and the new EPICA DC record produce clear evidence of the strong correlation between greenhouse gases (CO_2 and CH_4) and climate over glacial-interglacial cycles (EPICA Community Members, 2006; see also *Carbon dioxide and methane, Quaternary variations*).

Dust and aerosols found in Antarctic or Greenland ice cores have been collected at the surface of the ice sheets by dry or wet deposition. The ice record of their concentration and size distribution provides information about past extent of marine and continental sources as well as variations in atmospheric transport. Since marine sources can be influenced by the extent of sea ice, it may also be able to reconstruct past changes in sea ice. Ice cores also provide a precious volcanic record in the same way.

Apart from these natural variations in gases, dust and aerosols, ice cores record the impact of human activities, especially on greenhouse trace gases and sulfate compounds. They also document paleometallurgy activities from as early as Greek and Roman times and, during the last few decades, radioactive fallout and added lead in gasoline.

The ice core record also contains information about past changes of the ice sheets. The air content of polar ice depends on the atmospheric pressure when bubbles close-off, and thus gives information about past surface elevation. Physical properties of ice such as grain size and orientation are indicators of past ice flow in the vicinity of the drilling site.

Conclusion

Polar ice cores provide a wide range of information on the Earth system, some of which have a real impact on societal and educational issues. Because they play a central role in global change research, the international ice coring community is planning new projects in both Antarctica and Greenland under the International

Partnerships in Ice Core Sciences (IPICS) initiative (Brook and Wolff, 2006). IPICS aims to extend the ice core record in time and enhance spatial resolution. Concerning deep ice coring, one of the projects is to search for a 1.5 million year record of climate and greenhouse gases in Antarctica, during a time period when Earth's climate shifted from $\sim 40,000$ year to $\sim 100,000$ year cycles. In northwest Greenland, a deep ice core is planned to recover a complete record of the Eemian for the first time.

ICE CORES, MOUNTAIN GLACIERS

Introduction

With the help of recent innovations in light-weight drilling technology, ice core paleoclimatic research has been expanded from the polar regions to ice fields in many of the world's mountain ranges and on some of the world's highest mountains. Over the last few decades, much effort has been focused on the retrieval of cores from sub-polar regions such as western Canada and eastern Alaska, the mid-latitudes such as the Rocky Mountains and the Alps, and tropical mountains in Africa, South America, and China. Unlike polar ice cores, climate records from lower-latitude alpine glaciers and ice caps present information necessary to study processes where human activities are concentrated, especially in the tropics and subtropics where 70% of the world's population lives. During the last 100 years, there has been an unprecedented acceleration

in global and regional-scale climatic and environmental changes affecting humanity. The following is an overview of alpine glacier archives of past changes on millennial to decadal time scales. Also included is a review of the recent, global-scale retreat of these alpine glaciers under present climate conditions, and a discussion of the significance of this retreat with respect to the longer-term perspective, which can only be provided by the ice core paleoclimate records.

Locations of mountain ice core retrieval

The sites from which many of the high-altitude ice cores have been retrieved are shown in [Table I3](#). Among the earliest efforts to retrieve climate records from mountain glaciers were programs involving surface sampling on the Quelccaya Ice Cap (13°56' S, 70°50' W; 5,670 m a.s.l.) in southern Peru (1974–1979). The results from this preliminary research, conducted by the Institute of Polar Studies (now the Byrd Polar Research Center) at The Ohio State University, paved the way for the first high-altitude tropical deep-drilling program on Quelccaya in 1983, which yielded a 1,500-year climate record. Meanwhile, in western Canada, a 103-m ice core was drilled on Mt. Logan (60°35' N, 140°35' W; 5,340 m a.s.l.) by Canada's National Hydrology Research Laboratory. The record from this core extends back to 1736 AD. Recently, the ice caps on both these mountains have been redrilled, Mt. Logan in 2002 and Quelccaya in 2003. During the intervening decades, mountain ice core research has expanded significantly throughout the world, with programs successfully completed on the Tibetan Plateau and the Himalayas, the Cordillera Blanca of Northern Peru, Bolivia, East Africa, the Swiss and Italian Alps, Alaska, and the Northwest United States ([Table I3](#)).

Climatic and environmental information from mountain ice cores

The records contained within the Earth's alpine ice caps and glaciers provide a wealth of data that contribute to a spectrum of critical scientific questions. These range from the reconstruction of high-resolution climate histories to help explore the oscillatory nature of the climate system, to the timing, duration, and severity of abrupt climate events, and the relative magnitude of twentieth century global climate change and its impact on the cryosphere. Much of the variety of measurements made on polar ice cores, and the resulting information, is also relevant to cores from mountain glaciers. Researchers can utilize an ever-expanding ice core database of multiple proxy information (i.e., stable isotopes, insoluble dust, major and minor ion chemistry, precipitation reconstruction) that spans the globe in spatial coverage and is of the highest possible temporal resolution. The parameters that can be measured in an ice core are numerous and can yield information on regional histories of variations in temperature, precipitation, moisture source, aridity, vegetation changes, volcanic activity and anthropogenic input ([Figure I4](#)). Many of these physical and chemical constituents produce wet and dry/cold and warm seasonal signals in the ice, which allow the years to be counted back similar to the counting of tree rings.

Isotopic ratios of oxygen and hydrogen ($\delta^{18}\text{O}$ and δD , respectively) are among the most widespread and important of the measurements made on ice cores. Early work on polar ice cores on these "stable" (i.e., as opposed to unstable, or radioactive) isotopes indicated that they provide information on the precipitation temperature (Dansgaard, 1961), based on

Table 13 A sampling of mountain glaciers sites from which ice cores have been retrieved since 1980. This is by no means a complete inventory of all alpine ice cores ever collected

Mountain	Location	Elevation (m a.s.l.)	Year drilled	Leading organization	Length of core (m)	Length of record (yr)

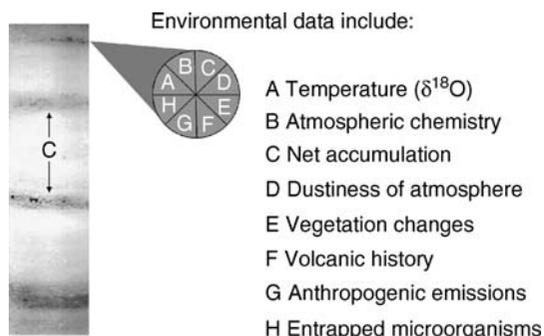

Figure 14 A large variety of environmental information can be obtained from high-altitude ice cores. On the left is an image of a core from a typical mountain glacier in Tibet. The dust bands were deposited during the dry seasons, and the space between them is cleaner ice from snow deposited during the wet seasons.

the fractionation of the oxygen and hydrogen atoms into their light and heavy isotopes (^{16}O and ^{18}O , ^1H and ^2H or deuterium (D)), and on the higher vapor pressure of H_2^{16}O over HD^{16}O and H_2^{18}O . The resulting ratios of the light and heavy isotopes

of these elements act as recorders of temperature both at the moisture source and at the deposition site.

The use of $\delta^{18}\text{O}$ and δD as temperature proxies for polar ice is now widely accepted; however, it is still a source of controversy for lower-latitude cores. Some who have studied the problem suggest that $\delta^{18}\text{O}$, rather than being a temperature recorder at lower latitudes, is a function of precipitation amount (Rozanski et al., 1993; Dahe et al., 2000; Shichang et al., 2000; Baker et al., 2001; Tian et al., 2001). However, real-time comparisons of air temperature and $\delta^{18}\text{O}$ measured on precipitation on the Northern Tibetan Plateau reveal a very close relationship between the two (Yao et al., 1996). Correlations between ice core records from the Himalayas and the Northern Hemisphere temperature records show that on longer time scales (longer than annual) the dominant factor controlling mean $\delta^{18}\text{O}$ values in snowfall must be temperature rather than precipitation (Thompson et al., 2000; Davis and Thompson, 2003). On seasonal to annual time scales, both temperature and precipitation influence the local $\delta^{18}\text{O}$ signal (Vuille et al., 2003).

The annual precipitation rate on an ice cap, or net balance, can be reconstructed by measuring the length of ice between seasonal variations in one or more parameters (e.g., $\delta^{18}\text{O}$ indicating warm or cold seasons or high aerosol concentrations characterizing dry seasons, Figure 14) Since ice is viscous, it

tends to flow not only horizontally but also vertically, resulting in annual layer thinning with depth. In order to correct for this deformation and reconstruct the original thickness of an annual layer at the time of its deposition in the past, vertical strain models are used that take into account the changing densities with depth, the thickness of the glacier, and the rate of thinning (Bolzan, 1985; Reeh, 1988; Meese et al., 1994).

Aerosols in the atmosphere are either deposited on mountain ice fields and glaciers as nuclei of snow (wet deposition) or carried by turbulent air currents to high altitudes (dry deposition). Either way, these insoluble mineral dust particles and soluble salts, such as chlorides, record variations in environmental conditions such as regional aridity. The concentration and size distribution of insoluble dust particles are also helpful for qualitative reconstructions of wind strength. Evidence of volcanic eruptions in the ice is provided by sulfate concentrations and/or the presence of microscopic tephra particles. If these volcanic layers are identifiable (e.g., the 1815 eruption of Tambora or the 1883 eruption of Krakatoa), they can serve as valuable reference horizons to calibrate the time scale. Biological aerosols, such as pollen grains (Liu et al., 1998) and nitrates that may have been injected into the atmosphere by vegetation upwind of a glacier (Thompson et al., 1995; Thompson, 2000), have been useful for reconstructing past climate and environmental changes that have had impacts on regional flora.

The record of human activity is also available from ice cores, although this type of research on high-altitude glaciers lags behind polar ice sheets. Research on heavy metal types and concentrations in high-altitude glaciers is relatively new, but what is available from Mont Blanc in the French-Italian Alps provides information about increasing industrial production and other activities associated with expanding populations and urbanization (Van DeVelde et al., 1999). Measurements of carbon dioxide and methane, as well as lesser gases, trapped in ice bubbles are not as extensive on ice from mountain glaciers as they are from polar cores; however, the research that has been done shows correlations of so-called "greenhouse" gas concentrations with the temperature proxy $\delta^{18}\text{O}$ (Yao et al., 2002a, b). The information from these ice core studies complements other proxy records that compose the Earth's climate history, which is the ultimate yardstick by which the significance of present and projected anthropogenic effects will be assessed.

The significance of climate records from mountain glaciers

Ice core records from high-altitude glaciers, when combined with high-resolution proxy histories such as those from tree rings, lacustrine and marine cores, corals, etc., provide an unprecedented view of the Earth's climatic history that can extend over several centuries or millennia. The longest of them have revealed the nature of climate variability since the Last Glacial Maximum (LGM), 18–20 thousand years ago, and even beyond. The more recent parts of the climate records, which are of annual and even seasonal resolution, can yield high-resolution temporal variations in the occurrence and intensity of coupled ocean-atmosphere phenomena such as El Niño and monsoons, which are most strongly expressed in the tropics and subtropics, and are of world-wide significance. This is particularly valuable information since meteorological observations in these regions are scarce and of short duration.

Four records from the Andes (Huascarán in Northern Peru, Coropuna in Southern Peru and Sajama and Illimani in Bolivia) and one from the Western Tibetan Plateau (Guliya) extend to or

past the end of the last glacial stage and confirm, along with other climate proxy records (e.g., Guilderson et al., 1994; Stute et al., 1995), that the LGM was much colder in the tropics and subtropics than previously believed. Although this period was consistently colder, it was not consistently drier through the lower latitudes as it was in the polar regions. For example, the effective moisture along the axis of the Andes Mountains during the end of the last glacial stage was variable, being much drier in the north than in the Altiplano region in the central part of the range (Thompson et al., 1995, 1998; Ramirez et al., 2003). In another example in Western China, the Guliya Ice Cap is partly affected by the variability of the southwest Indian monsoon system, which was much weaker during the last glacial stage than during the Holocene. However, this region of the Tibetan Plateau also receives (and received) moisture generated from the cyclonic activity carried over Eurasia by the prevailing wintertime westerlies. Not only were lake levels in the Western Kunlun Shan higher than tropical lakes during the LGM (Li and Shi, 1992), but the dust concentrations in the Guliya ice core record were consistent with those of the Early Holocene when the summer Asian monsoons became stronger, suggesting that local sources of aerosols were inhibited during this cold period by higher precipitation and soil moisture levels (Davis, 2002).

Ice cores from the Andes can also contribute to what is known about past environmental and climatic conditions of the Amazon Basin. The extent of biological activity in the Amazon rainforest during the LGM is controversial, and the nitrate concentration record from the Huascarán ice core has been included in the argument (Colinvaux et al., 2000). Pollen studies from the Amazon Basin suggest that the extent of the rainforest has not changed much between the glacial maximum and the Holocene. However, proponents of the "refugia" theory (i.e., Clapperton, 1993) assert that the cold, dry climate in the tropics caused a major retreat of the rainforest flora into a small, geographically isolated area, leaving most of the Basin covered by grasslands. In the Huascarán core, the nitrate concentration profile is similar to the $\delta^{18}\text{O}$ levels throughout most of the record, and the very low concentrations of nitrate, which are concurrent with very depleted $\delta^{18}\text{O}$, suggest that biological activity upwind of the Cordillera Blanca was impeded by the cold and dry climate ~19,000 years ago.

Most of the deep cores from the low latitudes extend through at least the Holocene, and show spatial variations in climate, even between records from the same region. For example, the Holocene $\delta^{18}\text{O}$ profiles from Huascarán and Illimani, while similar to each other in that they show Early Holocene isotopic enrichment, are different from that on Sajama, which has a relatively stable isotopic record through the last 10,000 years. Although Sajama and Illimani, both in Bolivia, are geographically close to each other, they are on opposite sides of the Andean Mountains, with Illimani located in the eastern range. Like Huascarán far to the north, it received most of its precipitation from the northeast after it had been recycled through the Amazon Basin. Sajama, which is located on the high, dry Altiplano, is more subject to Pacific influences and local hydrological effects.

Holocene ice core records from mountain glaciers around the world show evidence of major climatic disruptions, such as droughts and abrupt cold events during this period, which previously was believed to have been stable. Major dust events, beginning between 4.2 and 4.5 ka and lasting several hundred years, are observed in the Huascarán and Kilimanjaro ice cores

(Thompson, 2000; Thompson et al., 2002, respectively), and the timing and character of the dust spikes are similar to one seen in a marine core record from the Gulf of Oman (Cullen et al., 2000) and a speleothem $\delta^{13}\text{C}$ record from a cave in Israel (Bar-Matthews et al., 1999). This dry period is also documented in several other proxy climate records throughout Asia and Northern Africa (see contributions in Dalfes et al., 1994). Two other periods of abrupt, intense climate change in east Africa are observed in the Kilimanjaro ice core at ~ 8.3 ka and 5.2 ka (Thompson et al., 2002). The latter event is associated with a sharp decrease in $\delta^{18}\text{O}$, indicative of a dramatic but short-term cooling.

More recently, a historically documented drought in India in the 1790s, which was associated with monsoon failures and a succession of severe El Niños, was recorded in the insoluble and soluble aerosol concentration records in the Dasuopu ice core (Thompson et al., 2000). Another recorded Asian Monsoon failure in the late 1870s (Lamb, 1982) is noticeable in the Dasuopu dust flux record, which is a calculation that incorporates both the dust concentration and the annual net balance. The dust concentration on Dasuopu is also linked to the magnitude of the Southern Oscillation and the phase of the Pacific Decadal Oscillation (Davis, 2002), thus indicating a linkage between these tropical processes. However, recent research on Tibetan Plateau ice cores drilled north of 32°N shows that their climate records are not only influenced by the South Asian Monsoon and other tropical coupled atmospheric-oceanic processes such as the El Niño-Southern Oscillation (ENSO), but also by atmospheric pressure variations such as those seen in the North Atlantic Oscillation (Davis and Thompson, 2003; Wang et al., 2004). Thus, the high resolution isotope, chemistry, dust, and accumulation records from

ice cores retrieved from across the Plateau help us to reconstruct the spatial and temporal variability of the climate in this region.

There is little purpose in trying to reconstruct the history of global climate change from one ice core, especially at high resolution on short time scales. However, as discussed above, it is clear that certain parameters such as $\delta^{18}\text{O}$ do record large-scale regional variability in sea surface temperatures, while others such as aerosols may be more sensitive to local as well as regional conditions. Although the mountain ice core records that extend back through the last millennium show regional differences with each other and with the polar records, many of them also document common climatic variations on hemispheric, and even global, scales. This is illustrated in Figure 15, where composites of the decadal-averaged $\delta^{18}\text{O}$ profiles of three South American cores (Huascarán, Quelccaya, and Sajama) and three Tibetan Plateau cores (Dunde, Guliya and Dasuopu) show different interhemispheric trends (Thompson et al., 2003) (Figures 15a and 15b, respectively). For example, the “Little Ice Age,” a cold event between the fifteenth and nineteenth centuries that is recorded in many Northern European climate records, is more evident in the South American ice core composite than in the Tibetan Plateau. The “Medieval Warming,” a period before the “Little Ice Age,” which appears in the Greenland ice core records, is also obvious in the Andean ice cores. However, both the composites show isotopic enrichment (indicating warming) beginning in the late nineteenth century and accelerating through the twentieth century. When all six of the profiles from these mountain glaciers are combined, the resulting composite (Figure 15c) is similar to the Northern Hemisphere temperature records of Mann et al. (1998) and Jones et al. (1998) covering the last 1,000 years (Figure 15d).

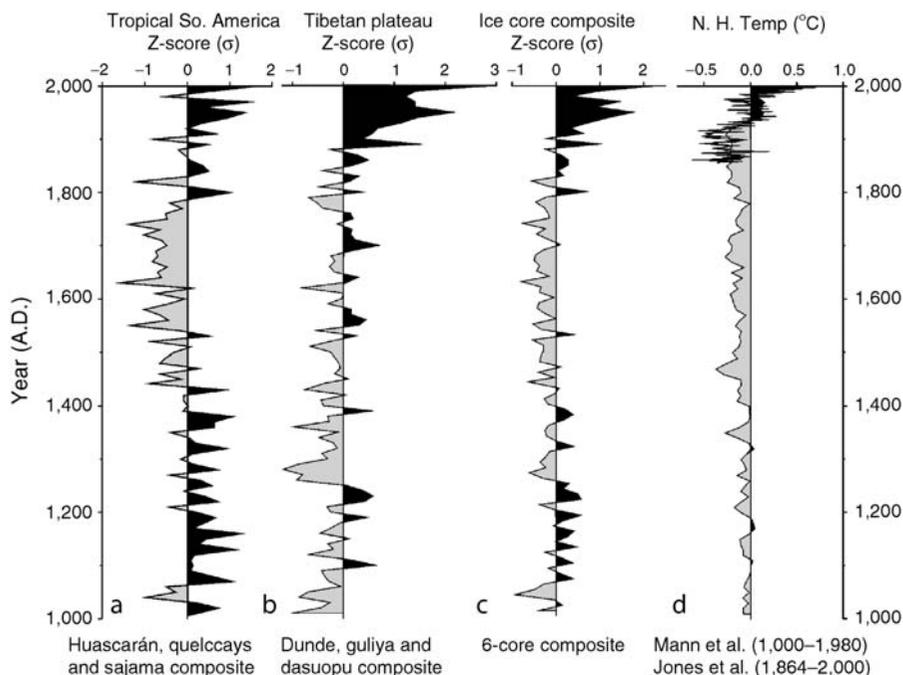

Figure 15 Composite records of decadal averages of $\delta^{18}\text{O}$ from ice cores from (a) the South American Andes (Huascarán, Quelccaya, Sajama) and (b) the Tibetan Plateau (Dunde, Guliya and Dasuopu) from 1000 AD to the present. All six ice-core records are combined (c) to give a total view of variations in $\delta^{18}\text{O}$ over the last millennium in the tropics, which is compared with the Northern Hemisphere reconstructed temperature record (d) (from Thompson et al., 2003).

Not only do these comparisons argue for the important role of temperature in the composition of oxygen isotopic ratios in glacier ice, but they also demonstrate that the abrupt warming from the late nineteenth century through the twentieth century (and continuing into this century) transcends regional variations, unlike earlier climatic variations. Indeed, on a global basis, the twentieth century was the warmest period in the last 1,000 years, which also encompasses the time of the “Medieval Warming.”

The modern climate warming and its effects on mountain glaciers

Meteorological data from around the world suggest that the Earth’s globally averaged temperature has increased 0.6°C since 1950. The El Niño year of 1998 saw the highest globally averaged temperatures on record, while 2002 (a non-El Niño year) was the second warmest, followed by 2003 and 2001 (a la Niña year). The recent warming of the past century, which has been accelerating in the last two decades, is recorded in alpine glaciers in other ways, both within the ice core records and by the rapid retreat of many of the ice fields. This glacier retreat is observed in almost all regions, from the Caucasus and other Eurasian mountain ranges in the mid-latitudes (Mikhaleenko, 1997), to central Europe and western North America (Huggel et al., 2002; Meier et al., 2003), and to the Tibetan Plateau and the tropics (Thompson et al., 1993; Dahe et al., 2000; Thompson et al., 2000). In the Andes, on the Tibetan Plateau and in the East Africa Rift Valley region, this climate change has left its mark. The many ice fields on Kilimanjaro covered an area of 12.1 km^2 in 1912, but today only 2.6 km^2 remains (Figure 16). If the current rate of retreat continues, the perennial ice on this mountain will likely disappear within the next 20 years (Thompson et al., 2002).

Future priorities

Ice cores from mountain glaciers, especially those from the tropical and subtropical latitudes where most of the world’s

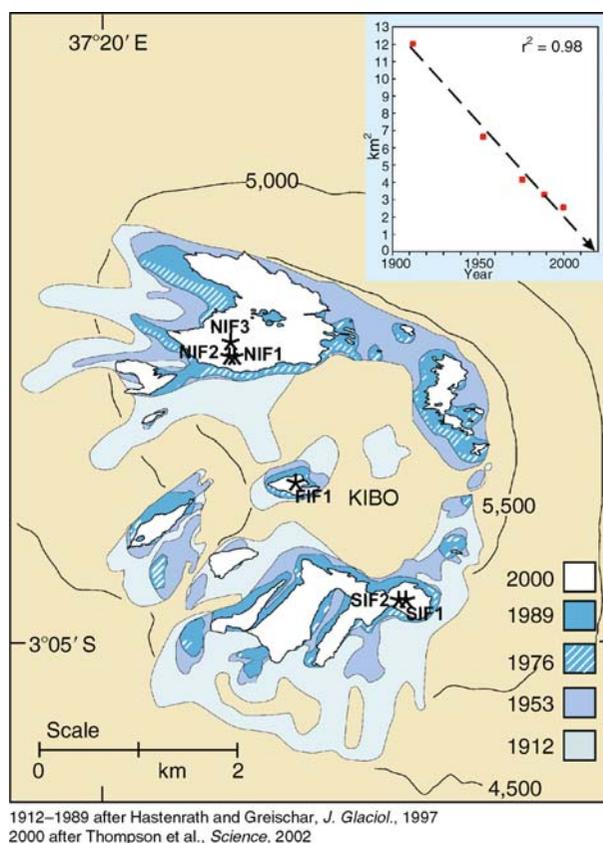

Figure 16 Retreat of ice fields in the Kibo Crater of Kilimanjaro, Tanzania. Shaded areas show “snapshots” of areas of ice cover at five times over the twentieth Century. At the rate of retreat shown here, all the ice on this mountain will disappear within the first half of the twenty first century (insert) (from Thompson et al., 2002).

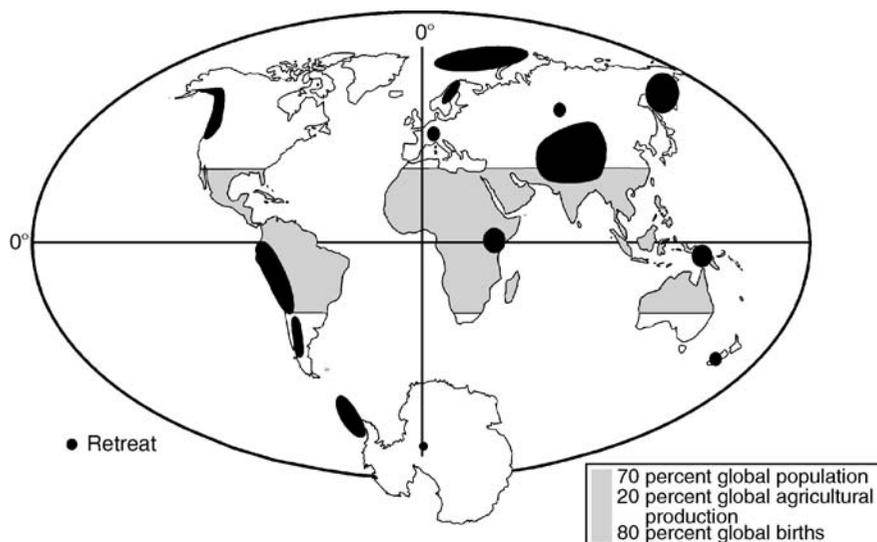

Figure 17 Map demonstrating the current condition of the Earth’s cryosphere. Dark shading depicts regions where glacier retreat is underway. The light shading represents over land between 30°N and 30°S .

population is concentrated, provide unique and valuable archives of climate information because they are able to record variations in atmospheric chemistry and conditions. Since 1982, the El Niño-Southern Oscillation phenomenon has gained worldwide attention as populations and governments have come to realize the extent of its widespread and often devastating effects on weather. As we begin to understand how this coupled atmospheric-oceanic process works, we also see its linkages with other important systems such as the Asian/African Monsoons. Because both of these tropical systems influence precipitation and temperature over large regions, their effects are also recorded by the chemistry and the amount of snow that falls on alpine glaciers. Seasonal and annual resolution of chemical and physical parameters in ice core records from the Andes Mountains has allowed reconstruction of the variability of the ENSO phenomenon over several hundred years (Thompson et al., 1984, 1992; Henderson, 1996; Henderson et al., 1999). Because the effects of El Niño and La Niña events are spatially variable, ice core records from the northernmost (Colombia) and southernmost (Patagonia) reaches of the Andes Mountains will help further resolve the frequency and intensity of ENSO, along with temperature variations, from long before human documentation. This will aid in placing the modern climate changes and the modern ENSO into a more comprehensive perspective. Variability of the South Asian Monsoon is also of vital importance for a large percentage of the world's population that lives in the affected areas. Cores from the Tibetan Plateau have yielded millennial-scale histories of monsoon variability across this large region and information on the interaction between the monsoon system and the prevailing westerlies that are traced back to the Atlantic Ocean.

The clearest evidence for major climate warming underway today comes from the mountain glaciers, recorded in both the ice core records and in the drastic reductions in both total area and total volume. The rapid retreat causes concern for two reasons. First, these glaciers are the world's "water towers," and their loss threatens water resources necessary for hydroelectric production, crop irrigation and municipal water supplies for many nations. The ice fields constitute a "bank account" that is drawn upon during dry periods to supply populations downstream. The current melting is cashing in on that account, which was built over thousands of years but is not currently being replenished. As Figure 17 illustrates, almost all the Earth's mountain glaciers are currently retreating. The land between 30° N and 30° S, which constitutes 50% of the global surface area, is home to 70% of the world's population and 80% of the world's births. However, only 20% of the global agricultural production takes place in these climatically sensitive regions. The second concern arising from the disappearance of these ice fields is that they contain paleoclimatic histories that are unattainable elsewhere and, as they melt, the records preserved therein are forever lost. These records are needed to discern how climate has changed in the past in these regions and to assist in predicting future changes.

"ICEHOUSE" (COLD) CLIMATES

Earth's climate has changed, within life-sustaining bounds, from warm to cool intervals, on scales from thousands to hundreds of millions of years. In the Phanerozoic Eon there have been three intervals of glaciation (Ordovician, Carboniferous and Cenozoic) lasting tens of millions of years, with ice down to sea level at mid-latitudes (Frakes et al., 1992; Crowell, 1999). These cool "icehouse" intervals were generally times of lower sea level, lower CO₂ percentage in the atmosphere, less net photosynthesis and carbon burial, and less oceanic volcanism than during alternating "greenhouse" intervals (Fischer, 1986). The transitions from Phanerozoic icehouse to greenhouse intervals were synchronous with some biotic crises or mass extinction events, reflecting complex feedbacks between the biosphere and the hydrosphere.

Figure 18 summarizes Earth's entire paleoclimate history, and Figure 19 shows the better-known Phanerozoic Eon, with carbon, strontium and sulfur isotopic ratios that are linked to major climate changes. Figure 110 shows an anti-correlation between atmospheric CO₂ levels and $\delta^{18}\text{O}$ values (proxy for oceanic temperature), which tracks the latitude of ice-rafted glacial debris.

The Cryogenian Period of Neoproterozoic time (about 750–580 Ma) contains rocks deposited in two or more severe Icehouse intervals (Harland, 1964; Knoll, 2000). Laminated cap carbonates with depleted $\delta^{13}\text{C}$ ratios are found on top of glacial marine diamictites in many successions (Kauffman et al., 1997). The sharp juxtaposition of icehouse versus greenhouse deposits has led some to suggest that rapid and extreme climate changes took place in Neoproterozoic time. The Snowball Earth hypothesis proposes that during these Neoproterozoic glaciations, the world ocean froze over. The cap carbonates are thought to have been deposited during a subsequent alkalinity event, caused by rapid warming and supersaturation of sea water on shallow continental shelves (Hoffman et al., 1998; Kennedy et al., 2001; Hoffman and Schrag, 2002).

The Earth's temperature has remained relatively constant for 3.8 by, within a range where life could exist (Figure 111), even though solar luminosity has increased and atmospheric

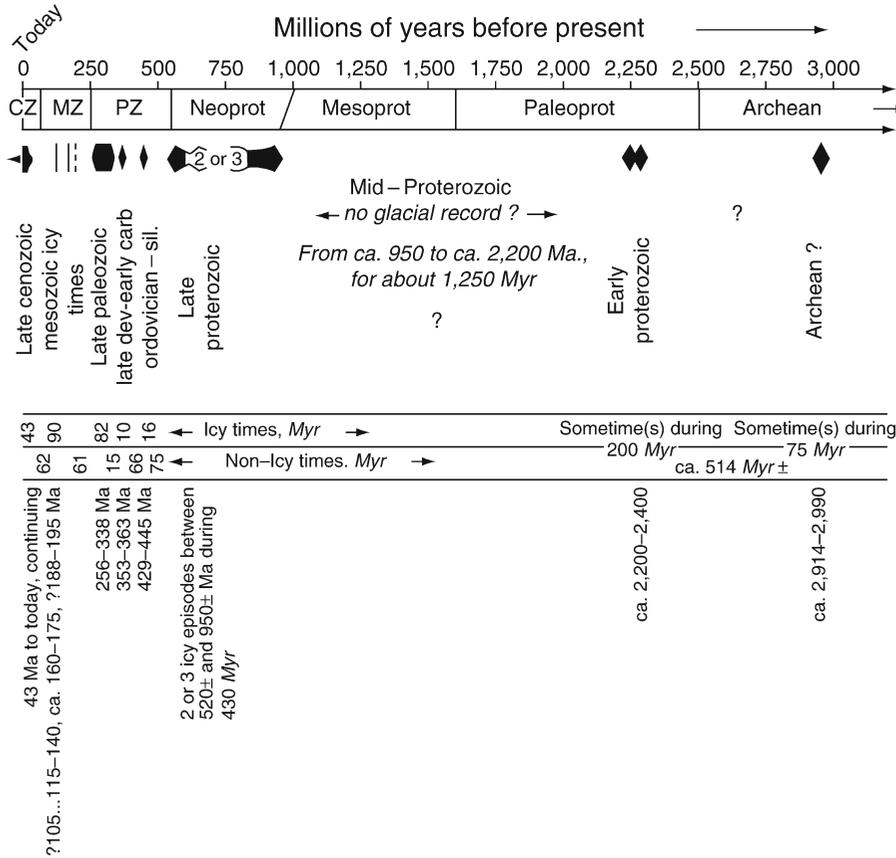

Figure 18 Major ice ages on Earth when the extent of continental glaciers was so great that tongues of ice reached the sea. Duration of icy and non-icy times is shown in the middle of the figure. CZ = Cenozoic; MZ = Mesozoic; PZ = Paleozoic; NEOPROT = Neoproterozoic; MESOPROT = Mesoproterozoic; PALEOPROT = Paleoproterozoic (from Crowell, 1999, Figure 1, used by permission of Geological Society of America).

CO₂ levels have steadily decreased, since Archean time. In the Phanerozoic, the atmospheric CO₂ concentration has varied drastically between icehouse and greenhouse times (Figure I10) (Berner, 1990, 1991; Veizer, 2000; Crowley and Berner, 2001). These concentrations are buffered by feedback loops involving water vapor within the hydrosphere and complex relations in the biosphere (Kump, 2002).

Icehouse characteristics

In general, icehouse conditions occur at times of lower sea level, less cumulative volcanic activity, more vigorous oceanic circulation and bottom water oxidation, less diversity in marine organisms, and deeper levels of the carbonate compensation depth. Relatively warmer, greenhouse intervals are characterized by marine transgression, extensive carbonate bank systems, organic-rich shale basins, marine chert and phosphorite deposition, and nutrient upwelling (Fischer and Arthur, 1977). During icehouse intervals, several or all of the tectonic, geochemical, and astronomical events discussed below coincide. However, determination of the relative cause and effect of each factor, each with its own feedback system, is complex. Both terrestrial and celestial components are involved.

Glaciation to sea level at mid latitudes

The empirical definition of an icehouse state as seen in the geological record is the presence of floating sea-ice at mid-latitudes (30°),

and therefore the presence of ice-rafted debris (dropstones) in marine sediments (Frakes et al., 1992). Glacial ice has likely been present in high mountains throughout the Phanerozoic but the preservation potential of such alpine glacial deposits is low (Crowell, 1999) (see *Ice-rafted debris (IRD)*; *Glacial geomorphology*).

Well-mixed and colder oceans

During an icehouse, the deep ocean floor is oxygenated, and oceans are well-mixed. Icehouse conditions are favored when continental positioning allows north-south ocean circulation to bring warm equatorial water into polar latitudes where it evaporates and generates snowfall. This was the case during the Quaternary. Pleistocene oceanic bottom water temperatures were 15 °C lower than during the Mesozoic greenhouse (Crowley and Berner, 2001).

Carbon dioxide in atmosphere is lower

The percent of CO₂ in the atmosphere is lower in icehouse times, and generally tracks, and partly causes, the net change in temperature (Berner, 1990). Today's CO₂ percentage is in the icehouse range, at 300–370 ppm (Crowley and Berner, 2001). Models show this to be 17% of the Late Cretaceous greenhouse value, and perhaps only 5% of Cambrian Greenhouse CO₂ levels (Figure I10) (Chen and Drake, 1986; Berner, 1990). CO₂ percentage dropped with the Devonian advent of land plants and resulting accelerated silicate weathering.

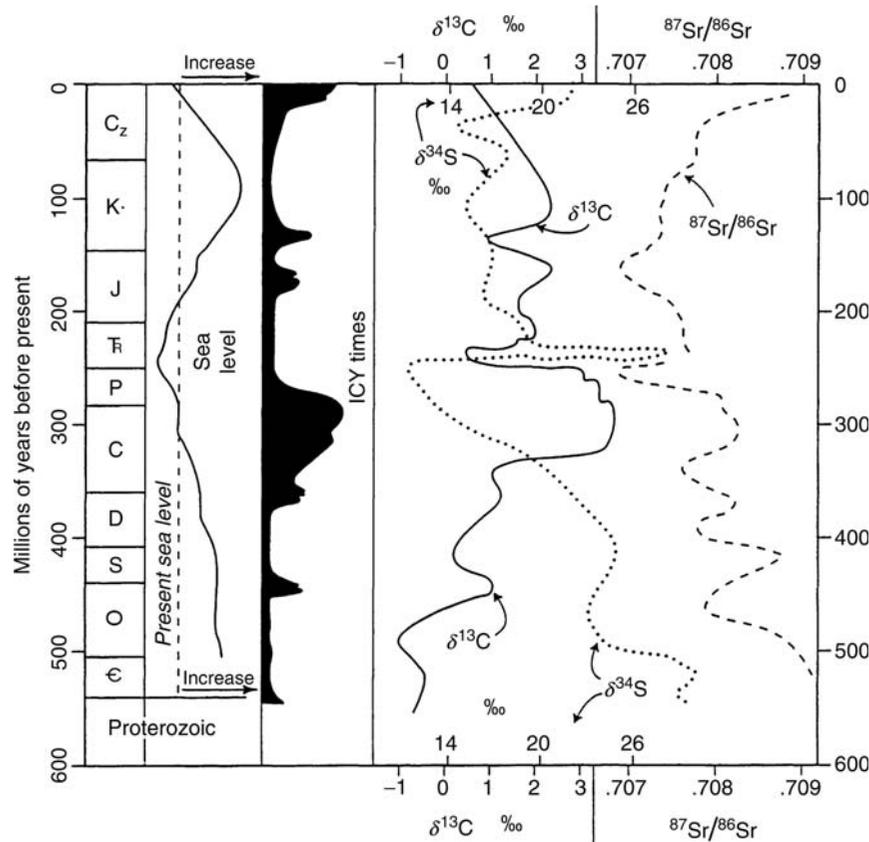

Figure 19 Carbon ($\delta^{13}\text{C}$), strontium ($^{87}\text{Sr}/^{86}\text{Sr}$), and sulfur ($\delta^{34}\text{S}$) isotopic ratios through Phanerozoic time compared with sea level and icy times. Cz = Cenozoic; K = Cretaceous; J = Jurassic; Tr = Triassic; P = Permian; C = Carboniferous; D = Devonian; S = Silurian; O = Ordovician; = Cambrian (from Crowell, 1999, Figure 25; originally modified from Veevers, 1994, Figure 1, used by permission of Geological Society of America).

Carbon isotope values are complex

Carbon is fractionated between organic matter (which is relatively concentrated in ^{12}C) and carbonate (inorganic carbon (which is heavier in $\delta^{13}\text{C}$). Mantle carbon and methane (organic carbon) are both depleted in ^{13}C . The more sedimentary carbon that is buried as organic matter, the heavier will be the remaining carbonate carbon (Knoll, 1991). Further, increased weathering of sediments that contain isotopically light organic carbon, in orogenic belts, or from exposed continental shelves during times of low sea level, will shift the $\delta^{13}\text{C}$ ratio in carbonate sediments to more negative values.

In the Pleistocene, more negative $\delta^{13}\text{C}$ values correspond with times of greater glaciation. In the Neoproterozoic, major negative $\delta^{13}\text{C}$ spikes are found in carbonate rocks deposited on top of glacial marine sediments.

However, for the Late Paleozoic Ice Age and the Ordovician glaciation, $\delta^{13}\text{C}$ values are heavier than during the intervening greenhouse intervals (Figure 19). This apparent ambiguity has caused much controversy.

Global sea level is lower

Sea level is relatively lower during icehouse modes (Figure 19). At such times, water is stored in glacial ice, causing significant drops in global sea level on timescales of 10^5 yr (100 kyr). The extent of sea ice has an important positive feedback on the

albedo or reflectivity of the Earth, which increases as sea level drops and ice expands. As the albedo increases, the Earth absorbs less solar radiation, and the climate becomes cooler. Conversely, during warmer, more humid times, sea level is high and polar ice is minimal, lowering the Earth's albedo. The ultimate long-term (10^8 years – first order) controls on sea level are tectonic, expressed as the average elevation of water-displacing, thermally inflated ocean floor, which is itself a function of the average rate of sea-floor spreading.

Bioherms and evaporites restricted to low latitude: aragonite seas

During icehouse intervals, bioherms and evaporites are restricted to less than 20° latitude. There is lower invertebrate diversity in high latitudes. Like today, aragonite and high-Mg calcite ooids precipitate in shallow marine environments (as opposed to low-Mg calcite ooids during greenhouse times) (Stanley and Hardie, 1998).

Reduced pelagic diversity

Diversity of the pelagic marine realm was reduced (oligotaxy) during icehouse intervals. Such oligotaxic times fostered intense blooms of opportunistic pelagic organisms at times of cumulative lowest diversity (Fischer and Arthur, 1977; Fischer, 1982, 1986).

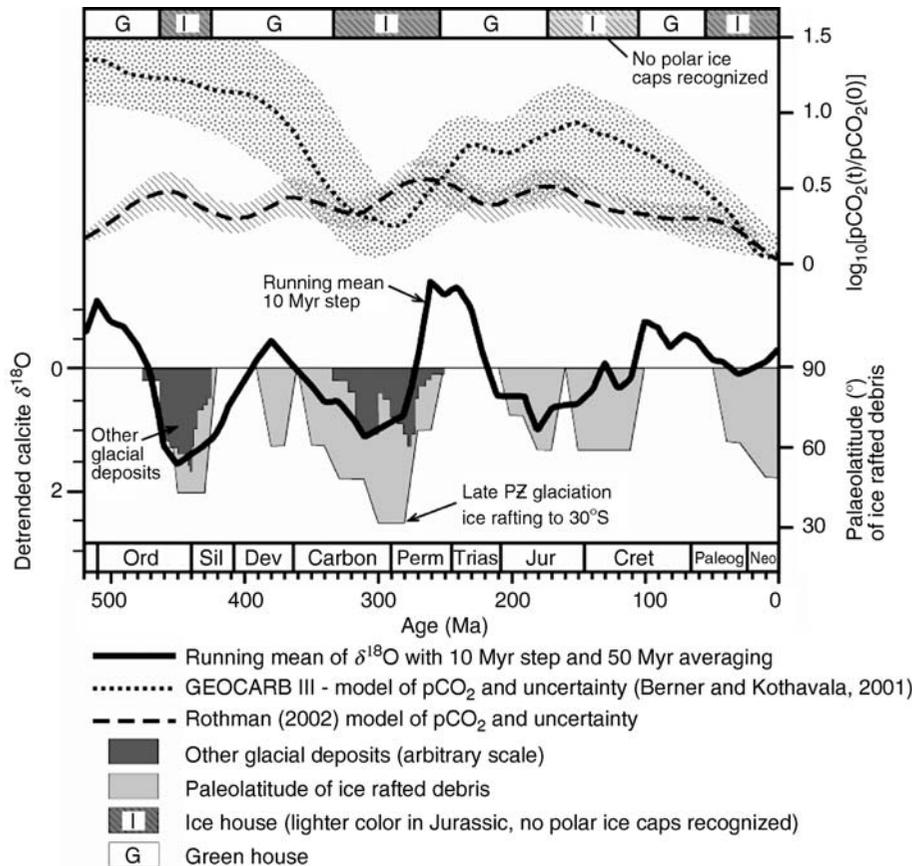

Figure 110 Phanerozoic climatic indicators and reconstructed $p\text{CO}_2$ levels (adapted from Shaviv and Veizer, 2003, Figure 1). Icehouse and greenhouse intervals are shown at the top of the diagram. Upper two curves represent estimated $p\text{CO}_2$ from the GEOCARB III CO_2 model (Berner and Kothavala, 2001) and the model of Rothman (2002). Oxygen isotope values from shells are shown with 10-Myr steps and 50-Myr averages. This smooths the curve and eliminates the highest readings. Paleolatitude of ice rafted debris and qualitative estimate of other glacial deposits are shown in the lower part of the diagram.

Carbonate compensation depth is deeper

During icehouse intervals, the CCD (carbonate compensation depth) is relatively deep within the world ocean, caused by the cooler oceanic temperatures and the resulting greater solubility of carbonate. Such conditions may not, however, apply to the Neoproterozoic, before the advent of pelagic carbonate-secreting organisms (Ridgwell et al., 2003).

Rates of carbon burial are reduced

In general, rates of carbon burial, or sequestration of organic carbon, are reduced in icehouse times, because the oceans are better aerated and the area of dysoxic restricted basins is smaller. The locations of such basins and associated carbon sinks are determined by plate configuration, global and local sea level, and by local organic productivity (controlled by upwelling). Low rates of accumulation of marine organic matter in Late Paleozoic time suggest well-ventilated Icehouse oceans.

Volcanic production of CO_2 is lower

In Phanerozoic cool periods, net production of CO_2 by volcanic activity is lower than during greenhouse events. Plate tectonic and mantle events cause these changes in net volcanic eruption

rates, with decreased rates reflecting periods of supercontinents and slow sea-floor spreading.

Plate tectonic causation

Icehouse climates are favored during times of relatively slow sea-floor spreading, which, in the Phanerozoic, have been times of supercontinent persistence. In general, large continents favor formation of ice sheets (Frakes et al., 1992). For the Late Paleozoic and Late Cenozoic ice ages, a north-south arrangement of continents, fostering longitudinal ocean circulation, was a first-order cause of climate cooling.

A decrease in worldwide volcanic activity, with reduction in CO_2 emission, is controlled by the rate of sea-floor spreading. Such a decrease is favorable for a long-term icehouse event. Slower sea-floor spreading leads to lower global sea level, another icehouse characteristic.

Veevers (1990) suggests that supercontinent cycles are the ultimate cause of icehouse climates, which occur at times of maximum continentality and slower sea-floor spreading. Apparent long-term periodicities in global tectonic phenomena and impact cratering have been linked to motions of the solar system through the galaxy (e.g., Rampino and Stothers, 1986).

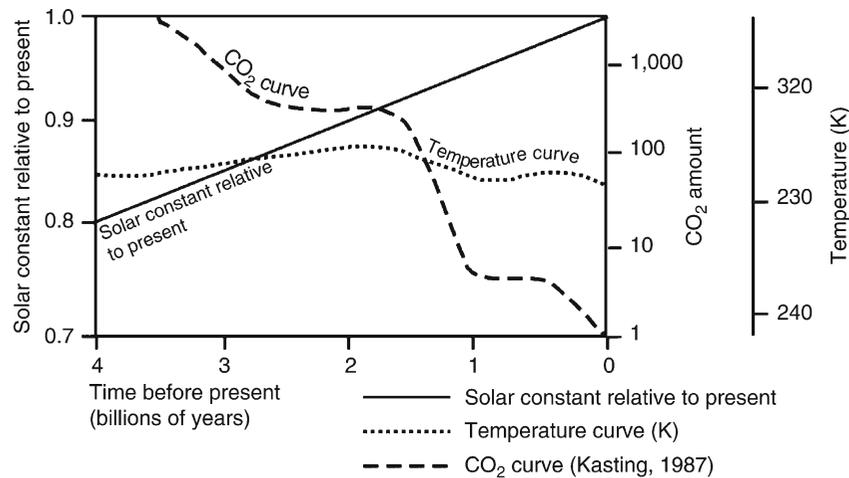

Figure I11 Variation of surface temperature, solar constant and atmospheric CO₂ over geologic time. Temperature curve refers to average surface temperature at 35° latitude. Note that CO₂ percentage has been falling steadily since the Archean, while solar output has been increasing. The net temperature has remained quite constant. Small-scale CO₂ changes, related to icehouse cycles, are superposed on this decreasing secular trend (simplified from Frakes et al., 1992, Figure 1.1).

However, Crowell (1999) does not recognize these tectonic supercycles. The presence or absence of deterministic chrono-tectonic supercontinent cycles is a recurring point of discussion in the study of Earth history.

Records of ancient glaciations

Glaciers are manifested differently at different latitudes, and include ice sheets, valley glacier and piedmont glacier complexes and mountain glaciers. Geological evidence for glaciation and glacial sedimentation are important to paleoclimatologists and sedimentologists, because they can indicate former cold climates (Harland, 1964; Deynoux et al., 1994; Crowell, 1999). Definitive ancient glacial deposits include poorly sorted diamictites, which may contain striated clasts and be associated with dropstone facies in proglacial lakes or seas (Link and Gostin, 1981).

A brief summary of the main icehouse intervals since 1,000 Ma follows. More detail is given in Crowell (1999).

Neoproterozoic (Cryogenian) glacial interval

Late Proterozoic glacial strata are found on all continents. The first evidence for ice sheets at low latitudes was marshaled by Harland (1964) who proposed the Great Infra-Cambrian ice age. Neoproterozoic paleocontinental positions suggest that most landmasses were at low latitudes, in areas of intense silicate weathering (Evans, 2000). This intense weathering traps carbonate and lowers global atmospheric CO₂ percentage (Kirschvink, 1992). Repeated studies have demonstrated low paleolatitudes for Neoproterozoic glacial marine strata (Sohl et al., 1999).

The Cryogenian Period of the Neoproterozoic is named for these icehouse intervals and has been investigated by the International Union of Geological Sciences (Knoll and Walter, 1992; Knoll, 2000; Narbonne, 2003).

Only recently have sufficiently accurate geochronologic data been obtained to place constraints on the Neoproterozoic glacial intervals, so that issues of synchronicity and extent of specific glacial advances remain controversial. Figure I12 shows the time and isotopic constraints, grouped into two broad icehouse

intervals, Sturtian (730–670 Ma) and Marinoan (640–580 Ma), each tens of millions of years long in duration and each with several glaciations. The Marinoan glacial interval is used here in the inclusive sense (Knoll, 2000) to encompass the Varanger, Ghaub, and Gaskiers glaciations and is succeeded by the Ediacaran (Vendian) Period. New radiometric ages from glacial strata reveal multiple ages for ice advance, rather than two synchronous global ice ages (Bowring et al., 2003; Lund et al., 2003; Calver et al., 2004; Fanning and Link, 2004; Hoffmann et al., 2004; Zhou et al., 2004). Purely lithostratigraphic correlations have been a first start, but, to be credible, must be verified by geochronology.

Cap carbonates

Neoproterozoic glacial marine diamictites are often overlain by laminated cap carbonates that have strongly negative $\delta^{13}\text{C}$ values (e.g., Kauffman et al., 1997; Hoffman et al., 1998; Kennedy et al., 2001). Some cap carbonates contain spectacular aragonite crystal fans that grew rapidly on the sea floor. The juxtaposition of glacial (icehouse) deposits with carbonate (greenhouse) deposits is striking. In the Snowball Earth scenario, which proposes that the world oceans froze entirely over (Hoffman et al., 1998; Hoffman and Schrag, 2002), cap carbonates play an integral role and are thought to have been deposited rapidly during a post-glacial marine alkalinity event that was fed by a deeply weathered carbonate-rich regolith formed during the glaciation.

The severity of Cryogenian climate cycles is represented by the wide range of $\delta^{13}\text{C}$ values from Neoproterozoic carbonates (Figure I12) (Kaufman et al., 1997; Lorentz et al., 2004). Documented negative $\delta^{13}\text{C}$ isotopic excursions for carbonates immediately above the glacial rocks are as great as 16‰, going from +10 to –6‰, which exceeds the magnitude of Phanerozoic excursions (Hoffman and Schrag, 2002). Levels of –6‰ suggest near-shutdown of the fractionation of ¹²C in organic matter, as would happen with rapid deposition of shallow-marine carbonate during post-glacial transgression.

Crowell (1999) points out that these carbonates may not represent immediately warmed ocean water, but rather, slowly

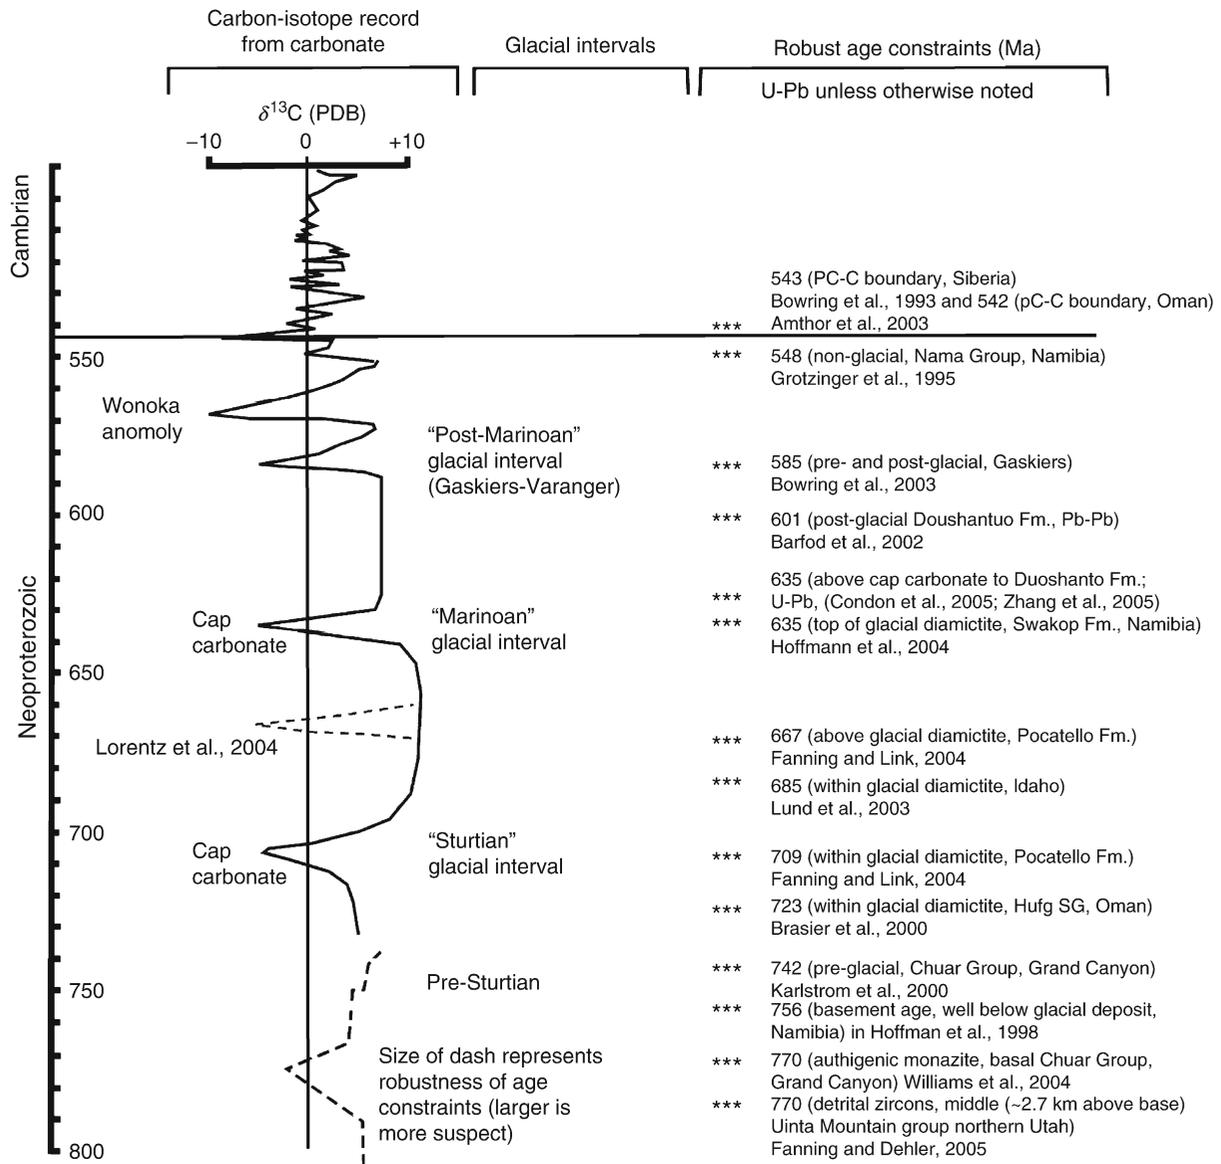

Figure 112 Late Neoproterozoic glacial intervals, carbon isotope values (Kaufman et al., 1997; Kennedy et al., 2001), and geochronologic constraints. Figure prepared by F. A. Corsetti, University of Southern California.

warming transgressive shelves above marine tillites. At least one post-glacial cap carbonate in south China has extremely low $\delta^{13}\text{C}$ values of -45% , suggesting local methane release caused by post-glacial sea level rise and flooding of continental shelves (Jiang et al., 2003).

Proposed explanations of low-latitude Cryogenian glaciation

Low latitude glaciation has been explained by several hypotheses:

1. A climate system similar to that of today with unusual paleogeographic and tectonic factors combining to allow low-latitude glaciation;
2. A Snowball Earth with an ice shelf covering the ocean. (Note that a modification into a "Slushball Earth" may be

necessary to account for evidence of meltwater during Neoproterozoic glaciations).

3. A greater inclination of Earth's spin axis such that polar regions have more equable climates than low-latitude positions (Williams, 1975);
4. True polar wander, where the lithosphere decouples from the asthenosphere and moves with respect to the magnetic field. This would cause inconsistent paleomagnetic pole positions on different continents;
5. Extraterrestrial influences, which may trigger climate cooling by the presence of abundant air-borne ejecta.

Late Ordovician and Early Silurian glaciations

During the Late Ordovician to early Silurian (~ 458 – 421 Ma), short but severe glaciations affected areas of South Africa,

the Saharan region of North Africa, and South America as the continents drifted over the South Pole. These glaciations were primarily due to continental positioning, and did not represent a global icehouse event. Atmospheric CO₂ percentage was high (Figure I10), but its effects were overridden by favorable continental positioning of Gondwanaland near the South Pole (Crowley and Berner, 2001).

Late Devonian and Early Carboniferous glaciations

Late Devonian and Early Carboniferous ice ages are recognized in isolated places in Brazil, in what were then high southern polar latitudes. Crowell (1999) includes these in his major episodes of glaciation, though Frakes et al. (1992) do not do so.

Late Paleozoic ice age

The Late Paleozoic ice age, from early Carboniferous to late Permian time (Figure I13) (~350–253 Ma) is the period of the

well-known Gondwanan glaciations. It produced striated surfaces and tillites on all Gondwanan continents (Australia, India, Asia, Antarctica, South America and Africa). Glaciers extended away from the South Pole as far as 40° S latitude. In most places, several advance and retreat cycles can be recognized, and they are diachronous on different continents, tracking movement through high southern latitudes. In the Northern Hemisphere, glacio-eustatic cyclothem are recognized in the North American mid-continent. Gondwanan glacial deposits were part of the evidence used by Wegener for continental drift. Stones derived from southern and western Africa are found in glacial deposits in Brazil and Argentina.

The Late Paleozoic ice ages ended at least 5 Myr before the mass extinction at the end of the Permian. The warming process may have been facilitated by the outpouring of the Siberian trap lavas and associated CO₂ emission (see *Glaciations, pre-Quaternary; Late Paleozoic climates*).

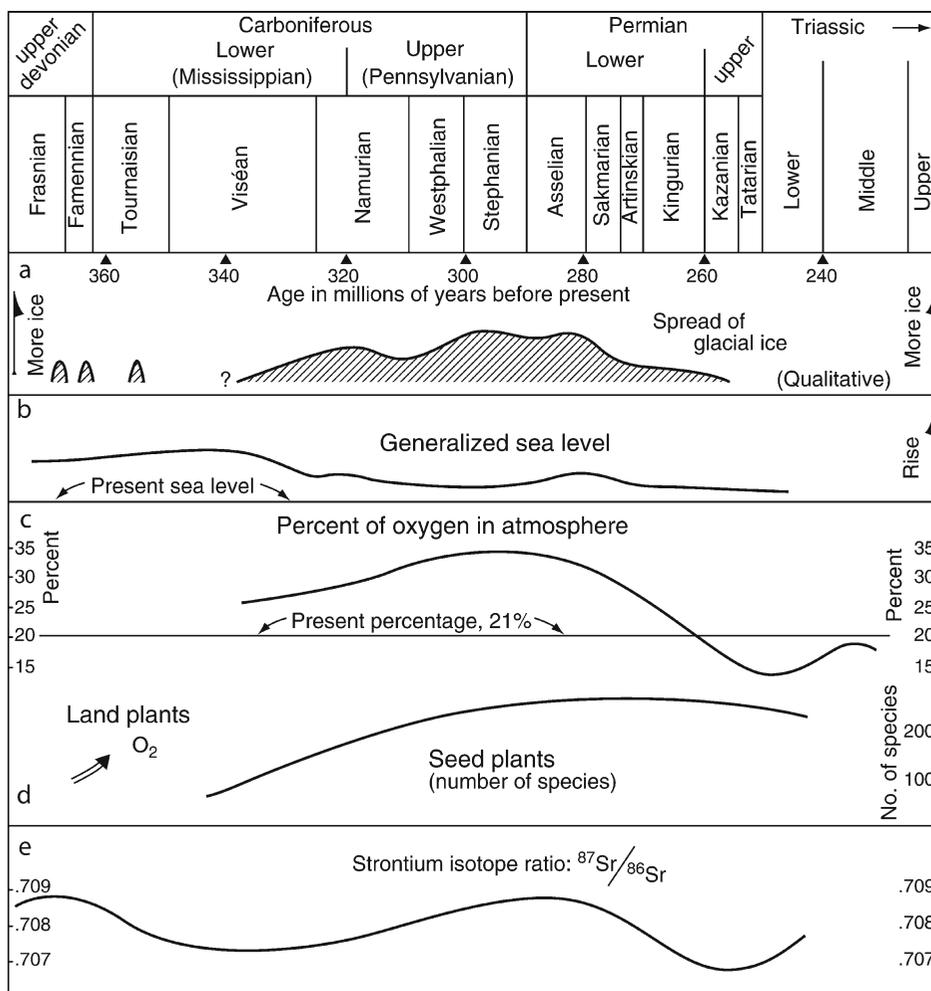

Figure I13 Time plot of glacial expansions during the Late Paleozoic ice age from Devonian through Triassic time. Figure shows several possible cause and effect factors related to glacial advances. Geologic time scale calibrations from Harland et al. (1990), generalized sea-level curve from Vail et al. (1977), percent of oxygen in atmosphere from Berner (1990), number of species of land plants from Niklas et al. (1985), strontium isotopic ratios simplified from Burke et al. (1982) and Holser et al. (1988) (from Crowell, 1999, Figure 39; used with permission of the Geological Society of America).

Late Cenozoic ice age

The Late Cenozoic, Eocene to Recent glaciation (~55–0 Ma) (Frakes et al., 1992) began slowly and locally in the Antarctic. Ice-rafterd sediment is present in 35 Ma Antarctic sediments. Worldwide cooling ensued by early Miocene time (22 Ma). Northern Hemisphere climates got progressively colder, as reflected by paleobotanical records of the southward migration of the extent of broad-leafed evergreen vegetation. The Cenozoic rise of the Himalayas intensified the Indian monsoon, and affected climate in numerous ways, including favoring Arctic cooling. The collision of India and Asia also created a CO₂ sink, due to enhanced chemical weathering of the uplifted Himalayan orogenic belt, which removed CO₂ from the atmosphere (see *Mountain uplift and climate change*). The greatest extent of glaciation was reached in the Pleistocene. Pleistocene climate cyclicity is recorded in δ¹⁸O curves as measured from CaCO₃ shells of foraminifera, with the δ¹⁸O values inversely related to ocean-water temperature (i.e., positive values indicate cold ocean temperatures and vice-versa; see *Oxygen isotopes*). Pleistocene glacial cyclicity generally follows Milankovich astronomical controls (see *Astronomical theory of climate change; Pleistocene climates; Glaciations, Quaternary*).

Summary

Earth has undergone several Icehouse periods, with the Pleistocene being the most recent. The controlling factors are both cyclic (external or astronomical) and secular (internal to the Earth), largely the product of plate tectonics (see *Climate change, causes*). In his synthesis of pre-Mesozoic ice ages, Crowell (1999) sees an irregular pattern of major glaciations, caused by changes in paleogeography and driven by plate tectonics, with secondary atmospheric and astronomical influence.

Earth's orbital variations are surely cyclic: "Alloccyclic sedimentary rhythms – driven by orbital reaction of the Earth with this moon, its sibling planets, and the Sun, and transmitted through climate – are real" (Fischer, 1986). Luckily for us, Earth's history of extraterrestrial interactions has not fundamentally disrupted the life-sustaining Earth-Ocean-Lithosphere system. As shown in Figure I11, Earth's surface temperature has remained relatively constant within limits since the Archean, even though the luminosity of the Sun has increased and the amount of CO₂ in the atmosphere has decreased. Water vapor has acted as a buffer and climate moderator (Kump, 2002; Shaviv and Veizer, 2003).

CO₂ cycling through the biosphere is internal to the climate system, and thus cannot drive a secular change through time, but does affect feedbacks (see *Carbon cycle*). Net volcanism, related to sea-floor spreading rate, is an external forcing factor to the climate system, and had a major effect on the levels of CO₂ during the Mesozoic Greenhouse period (Kump, 2002). Even though the burning of fossil fuels has caused atmospheric CO₂ concentration to rise steadily since observations on Mauna Kea began in 1958 (Chen and Drake, 1986), changes in climate owing to human activity are geologically ephemeral. In taking a long-time view of the Earth's history, they represent but a quick excursion.

ICE-RAFTED DEBRIS (IRD)

Introduction

Ice-rafted debris (IRD) is sediment of any grain size that has been transported by floating ice and released subsequently into an aqueous environment; the ice acts as a raft, providing buoyancy to any debris included within it or on its surface. Although IRD is often assumed to be transported by icebergs, the ice raft can be in the form of either icebergs, derived from

glaciers and ice sheets, or from sea ice formed by the freezing of sea water. IRD is usually deposited by icebergs and sea ice floating in marine waters, but icebergs, lake and river ice can also transport debris and release it subsequently into lakes.

Sources and distribution of debris

The best-known source of IRD is from glaciers and ice sheets. This form of IRD is heterogeneous in grain size, ranging from fine clays and silts to large boulders. This is because glacier ice can erode and transport material of all grain sizes. Sediments produced in the zone of shearing and crushing at the base of an ice sheet often show microscopic and larger edge rounding, together with striations and faceting of their surfaces. The modal shape class of this debris is sub-rounded in terms of Powers' visual roundness index. Such basally-derived glacial debris is usually found in the lowermost few centimeters to meters of glacier ice, at concentrations ranging from a few percent to a few tens of percent (Anderson et al., 1980). It can be present at higher levels in a glacier, usually in discrete bands of debris-rich ice, as a result of glaciotectonic processes such as folding and thrusting.

By contrast, debris incorporated at the glacier surface is usually derived from either rockfall or dirty-snow avalanching onto the ice, although finer-grained material can be deposited by the action of wind. Rockfall and avalanche debris is produced predominantly from weathering of exposed rock on valley walls, and is often relatively coarse-grained and angular in shape, with a sub-angular or angular modal Powers' roundness. Wind-blown debris is of silt and clay size, and is well sorted. Except locally, where significant rockfalls and avalanches have taken place, most of the debris load of glaciers is of basally-derived debris that is eroded or reworked at the glacier bed (Dowdeswell, 1986).

Sea ice also provides a vehicle for the long-distance ocean transport of sediments, although its load is typically of fine-grained material with rather few large clasts (Nürnberg et al., 1994). Fine sediments, entrained in shallow waters during storms, are incorporated when the sea-surface freezes during winter (Barnes et al., 1982). In addition, sediments can be entrained from the sea floor where the ice contacts it in shallow water, or where supercooled water freezes at the sea bed and entrains debris – such anchor ice can incorporate sand and coarser debris. Finally, debris can be introduced to the sea-ice surface through delivery by wind action or from the sediment load of rivers which can flow across shorefast sea ice during spring melting.

Debris release by melting and dumping

Icebergs are formed when ice breaks off, or calves, from the marine or lake margins of glaciers and ice sheets. The icebergs, and any included debris, then drift under the action of ocean currents and, to a lesser extent, wind. The icebergs melt and fragment during their drift. As they melt, at a rate dependent on the temperature of the water, and their size and velocity, any included sediment is released. Coarser material rains out to the sea floor directly, whereas silts and clays have a residence time in the water column linked to particle size, surface roughness and water viscosity. Those parts of an iceberg exposed above water also melt, and debris released there can build up on the surface to be deposited as a single event when the iceberg fragments or overturns. Icebergs vary in diameter from meters to tens and even over 100 km on initial calving,

and can be hundreds of meters in thickness. They may travel up to several thousand kilometers from their glacier source before complete melting, providing a mechanism of long-distance transport for included debris.

Sea ice forms during winter as the sea-surface freezes. Its drift is controlled mainly by wind because, at only a few meters in thickness but covering millions of square kilometers of the ocean, wind shear on its surface is particularly important. Sea ice melts from its base as it drifts into warmer waters, and at its surface due to increased radiative energy in summer. Predominantly fine-grained sediments are released in this way, in contrast to the delivery of material of heterogeneous grain size from icebergs.

Sedimentology of IRD

Deep-ocean sediments are usually fine-grained muds or ooze that are deposited in an environment of low energy. Floating ice, mainly in the form of icebergs, is the only mechanism by which significant quantities of very coarse-grained debris can be delivered into such environments. Individual pebbles, sometimes referred to as dropstones or lonestones, within fine-grained massive muds are a clear indicator of IRD deposition. Often dropstones exhibit striated and faceted surfaces, confirming their glacial origin. In higher energy marine environments, closer to the glacier source of icebergs and meltwater, isolated pebbles can be found within laminated silts and clays. Sometimes the laminations beneath the pebble have been deformed downward by the clast, and overlying sediments are, in turn, draped over it. Where large numbers of icebergs have traversed an area, releasing debris on melt or overturn, layers of sandy material have been observed, known as ice-rafted debris layers (Bond et al., 1992).

Paleoenvironmental significance

At timescales of hundreds of millions of years, the occurrence of isolated dropstones has been used to provide evidence of past ice ages, during which sufficient ice built up on land to reach the sea and produce sediment-laden icebergs. The occurrence of six ice ages over the past thousand million years of Earth history has been inferred using this and other evidence (Eyles, 1993). The first occurrence of IRD in long cores from the Late Cenozoic geological record has also been used to identify the initial growth of ice sheets on Antarctica and Northern Hemisphere landmasses.

The record of IRD deposition is usually constructed by counting the numbers of grains larger than a given size, often between 0.5 and 2 mm, per increment of core depth. Cores spanning the last glacial-interglacial cycle of about 115,000 years have also been examined at high resolution. The most easily distinguished ice-rafted layers yet found are the six so-called "Heinrich Layers," deposited as six events in North Atlantic cores over the past 60,000 years or so (Heinrich, 1988; Bond et al., 1992). Each IRD layer represents a collapse of the Hudson Bay-Hudson Strait drainage basin of the North American Ice Sheet, with the discharge of huge numbers of icebergs into the North Atlantic. The thickness of these Heinrich Layers decreases from about 0.5 m offshore of eastern Canada, to just a few centimeters some 3,000 km away off western Europe (Dowdeswell et al., 1995). Other IRD layers, less thick and continuous over space, probably indicate instabilities within smaller ice-sheet drainage basins, and have also been used to infer regional climatic and sea-level changes. However, IRD

layers are sometimes difficult to correlate over large distances because the very nature of iceberg drift and fragmentation is statistical, and long-distance correlations of IRD layers may be restricted to the products of major ice-sheet collapse events (Dowdeswell et al., 1999).

Finally, the sources and drift tracks of icebergs can be reconstructed from the mineralogical analysis of IRD grains. Debris derived from characteristic source rocks can be identified several thousands of kilometers distant, allowing patterns of past ocean currents to be reconstructed. The work of Bischof (2001) on the sources and drift tracks of icebergs in the Arctic Ocean provides an example of the use of mineralogical tracers.

INTEGRATED OCEAN DRILLING PROGRAM (IODP)

Introduction

Studies of the ocean floor have greatly improved our understanding of processes responsible for the evolution of oceans and continents. Because the geology of oceans is simpler than that of continents and because the oceans are relatively young, reconstruction of their geologic history is simpler. However, the

oceans hide crustal rocks under sediment cover that can be several kilometers thick. We can study the underlying rocks by remote-sensing geophysical means and geochemical analyses of rocks recovered by coring and dredging. Definitive knowledge about the composition of underlying rocks and the processes responsible for their formation can only be obtained by acquiring samples, and that can only be accomplished by drilling and coring operations. It is not surprising, therefore, that scientific deep-ocean drilling, which started in 1968, has greatly increased our knowledge about the Earth. The Integrated Ocean Drilling Program is a complex international scientific drilling program that currently operates throughout the world.

Legacy programs

Scientific deep-ocean drilling started in 1968 with the Deep Sea Drilling Project (DSDP). The project's drillship was the *GLOMAR CHALLENGER*, whose operations were managed by the Scripps Institution of Oceanography. The drillship succeeded in overcoming several technical challenges, including dynamic positioning (how to keep the drillship positioned over the borehole in the presence of currents) and heave compensation (how to compensate for the ship's heave, so that the cores represent proper vertical positioning of the rock layers). DSDP's spectacular achievements became evident through the wealth of scientific results that emerged after drilling and coring at more than 600 sites throughout the world's oceans – all oceans except the Arctic. The DSDP verified seafloor spreading in the South Atlantic – ages were determined from examination of marine magnetic anomalies and were confirmed radiometrically, by comparing age from basement core samples. By obtaining core samples in all the oceans and by correlating the layering in the samples to environmental conditions, the field of paleoceanography was launched. Before DSDP started, a large number of seismic reflection profiles had been obtained in the world's oceans. Drilling, however, established the identity of layering in the seismic reflection profiles.

DSDP was succeeded by the Ocean Drilling Project (ODP) in 1985. The *JOIDES RESOLUTION* was the drillship used and the project was run by Texas A&M University. This program continued until 2003 and involved drilling at more than 650 sites. As more and more complex targets were attempted, technical innovations became necessary and a number of scientific discoveries were made. Among these were the presence of extensive microbial populations and the recovery of frozen methane reservoirs beneath the deep seafloor. It became possible to investigate fluid flow in the crust in several environments. The presence of vast sand deposits in deep water was discovered. Much was learned about the evolution of continental margins and new investigations probed the enigmatic large igneous provinces in the oceans.

Some of the major paleoclimate discoveries made under DSDP and ODP include:

- *Development of the field of paleoceanography.* The near-global network of continuous stratigraphic sections obtained by ocean drilling is the foundation of the field of paleoceanography.
- *Orbital variability during the Cenozoic.* By linking the record of climatic variation preserved in deep-sea sediments to calculated variations in Earth's orbital parameters, scientists have demonstrated the role of orbital variability in driving climate change.

- *Development of high-resolution chronology.* Complete recovery of fossiliferous marine sedimentary sections has greatly facilitated linking Earth's geomagnetic polarity reversal history to evolutionary biotic changes and to the isotopic composition of the global ocean.
- *Ocean circulation changes on decadal to millennial time-scales.* The record preserved in marine sediments and recovered by ocean drilling has clearly demonstrated that deep- and surface-ocean circulation is variable on decadal to millennial timescales, confirming results from polar ice cores.
- *Global oceanic anoxic events.* Deep-sea sediments exhibit specific times when the surface water productivity of large areas of the ocean was unusually high.
- *Timing of ice-sheet development in Antarctica and the Arctic.* Drilling has revealed that Earth's entry into its current Ice Age extended over 50 Myr.
- *Sea-level change and global ice volume.* Marine sediments recovered from shallow water areas have shown that important global sea-level changes have occurred synchronously through at least the past 25 Myr, and that these changes can be matched to oxygen isotope records of climate produced from the deep sea.
- *Uplift of the Himalayas and the Tibetan Plateau.* Drilling results have shown that the onset and development of both the Indian and Asian monsoons are the result of climate change associated with this uplift.

The Initial Science Plan for IODP

The success of DSDP and ODP encouraged scientists interested in scientific drilling to inquire whether a new program could be launched aimed at previously unreachable drilling targets. Some of these targets were located beneath the ice-covered Arctic Ocean. Others involved drilling to great depths, where the stability of the borehole could not be assured with existing techniques, or where the release of hydrocarbon fluids under pressure could lead to blow-outs. A number of international conferences were held based on the premise that the drilling program needed enhancements – new drilling platforms were needed that could deal with problems associated with stability of drill hotels, with blow-out prevention, and with difficult locations such as ice-covered seas and shallow water depths (where the *JOIDES RESOLUTION* could not be used). These conferences included the Conference on Cooperative Ocean Riser Drilling (CONCORD) in Tokyo (1997), the Conference on Multiple Platform Exploration of the Ocean (COMPLEX) in Vancouver (1999), and a workshop on Alternate Drilling Platforms (APLACON) in Brussels (2001), as well as several other workshops and conferences. The conclusions from these meetings formed the basis of deliberations by an Integrated Ocean Drilling Program (IODP) Planning Subcommittee (IPSC), which provided a report entitled “Earth, Oceans, and Life.” The report outlines the IODP Initial Science Plan for 2003–2013 and constitutes the program's scientific basis. It outlines three principal scientific themes and eight new initiatives derived from these themes, as well as principles of implementation.

The principal themes include *the deep biosphere and the sub-seafloor ocean; environmental change, processes, and effects; and solid Earth cycle and geodynamics.*

Within the science plan themes, the following initiatives are detailed:

- *Deep biosphere*

“Define bounding temperatures, pH and redox potential of the subseafloor biosphere ecosystem.”

“Evaluate the biogeochemical impacts of the subseafloor microbiota.”

“Provide uncontaminated samples necessary for high priority studies of deep-biospheric trophic strategies.”

- *Gas hydrates*

“Explore the nature of gas hydrates and the range of depositional settings; study the origin of the gas and the processes of its migration and entrapment.”

- *Extreme climates*

“Understand the mechanisms by which climate extremes develop and are maintained.”

Understanding the mechanisms by which climactic extremes develop, are maintained and end is fundamental to a quantitative description of global change. Earth is now in one of those extremes, the geologically unusual situation of bipolar glaciation. Our knowledge of how Earth's system operates to maintain the current climate is relatively good, but we are still debating how the climate has reached this state.

A question of fundamental importance is how, once established, Earth's climate system operated to maintain the low thermal gradients indicated by warm, high-latitude climates. The paradox in this case is the apparent requirement to transport the great amount of heat needed to warm the poles, versus the sluggish oceanic and atmospheric circulation suggested by low pole-to-equator thermal gradients.

- *Rapid climate change*

“Recover detailed marine sedimentary records to examine the presence of rapid climate changes in the past.”

One of the most striking results of recent paleoclimate research has been the determination that climate can change abruptly across the globe. For example, during the last glacial cycles, jumps between warmer and colder states occurred within decades, and these jumps were often associated with alternations in ocean circulation patterns.

Records of “natural” rapid climate change provide an indispensable context for evaluating contemporary anthropogenic inputs to the environment. The timing and distribution of the present warming trend may match those of previous times, or they may differ in some way explainable only by anthropogenic forcing. Such comparisons are greatly facilitated by recovery and use of detailed marine sedimentary records with resolutions approaching those of instrumental records.

The Arctic Ocean is essentially unknown, yet has the potential to advance our knowledge of rapid climate change processes enormously.

- *Continental break-up and sedimentary basin formation*

“Investigate difference in continental break-up and sediment basin formation at volcanic and non-volcanic margins.”

- *Large igneous provinces*

“Understand mantle behavior during the massive episodic magmatic events that are responsible for the formation of large igneous provinces and determine potential causal relationships and feedback mechanisms between their formation and environmental change.”

- *Twenty-First Century Mohole*

“Recover a complete section of oceanic crust and uppermost mantle and advance significantly our understanding

of the processes governing the formation and evolution of oceanic crust.”

- *Seismogenic zone*

“Understand the nature of the seismogenic zone and mechanics of the earthquake cycle through a comprehensive, multidisciplinary project focused on the behavior of rocks, sediments and fluids in the fault zone region.”

The above initiatives give a flavor of IODP plans. IODP is to be dynamic in nature and further initiatives will result as drilling proceeds.

Certain principles have been agreed on during IODP’s implementation. Foremost is the coordinated use of multiple drilling platforms. (The individual drilling platforms will be discussed in the next section.) A comprehensive engineering development program will be developed to provide a number of special measurement and sampling tools. Existing logging programs will be reviewed and enhanced as necessary. Boreholes drilled as part of IODP will be instrumented to serve as sub ocean-bottom observatories. These initiatives will require coordination with other scientific programs that demonstrate interest in such observatories. For example, coordination and cooperation with programs involved in climate change may be desirable, as well as with industry, which shares similar goals with IODP.

Drilling ships and platforms

Scientists participating in the IODP will be able to make use of three drilling platforms:

- The riser-equipped drilling vessel, the *CHIKYU*, built by JAMSTEC (acronym for the Japan Agency for Marine-Earth Science and Technology);
- A riserless platform provided by the United States, the *JOIDES RESOLUTION*, a 143-m long drillship used in IODP and for the first phase of IODP operations has recently undergone major renovations.
- Mission-specific platforms contributed by European countries that can operate in ice-covered oceans, shallow water zones, and areas inaccessible to the drilling vessels *CHIKYU* and *JOIDES RESOLUTION*.

The centerpiece of IODP is the drilling vessel *CHIKYU*. Built at a cost of more than \$500 million, the ship is 210 m long, and has a gross tonnage of 57,500 tons. The top of her 70-m derrick rises 116 m above the waterline. A dynamic positioning system can keep her within a 15-m radius above a drill hole. The *CHIKYU* contains a number of laboratories for intensive, non-destructive core analysis. These include a microbiology laboratory, a paleomagnetism laboratory, and a laboratory that includes an X-Ray CT scanner. It can drill 7 km beneath the ocean floor and can thus penetrate oceanic crust and reach the mantle. Drilling at a water depth of 2.5 km, the *CHIKYU* can wield a total drill pipe length of 9.5 km. Other distinguishing features of the *CHIKYU* include the availability of a riser and a blow-out preventer. The riser consists of a large diameter pipe which connects the drillship to the wellhead on the ocean floor and contains the drill pipe. Drilling fluid, which consists of “drilling mud,” is pumped down through the drill pipe together with the cuttings (ground up bits of rock), and returns through the space between the drill pipe and the riser pipe to the drillship. The cuttings are separated by filtering, and the drilling fluid is recycled. Circulating the drilling mud through the riser pipe provides several advantages.

Drilling mud is superior to seawater (which has to be used if there is no return circulation) in flushing the cuttings out, which otherwise could clog the drill hole. Appropriately dense mud can be used to line the drill hole and prevent it from caving in. In the absence of coring, the cuttings provide information about the formation that is being drilled through. When a riser is being used, a blow-out preventer sits over the drill hole. It acts as an automated shut-off device which provides protection against unintentional release of high pressure fluids and gases. The *CHIKYU* uses a massive 380-ton blow-out preventer, which contains a pressure-control system that maintains pressure at 15,000 pounds per square inch.

Mission-specific platforms are chosen for each mission-specific expedition. The Arctic Coring Expedition (ACEX) included a fleet of three icebreaker-class ships: a drilling vessel, the *VIDAR VIKING*, which remained at a fixed location and suspended more than 1,600 m of drill pipe through the water column and into the underlying sediments; a Russian nuclear icebreaker, the *SOVETSKIY SOYUZ*; and a diesel-electric icebreaker, the *ODEN*. The *SOVETSKIY SOYUZ* and *ODEN* protected the *VIDAR VIKING* by breaking “upstream” floes into smallish iceberg bits that allowed the *VIDAR VIKING* to stay positioned and recover sediment cores.

IODP structure

The IODP organization is complex. It includes Funding Agencies; Implementing Organizations, which run the drillships; the Science Advisory Structure, which provides scientific advice; and a Central Management Organization. The two Lead Funding Agencies are the U.S. National Science Foundation (NSF) and the Japanese Ministry of Education, Culture, Sports, Science and Technology (MEXT). They provide equal funds for the program. Funds also are contributed by the European Consortium for Ocean Research Drilling (ECORD), which consists of 17-member countries. China’s Ministry of Science and Technology (MOST) is an associate funding agency. The Implementing Organizations (IOs) include: the USIO comprising the Consortium for Ocean Leadership, Texas A&M University, and Lamont-Doherty Earth Observatory – the USIO operates the *JOIDES RESOLUTION*; CDEX, the Center for Deep Earth Exploration, part of JAMSTEC, operates the *CHIKYU*; and ESO, the European Consortium for Research Drilling (ECORD) Science Operator, which operates mission-specific platforms. The Science Advisory Structure (SAS) includes a number of committees and panels that provide scientific advice. Several hundred scientists serve on these committees and panels. IODP Management International (IODP-MI), a nonprofit corporation, serves as the Central Management Organization.

The structure of IODP can be perceived as a matrix with international funding agencies as program sponsors along one axis, and the Science Advisory Structure and Implementing Organizations along another axis, with the Central Management Office providing program focus.

Expeditions

IODP’s first two expeditions (in 2004) were the Juan de Fuca Hydrogeology Expedition and ACEX. IODP’s inaugural voyage was conducted at the Juan de Fuca Ridge in the summer of 2004, 200 km off the coast of British Columbia. Its objective was to conduct a series of studies to evaluate how fluid flows within oceanic crust. To succeed, the science party had to establish three “borehole observatories.” Two new observatories were

installed nearly 600 m below the seafloor, and another was established to replace an existing observatory. When completed within the next few years, the observatory network will enable scientists to discern the flow pattern in the oceanic crust. Expedition 301, the Juan de Fuca, also sampled sediments, basalt, fluids and microbial samples, and collected wireline logs in the deepest borehole.

The Arctic Coring Expedition, the first scientific drilling expedition to the central Arctic Ocean followed, in late summer 2004. Expedition 302 recovered sediment cores deeper than 400 m below seafloor in water depths of ~1,300 m at a location only 250 km from the North Pole.

ACEX's destination was the Lomonosov Ridge, hypothesized to be a sliver of continental crust that broke away from the Eurasian Plate at ~56 Ma. As the ridge moved north and then subsided, marine sedimentation occurred and continued to the present, resulting in what was anticipated (from seismic data) to be a continuous paleoceanographic record. The elevation of the ridge above the surrounding abyssal plains (~3 km) ensures that sediments atop the ridge are free of turbidites. ACEX's primary scientific objective was to continuously recover this sediment record and sample the underlying sedimentary bedrock by drilling and coring from a stationary drillship.

ACEX's biggest challenge was maintaining the drillship's location while drilling and coring 2–4-m thick sea ice that moved at speeds approaching half a knot. Sea-ice cover over the Lomonosov Ridge moves with the Transpolar Drift and responds locally to wind, tides, and currents. Never before had the high Arctic Ocean Basin (known as "mare incognitum" within the scientific community) been deeply cored, primarily because of these challenging sea-ice conditions.

Initial offshore results, based on analysis of core catcher sediments, demonstrated that biogenic carbonate only occurs in the Holocene-Pleistocene interval. The upper ~170 m represent a record of the past ~15 Myr composed of sediment with ice-rafted sediment and occasional small pebbles, suggesting that ice-covered conditions extended at least this far back in time. Earlier in the record, spanning a major portion of the Oligocene to late Eocene, an interruption in continuous sedimentation occurred. This may represent a hiatus encompassing a time interval of non-deposition or an erosional episode that removed sediment of this age from the ridge. The sediment record during the middle Eocene is of dark, organic-rich siliceous composition. Isolated pebbles, interpreted as ice-rafted dropstones, are present well into the middle Eocene section. An interval recovered around the lower/middle Eocene boundary contains an abundance of *Azolla* spp., suggesting that a fresh/low-salinity surface-water setting dominated the region during this time period. Drilling revealed that, during the latest Paleocene to the earliest Eocene boundary interval known as the Early Eocene Thermal Maximum (EETM) or the Paleocene-Eocene Thermal Maximum (PETM), the Arctic Ocean was subtropical with warm surface-ocean temperatures. ACEX penetrated into the underlying sedimentary bedrock, revealing a shallow-water depositional environment of Late Cretaceous age.

IODP expeditions aboard the *JOIDES RESOLUTION* continued through 2005 into 2006. As of July 2005, six riserless expeditions were completed. Of the six, five occurred in the North Atlantic; the sixth was conducted in the deep Gulf of Mexico. The *JOIDES RESOLUTION* proceeded to the Pacific for the remainder of 2005 and a portion of 2006.

Two mission-specific operations, the Tahiti Sea Level and the New Jersey Sea Level Expeditions, were planned for implementation by ESO.

Brief descriptions of 2004–2005 IODP expeditions follow.

North Atlantic Climate

The objective of these two back-to-back expeditions was to establish the intercalibration of geomagnetic paleointensity, isotope stratigraphy, and regional environmental stratigraphies for the Late Neogene to Quaternary period, and to develop a millennial-scale stratigraphic template for the North Atlantic. Other objectives were: (a) to better understand the relative phasing of atmospheric, cryospheric, and oceanic changes central to the mechanisms of global climate change on orbital or millennial timescales; and (b) to improve our knowledge of the temporal and spatial behavior of the geomagnetic field through high-resolution records of directional secular variation and geomagnetic paleointensity. A total of 36 holes was drilled at 11 sites, and 6,998 m of core were retrieved from beneath the seafloor.

Complete sedimentary sections were drilled by multiple advanced piston coring directly south of the Central Atlantic "ice-rafted debris belt" and on the southern Gardar Drift. In addition to the North Atlantic paleoceanography study, a borehole observatory was successfully installed in a new 170 m deep hole close to an earlier Ocean Drilling Program site.

Core Complex

This two-expedition program was aimed at documenting the conditions under which oceanic core complexes (OCCs) develop. These large shallow seafloor features appear to be related to rifting and accretion at slow-spreading mid-ocean ridges. However, currently available data are inadequate to characterize the magmatic/tectonic/metamorphic history, which is needed to better understand the mechanisms of OCC uplift and emplacement. Two sites were drilled: a deep-penetration site on the central dome of Atlantis Massif to sample the detachment fault zone and the alternation front and to drill into unaltered mantle (core and logging analyses were planned); and a shallower-penetration site through the hanging wall to sample rock just above the detachment, the shallowest part of the unexposed fault, and through the fault zone (core and logging analyses were planned). Twenty-two holes were drilled at four sites, with a total of 1,113 m of core retrieved. Unfortunately, the unaltered mantle was not reached.

Porcupine Basin Carbonate Mounds

The Porcupine Basin Carbonate Mounds Expedition included drilling a downslope suite of three sites on the eastern slope of Porcupine Sea Bight, west of Ireland. The sites are centered on "Challenger mound," a 170-m high, partly buried carbonate mound in the "Belgica mound province," topped by dead, cold-water coral rubble. The Belgica mound province belongs to one of the world's most well-documented carbonate mound provinces. The on-mound site was expected to unveil the environmental record locked in a carbonate mound and to shed light on the processes which may have controlled the genesis of the mound – in particular to test the hypothesis of the possible role of fluid venting as a trigger for mound growth and to assess the importance of environmental forcing factors. Particular attention was paid to microbiological and biogeochemical processes in mound genesis and development.

Deepwater Gulf of Mexico

This expedition was named "Overpressure and Fluid Flow Processes in the Deepwater Gulf of Mexico: Slope Stability, Seeps,

and Shallow Water Flow.” It was designed to explore the relationships that exist among and between overpressure, flow, and deformation in passive margin settings, and to test a multi-dimensional flow model by examining how physical properties, pressure, temperature, and pore fluid composition vary within low-permeability mudstones that overlie a permeable and over-pressured aquifer.

Superfast Spreading Crust

Two expeditions to examine the superfast spreading crust returned to an earlier ODP borehole to recover a complete section through $>200 \text{ m yr}^{-1}$ oceanic crust. Multiple trips to the drill sites resulted in retrieval of gabbros from intact ocean crust. In addition, for the first time, Scientists were able to drill through the entire sequence of volcanic rocks that cap the ocean crust to reach a fossil magma chamber 1.4 km beneath the seafloor. A complete section of the upper oceanic crust, drilled 1005 meters into the basement, was recovered.

Tahiti Sea Level

This expedition drilled a series of boreholes along a number of transects to: (a) reconstruct the deglaciation curve for the period 20,000–10,000 yBP in order to establish the minimum sea-level during the Last Glacial Maximum (LGM), and to assess the validity, timing and amplitude of meltwater pulses (so-called MWP-1A and MWP-1B events; ca. 13,800 and 11,300 cal. yBP), which are thought to have disturbed the general thermohaline oceanic circulation and, hence, global climate; (b) establish the sea surface temperature (SST) variation accompanying the transgression at each transect. These data will allow the examination of the impact of sea-level changes on reef growth, geometry and biological makeup, especially during reef drowning events, and will help improve the modeling of reef development; and (c) identify and establish patterns of short-term paleoclimatic changes that are thought to have punctuated the transitional period between present-day climatic conditions following the LGM. It is proposed to quantify the variations of sea surface temperatures based on high-resolution isotopic and trace element analyses on massive coral colonies. A attempt was made to identify specific climatic phenomena such as El Niño-Southern Oscillation (ENSO) in the time frame prior to 10,000 yBP.

Cascadia Margin Gas Hydrates

The Cascadia Margin Gas Hydrates proposal, designed in an accretionary prism environment, aimed to better constrain the models concerning the formulation of gas hydrates. Expedition 311 drilled a series of sites across the northern Cascadia accretionary prism to improve understanding of the deep origin of methane, its upward transport, its incorporation in gas hydrate, and its subsequent loss to the seafloor.

New Jersey Sea Level

This IODP expedition is to obtain continuous cores and down-hole logging measurements of siliciclastic sequences from this modern continental margin within crucial paleo-inner-shelf facies at three sites that represent the most sensitive and accessible locations for deciphering amplitudes and testing facies models.

Conclusion

While surface samples in the ocean bottom can be recovered by coring and dredging, samples of deep rocks can only be

recovered by deep drilling and coring. The deep drilling programs DSDP, ODP, and now IODP are programs that obtain rocks at great depths by coring and are therefore, by examination of these rocks, able to tell us much of climate conditions and ocean conditions at the time that the sediments that constitute the rocks were laid down. The science of paleoceanography can thus be said to have developed largely as a result of these drilling programs. Climate changes with frequencies ranging from several hundreds of thousands of years to the millennial scale have thus been elaborated through an examination of the cored rocks. The goals of IODP with respect to paleoceanography are focused on a number of specific problems; these include the studies of rapid climate change, as well as extreme climates and the variables that relate oceans to climate. During the next five years we expect major discoveries with respect to climates and oceans of the past, which in turn may give us clues as to what we can expect of climate and oceans in the future.

INTERSTADIALS

Definitions

Interstadials are regarded as the relatively short-lived periods of thermal improvement during a glacial phase, when temperatures did not reach those of the present day and, in lowland mid-latitude regions, the climax vegetation was boreal woodland (Lowe and Walker, 1997). Jessen and Milthers (1928) defined interstadials as periods that are either too short or too cold to allow the development of temperate deciduous forest of interglacial type in the same region. Interstadials are, however, not only defined on biostratigraphical grounds. In the USA, for instance, an interstadial is formally regarded as a climatic episode within a glaciation during which a secondary recession or standstill of glaciers took place (Gibbard and West, 2000).

Table 14 Interstadials during the Weichselian in Europe: Denmark (DK), The Netherlands (NL), Germany (D) France (F), Great Britain (UK), compared to GRIP Summit glacial interstadials IS as defined by Dansgaard et al. (1993)

Interstadials during the Weichselian

Many different interstadials are defined in Europe based on palynology. The interstadials that occurred during, for instance, the Weichselian Glacial have been named after the place where the interstadial was described for the first time. Many of these Weichselian interstadial stratotypes have been defined in NW Europe and are described by Behre (1989), Zagwijn (1989), and de Beaulieu and Reille (1992) (Table 14). Dansgaard et al. (1993) described 24 interstadial phases in the GRIP oxygen isotope record from the Greenland ice, characterized by a sudden increase and gradually decrease of oxygen isotope values. Recent evidence points to a total of 25 interstadial phases that are resolved in the Greenland ice core (NGRIP Members, 2004). These so-called Dansgaard-Oeschger interstadial events can be correlated with low percentages of the planktonic cold water foraminifera *Neogloboquadrina pachyderma* in high-resolution records from the North Atlantic (Bond et al., 1993).

IRON AND CLIMATE CHANGE

Iron availability limits the ability of phytoplankton in some parts of the surface ocean to photosynthesize biomass from dissolved CO₂ in seawater. An important source of iron to phytoplankton is the deposition of dust from continents. The sensitivity of dust deposition to climatic factors such as aridity and windiness makes iron a possible link between climate and the CO₂ concentration in the atmosphere. Iron climate linkages and their biogeochemical ramifications are explored further in a recent article by Jickels et al. (2005).

The element iron is abundant in the core and crust of the Earth. In the early Earth, the oceans contained high concentrations of dissolved iron in the form of Fe²⁺. However, as the oceans became oxidized by increasing O₂ concentrations in the atmosphere, iron oxidized to the relatively insoluble state Fe³⁺, and deposited into sedimentary structures known as Banded Iron Formations. Except for anoxic regions such as in sediments or isolated basins such as the Black Sea, dissolved iron concentrations have remained low in the oceans ever since.

However, iron is not absent in the oxic ocean. Fe³⁺ is stabilized in the dissolved form by complexing organic compounds called chelators or siderophores (Rue and Bruland, 1995). These compounds appear to be biogenic, but little is known of their structure, lifetime, or origins. Similar compounds are secreted in soil and freshwater systems to enable plants, fungi, and bacteria to acquire iron. A vast majority of the iron in seawater is found to be complexed to siderophores. In addition, the precipitation of Fe³⁺ into solid form does not result in its immediate removal by sinking when the particles generated are very small. More than half of the Fe³⁺ in seawater is found in colloidal form, too small to sink but potentially too large to be biologically useful. In particular, the diffusion coefficient of colloidal complexed iron will be slower than that for truly dissolved iron, and its availability for biological uptake will be correspondingly less (Wu et al., 2001).

In spite of its scarcity, iron is an essential co-factor in enzymatic systems such as the light-harvesting photosynthesis systems, and in nitrogenase, the enzyme which fixes NH₄⁺ from molecular N₂ (Falkowski et al., 1998). Because of its low solubility in oxic seawater, iron has been shown to limit the production of biomass in several regions of the surface ocean. These regions, historically called High Nutrient Low Chlorophyll (HNLC) regions, include the equatorial Pacific, the North Pacific, and the Southern Ocean. When the iron concentration in the surface ocean is artificially increased in these areas, the iron stimulates increases in chlorophyll concentration, photosynthetic efficiency, and phytoplankton growth rates (Coale et al., 1996). These iron fertilization experiments constitute one of the most dramatic breakthroughs in biological oceanography in several decades.

The link between phytoplankton and the CO₂ concentration of the atmosphere occurs via the biological pump in the ocean. Photosynthesis produces particles that can leave their source waters by sinking. The downward net flux of biological material leaves the surface ocean depleted in nutrients such as NO₃⁻ and PO₄⁻, as well as dissolved CO₂. CO₂ gas dissolves into surface seawater, or evaporates into the atmosphere, according to its concentration in seawater or air, and its solubility (mostly controlled by temperature). Depletion of CO₂ from surface waters by biological activity therefore draws down the CO₂ concentration of the atmosphere. In the present-day ocean, Southern Ocean surface waters contain the majority of the potentially biologically usable nutrients NO₃⁻ and PO₄⁻. In addition, because the Southern Ocean is a conduit to the largest oceanic carbon reservoir – the deep ocean, atmospheric pCO₂ in models is more sensitive to surface chemistry changes in the Southern Ocean than other oceanographic regions. Therefore, the search for an explanation for lower glacial pCO₂ values has centered on deposition of iron onto the Southern Ocean.

There are arguments for and against the Southern Ocean fertilization hypothesis. On the positive side, the deposition of dust and Fe in Antarctic ice cores was indeed higher during glacial times, by more than an order of magnitude. Most of this dust appears to originate from a specific region in Patagonia, but dust deposition increased globally by a factor of two or more. The decline in Antarctic dust deposition is also one of the earliest indicators of the coming deglaciation (suggesting that dust decrease could be an ultimate cause for the other aspects of the deglaciation) (Broecker and Henderson, 1998).

On the other hand are arguments against the Southern Ocean fertilization hypothesis. Several models of iron geochemistry in the ocean conclude that the dominant iron source to the Southern Ocean surface is from below, in the upwelling water, and that increasing the negligible deposition flux will have little effect (Archer and Johnson, 2000). Fertilization experiments in the Southern Ocean have not resulted in increased sinking of organic matter into deep waters, but rather an increased standing biomass stock in surface waters as the added iron is efficiently recycled (Boyd et al., 2000). Trace element tracers for sea surface nutrient concentration in the Southern Ocean have not shown a substantial drawdown during glacial time (Boyle, 1992). Furthermore, the pCO₂ sensitivity to the Southern Ocean decreases with increasing model complexity and realism, such that even a complete drawdown of Southern Ocean nutrients would not be enough to generate glacial pCO₂ values (Archer et al., 2000). Finally, an increase in the biological pump would result in a decrease in the O₂ concentration of the deep ocean, which is not apparent in the sedimentary record.

With these counter-arguments in mind, the community is also investigating the possibility that an increased glacial iron supply might stimulate an increase in nitrogen fixation, resulting in an increase in the nitrate inventory of the ocean (Broecker and Henderson, 1998). A release from nitrogen limitation might result in a stronger biological pump, although phosphorus availability could limit this effect. In addition, iron fertilization is being explored as a potential fix for rising CO₂ concentrations resulting from fossil fuel consumption.

ISOTOPE FRACTIONATION

Isotopes are atoms whose nuclei contain the same number of protons but a different number of neutrons. The term ‘isotope’ is derived from a Greek word meaning equal place: the various isotopes of an element occupy the same position in the periodic table. Isotopes of an element can be either stable or unstable (radioactive). Differences in chemical and physical properties arising from variations in atomic mass of an element are called ‘*isotope effects*’. The partitioning of isotopes between two substances or two phases of the same substance with different proportions of isotopes is called ‘*isotope fractionation*’ (Hoefs, 1997; Criss, 1999).

The isotopic composition of materials contains information that can be used, for example, to reconstruct the palaeo-environment and to understand the hydrological cycle and biochemical pathways.

History

In 1913, isotopes were discovered by J. J. Thomson who found that the element neon has two different kinds of atoms with atomic weights 20 and 22. A few years later, 212 of the 287

naturally occurring isotopes were known. The reason for the existence of isotopes was, however, unclear until the discovery of the neutron by Chadwick in 1932. The seminal papers by Urey (1947) and Bigeleisen and Mayer (1947) on the thermodynamic properties of isotopic substances provided the basis for the utilization of stable isotopes in geology, geochemistry, biogeochemistry, paleoceanography and elsewhere.

Notation, definitions

Isotopic ratios, R , are measures of the relative abundances of isotopes of an element, E ; they are usually arranged so that the lightest stable isotope (index a), which is often also the most abundant isotope, appears in the denominator: ${}^bR = {}^bE/{}^aE$ (stable boron isotopes are an exception: ${}^{11}\text{B}$ is about four times more abundant than ${}^{10}\text{B}$). The three stable oxygen isotopes ${}^{16}\text{O}$, ${}^{17}\text{O}$, and ${}^{18}\text{O}$ will be used to explain the notation and basic definitions.

The oxygen isotope with mass number 16 contains 8 protons and 8 neutrons and is denoted by ${}^{16}\text{O}$. It is by far the most abundant (99.76%) of the three stable oxygen isotopes. For example, the ratio of ${}^{17}\text{O}$ to ${}^{16}\text{O}$ in water, or the ratio of ${}^{18}\text{O}$ to ${}^{16}\text{O}$ in carbon dioxide can be written as:

$${}^{17}R_{\text{H}_2\text{O}} = \frac{[\text{H}_2^{17}\text{O}]}{[\text{H}_2^{16}\text{O}]}, \quad {}^{18}R_{\text{CO}_2} = \frac{2[\text{C}^{18}\text{O}^{18}\text{O}] + [\text{C}^{18}\text{O}^{16}\text{O}]}{2[\text{C}^{16}\text{O}^{16}\text{O}] + [\text{C}^{18}\text{O}^{16}\text{O}]}$$

The *isotopic composition*, δ , of a sample, determined by mass spectrometric methods, is measured with respect to a standard (std):

$$\delta^b E_{\text{sample}} = \left(\frac{{}^bR_{\text{sample}}}{{}^bR_{\text{std}}} - 1 \right) \cdot 1,000$$

where b is the atomic mass of the isotope and the factor 1,000 converts the δ value to per mil. The standards (cf. Hoefs, 1997) used for stable oxygen isotopes are V-SMOW (Vienna-Standard Mean Ocean Water; ${}^{18}R_{\text{V-SMOW}} \cdot 10^6 = 2,005.20 \pm 0.43$) and V-PDB (Vienna-Pee-Dee Belemnite, ${}^{18}R_{\text{V-PDB}} \cdot 10^6 = 2,067.1 \pm 2.1$).

The *fractionation factor*, α , is defined as the ratio between the isotopic ratio in compound X and that in compound Y:

$${}^b\alpha_{(X-Y)} = \frac{{}^bR_X}{{}^bR_Y} = \frac{\delta^b E_X + 1,000}{\delta^b E_Y + 1,000}$$

It is a measure of the partitioning of isotopes between two or more phases in response to an isotope effect.

Whereas the δ value is the result of the whole history of the sample, the α value is characteristic for, say, an equilibrium between X and Y or for a process that leads from X to Y. Since α values are usually very close to 1.0, the ϵ notation is commonly used to express isotope fractionations in per mil ($\pm\%$):

$${}^b\epsilon_{(X-Y)} = ({}^b\alpha_{(X-Y)} - 1) \cdot 1,000$$

Isotope effects

The most important isotope effects arise from differences in: (a) random mean velocities and (b) vibrational frequencies of molecules.

a) Random mean velocity effects. In (local) thermodynamic equilibrium, the mean kinetic energy is equal for all molecules and determined by temperature alone:

$$\langle E_{\text{kin},j} \rangle = \frac{1}{2} m_j \langle v_j^2 \rangle = \frac{3}{2} k_B T = E_{\text{thermal}}$$

$$\text{where } m_j \text{ and } v_{\text{rms},j} = \sqrt{\langle v_j^2 \rangle}$$

are mass and random mean square (rms) velocity of molecule j , k_B is Boltzmann's constant, and T is absolute temperature. At a given temperature, the rms velocity varies with the mass of the molecule: light molecules are faster than heavy molecules (Graham's law of diffusion):

$$v_{\text{rms},1}/v_{\text{rms},2} = \sqrt{m_2/m_1}$$

As a consequence, molecules containing the light isotope diffuse faster. The ratio of the diffusion coefficients D_v for the light (mass m_a) and the heavy molecule (mass m_b) of a gas that diffuses through air (mass $m_c = 29$) is given by

$$\alpha_{(a-b)} = \frac{D_b}{D_a} = \sqrt{\frac{m_b + m_c}{m_b \cdot m_c} \frac{m_a \cdot m_c}{m_a + m_c}}$$

For ${}^{13}\text{CO}_2$ and ${}^{12}\text{CO}_2$, one obtains

$${}^{13}\alpha_{\text{diff. CO}_2 \text{ in air}} = \sqrt{\frac{45 + 29}{45 \cdot 29} \frac{44 \cdot 29}{44 + 29}} \approx 0.9956$$

The relation does not apply, however, for diffusion of gases through liquids where the ratio of the diffusion coefficients is closer to one (${}^{13}\alpha_{\text{diff. CO}_2 \text{ in water}} \approx 0.9993$). The variation of the rms velocity with mass also leads to differences in evaporation.

b) Effects due to molecular vibrations. The zero-point energy of vibrations in molecules, E_0 , is mass dependent. For diatomic molecules $E_0 = hv/2$, where h is Planck's constant and ν is the (vibration) frequency. The ratio of frequencies ν and ν' for two diatomic molecules of different isotopic composition is approximately given by $\nu'/\nu = (\mu/\mu')^{1/2}$ where $\mu = m_1 \cdot m_2/(m_1 + m_2)$ is the reduced mass and m_1 and m_2 are the masses of the two atoms involved.

Example: compare the frequencies for ${}^{16}\text{O}^{16}\text{O}$ ($\nu, \mu = 16 \cdot 16/(16 + 16) = 8$), ${}^{17}\text{O}^{16}\text{O}$ ($\nu', \mu' = 17 \cdot 16/(17 + 16) \approx 8.2424$), and ${}^{18}\text{O}^{16}\text{O}$ ($\nu'', \mu'' = 18 \cdot 16/(18 + 16) \approx 8.4706$): $\nu'/\nu \approx 0.9852$, $\nu''/\nu \approx 0.9718$, i.e., the strength of the isotope effect increases with the mass difference and thus it is not surprising that the resulting isotope fractionation is also 'mass-dependent', as a rule.

Isotope fractionation

The difference in isotopic composition between various compounds or between various phases of a single compound is called isotope fractionation. It is noted that even the largest isotope effect may not cause fractionation if the reaction goes to completion, i.e., a quantitative reaction in which the reactant is completely transformed into the product. However, an isotopic fractionation will always be observed when a reaction has an isotope effect and the formation of the product is not quantitative (Hayes, 1982).

Equilibrium isotope fractionation

Isotope fractionation can occur in equilibrium, for example, between the various isotopic forms of carbon dioxide, bicarbonate, and carbonate ions (Zeebe and Wolf-Gladrow, 2001). As a rule: "The heavy isotope goes preferentially to the chemical compound in which the element is bound most strongly." (Bigeleisen, 1965). For example, in the temperature range between 0 and 25°C, the

$\delta^{13}\text{C}_{\text{CO}_2}$ in seawater is 8–10‰ lower (“isotopically lighter”) than $\delta^{13}\text{C}_{\text{HCO}_3^-}$.

The fractionation factors for equilibrium fractionation involving three isotopes with masses $m_1 < m_2 < m_3$ usually scale such that $\alpha_{2/1} = \alpha_{3/1}^\beta$, where $\beta = (1/m_1 - 1/m_2)/(1/m_1 - 1/m_3)$ (Young et al., 2002). For the three stable oxygen isotopes: $^{17}\alpha = (^{18}\alpha)^{0.529}$.

Nonequilibrium (“kinetic”) isotope fractionation

Nonequilibrium effects are associated with incomplete or unidirectional processes such as evaporation, kinetic isotope effects in chemical reactions, diffusion, or metabolic effects. Kinetic isotope effects in chemical reactions occur when reaction rates for compounds containing light or heavy isotopes are different, which is almost always the case and thus isotope fractionation can be expected. If the reservoir of reactants is finite, the isotope effect associated with the reaction will not only yield a product of different isotopic composition but will lead to a change in the isotopic composition of the reservoir as well (*Rayleigh distillation*; Bigeleisen and Wolfsberg, 1958). Kinetic isotope effects can quantitatively be understood on the basis of the ‘transition state theory’ (Bigeleisen and Wolfsberg, 1958). The fractionation factors for kinetic fractionation involving three isotopes with masses $m_1 < m_2 < m_3$ often scale such that $\alpha_{2/1} = \alpha_{3/1}^\beta$, where $\beta = I_n(m_1/m_2)/I_n(m_1/m_3)$ (Young et al., 2002). For the three stable oxygen isotopes: $^{17}\alpha = (^{18}\alpha)^{0.515}$.

“Mass-independent” fractionation

A mass-independent fractionation of stable oxygen isotopes was reported (for the first time) in 1973 in meteorites and in 1983 in laboratory studies (Thiemens and Heidenreich, 1983). These studies show differences in the isotopic compositions for certain compounds that contain ^{16}O only (Substance X) and Compounds X and compound Y with fractionation factors $^{17}\alpha$ and $^{18}\alpha$ (between X and Y) that are almost equal, i.e., $^{17}\alpha \approx ^{18}\alpha$. These fractionation processes are called ‘mass-independent’. They may occur at low pressures and, for example, play an essential role for stratospheric ozone. The resulting unusual composition of atmospheric oxygen has been used in the so-called ‘triple-isotope method’ to derive estimates of the biosphere productivity (Luz et al., 1999). A theoretical

explanation based on an extension of the Rice, Ramsperger, Kassel, Marcus (RRKM) theory has been developed only recently (Gao and Marcus, 2001). A mass-independent isotope effect has also been observed during thermal decomposition of carbonates in vacuo (Miller et al., 2002).

K

KAMES

A kame is an ice contact glaciofluvial landform. It is composed of sediment deposited by water in contact with glacier ice either at the side of, or on the surface of a glacier. The sediment fills of supraglacial streams and lakes, ice marginal channels and ice-dammed lakes often form flat-topped hills or terraces after the ice has disappeared. The term kame is a Scottish word to describe such flat-topped hills. Kames are closely related to eskers, and transitional forms between the two occur. Generally kames are less continuous and are associated with supraglacial or ice-marginal water, whereas eskers are more continuous and are associated with subglacial water. The presence of flat or gently sloping surfaces, representing fluvial surfaces, is sometimes said to be a diagnostic characteristic of kames. However, postglacial collapse following the loss of ice support can seriously disturb kame morphology.

Kames generally consist of well-sorted, stratified sediments. If deposited by glacial streams they are dominated by sands and gravels. If deposited in lakes they are characterized by clay, silt and fine sand. Kames can occur as individual hills, as plateau areas or as terraces. At the smallest end of the spectrum of kame forms are supraglacial crevasse fillings. Where many kames occur together within an area the term kame field is sometimes used. Kames are often associated with kettle holes to produce “kame and kettle” topography. Kame landscapes tend to reflect environments where ice retreat was accompanied by abundant meltwater and sediment supply.

The term “kame” is often applied to mean “ice contact” in compound terms such as kame terrace, kame delta or kame plateau. Terraces generally form where streams flow along margins of glaciers, and therefore they lie parallel to the ice margin where the margin lies on a reverse slope. So-called “flights” of terraces at different levels may be created as a glacier surface reduces in elevation during ice retreat. Kame deltas, also known as delta moraines or simply ice-contact deltas, form where glacial streams emerge from the glacier into water.

As they are created in ice-contact situations kames are prone to collapse as ice retreats. Their sedimentary architecture

therefore reflects not only the processes of deposition but also the processes of structural collapse. Supraglacially-derived sediments are likely to be more disturbed than ice marginal deposits. Survival of extensive kames indicates that an area was dominated by down-wasting and meltout of ice after any phase of extensive proglacial fluvial erosion, which would have removed the kames. Benn and Evans (1998), Bennett and Glasser (1996) and Hambrey (1994) provide useful reviews of this topic.

KETTLES

A kettle, or kettle hole, is an enclosed depression within glacial sediments, caused by the melting of ice that was buried within the sediments. The ice may be a remnant of the glacier margin detached by ablation, or an ice block deposited from a glacial stream. Kettles are characteristic of proglacial outwash plains and areas of stagnant ice. They very often fill with water to form kettle lakes. Kettles vary in size and may be just a few meters or several hundred meters in diameter.

Some kettles form from the melting of completely buried ice blocks, others from the melting of partially covered ice blocks,

and the morphology of the holes created reflects their origin. Where ice is completely buried, as may be the case when stagnant glacier ice is blanketed by supraglacial meltout sediment or where ice blocks in a proglacial flood are deeply buried in glacialfluvial deposits, kettles form by subsidence and may initially be very steep sided. Where ice blocks are partially exposed, as may be the case where ice blocks are deposited on a sandur plane during a short proglacial flood, the debris content of the ice block and the depth of burial have a significant impact on the form of the kettle. Debris released from the melting ice block may create a ridge around the edge of the kettle or may completely fill the kettle with debris, creating a mound rather than a hollow (Maizels, 1992). Different forms that have been described include “rimmed,” “crater,” and “till-fill” kettles. Where an outwash plain is marked by a large number of kettles the term “pitted plain” is sometimes used. Many ice blocks are deposited on outwash plains during glacial floods, and the distribution of kettles on an outwash plain can be used to reconstruct the routing and magnitude of flow during flood events.

Kettles may be completely filled with sediment if deposition occurs after the ice has completely melted, but will still be recognizable in the sedimentary record. The kettle will be represented

by a downfaulted block, and the amount of downfaulting at different levels in the profile will indicate the depth above which sediment was deposited after the ice completely melted. Benn and Evans (1998) and Bennett and Glasser (1996) provide useful reviews of this topic.

L

LACUSTRINE SEDIMENTS

Introduction

Concerns about global change and its potential effects on human activities, including economic, social, and political affairs, are exerting great pressure on science to produce models and predictions for future climatic variability. In this regard, the key to the future is a proper understanding of the past. In principle, data sources for past climatic variations are instrumental meteorological and historical data. However, meteorological time series are rather short and thus limited for interpretation (Bradley, 1999). Historical data are available for the last couple of centuries, prior to the instrumental record, and these enable a more or less accurate determination of natural climatic and anthropogenic changes. These data, however, become scarce and unreliable for longer timescales and thus need to be complemented by information from indirect archives for a better interpretation of the past. On the continents, lacustrine sediments provide an excellent archive for the extension of instrumental and historical data of environmental and climatic changes on a high-resolution decadal or even annual timescale.

Lacustrine sediments contain a wide variety of information indirectly reflecting environmental conditions. They can be analyzed by sedimentological, geochemical, geophysical, and biological methods combined within the field of paleolimnology (Berglund, 1986; Last and Smol, 2001; Cohen, 2003). The obtained data are generally called “paleoclimate proxy data” or “proxies” and are used to evaluate the variability of past climatic conditions as well as human influences on the lake system and on the catchment basin. This is possible because lacustrine sediments record many environmental processes that occur in the water column and in the drainage area of the lake.

Due to this availability of multi-proxy data sets in combination with high resolution and accurate dating, lacustrine sediments often provide a more comprehensive environmental interpretation than other continuous continental records like

tree rings, peat bogs, and speleothems. Discontinuous records like fluvial, colluvial, and loess deposits or soils are prone to hiatuses and therefore are only suitable for environmental reconstructions under special circumstances, for short time intervals, or for certain scientific questions.

The formation of lacustrine sediments is controlled by atmospheric processes (climate) but also by the geology of the catchment basin, which is connected to the lake system through (climatically-controlled) hydrology (Figure L1). Climate and geology also control the formation of soils and plant cover in the catchment as well as water chemistry and plankton communities in the lake (Wetzel, 2001). As geology does not change significantly through the life span of most lakes, variations recorded in the sedimentary record are almost certainly related to climate variability, which itself is controlled by solar forcing. However, in the most recent past anthropogenic influences have become increasingly important.

Occurrence

Lakes are standing bodies of water that accumulate sediments from the surrounding environment and from their water column. Lakes are relatively young features ($\leq 10^4$ years) that have predominantly been formed during the last cold period of the Pleistocene by glacial activities (Hutchinson, 1957; Gierlowski-Kordesch and Kelts, 1994). Sediments deposited in these lakes generally provide excellent archives for a large variety of Late Glacial and Holocene paleoenvironmental investigations. Lakes can also be found in volcanic regions (crater lakes). In some rare occurrences, lakes of tectonic origin (e.g., along the Great African Rift System) or impact crater lakes exist, all of which may contain much longer sediment records than glacial lakes, covering several glacial/interglacial cycles or even the entire Quaternary (up to 10^6 years).

Formation of lacustrine sediments

The formation of lacustrine sediments depends on climatic factors and therefore, under natural conditions, the dominating regional climate controls the type of lacustrine sedimentation (clastic, biogenic, or evaporitic). Lacustrine sediments are the

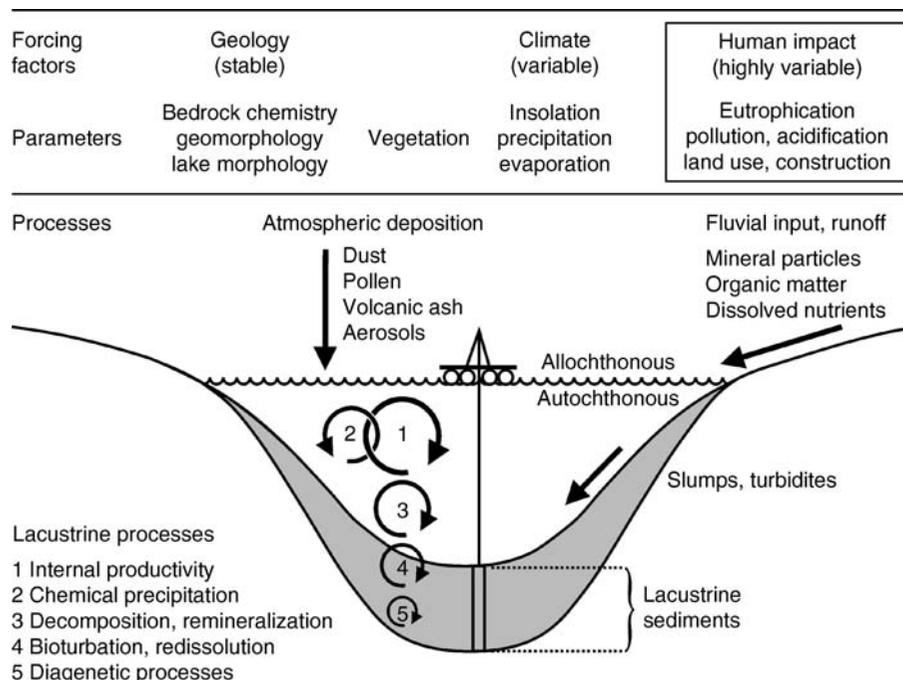

Figure L1 Simplified illustration of forcing factors and parameters as well as processes that lead to the formation of lacustrine sediments.

result of three different mechanisms (Håkanson and Jansson, 1983):

- The flux of mineral particles through fluvial input from the catchment area or by atmospheric deposition forms clastic sediments, which to a certain extent may contain organic particles, e.g., leaves or pieces of wood carried into the lake by runoff.
- Biological productivity in the lake generates organic or biogenic sediments as the dead organic matter sinks and accumulates at the lake bottom.
- Chemical precipitation of minerals from the water column forms evaporitic sediments.

In general, sediment components can be classified into two groups: those produced in the lake (autochthonous components) and those formed in the catchment basin (allochthonous components), which are transported to the lake by overland flow, rivers and streams, or by eolian activities. Although there are clear constraints for the environmental conditions necessary for the formation of clastic, organic, or evaporitic sediments, lacustrine sediments usually are the result of a combination of these processes.

Clastic lacustrine sediments

Clastic (detrital) sediments predominate under cold climatic conditions, e.g., at high latitudes or in alpine regions. Such clastic or minerogenic sediments are typical of proglacial lakes. Intensive physical weathering and the lack of a dense vegetation cover provide high amounts of minerogenic detritus, which can easily be eroded and transported to the lake. In general, the sediment transfer from the catchment area into the lake is correlated with the amount of runoff. In regions with a continental climate, runoff is governed by the melting of snow and ice through solar insolation during the summer. Under oceanic

climatic conditions, runoff is controlled either by the melting of snow and ice through advective heat transport associated with increased rainfall or solely by precipitation. Lakes with clastic deposits are generally poor in nutrients (oligotrophic) inhibiting high organic productivity.

Organic lacustrine sediments

Under temperate or warm, humid climatic conditions, the catchment area is vegetated, reducing the availability and the transport capability of clastic material into the lake. Chemical weathering prevails and releases nutrients from the bedrock that are incorporated into plant organic matter, buffered in soils, or washed out and transported as dissolved ions into the lake. This results in higher nutrient levels in the lake (mesotrophic to eutrophic conditions) and the related increase of organic productivity leads to the formation of organic or biogenic sediments. Algal blooms start with diatoms in spring, are followed by green and blue-green algae during summer, and are sometimes terminated by a second diatom bloom in fall. While green and blue-green algae are easily decomposed during deposition, siliceous diatom frustules are much more resistant to dissolution and are generally well preserved in the sedimentary record. In addition to this autochthonous sedimentary component, an allochthonous component may occur during winter: as the plant cover is reduced and thus soils become more susceptible to erosion, runoff increases and transports minerogenic as well as organic debris of littoral and terrestrial origin to the lake. The latter two components are washed into the central part of the lake basin during runoff events related to fall or winter rains.

If carbonates are present in the catchment area, autochthonous calcite precipitation adds an additional component to the organic sediment fraction. Carbonaceous rocks are dissolved and the solutes are transferred into the lake. In these hard water

lakes, calcite crystals are produced by autochthonous biochemical precipitation: Ca^{2+} and HCO_3^- in the lake water stay in solution only until the saturation point is reached. This is partly achieved by the seasonal temperature increase in the surface water layer during the summer insolation maximum. As CaCO_3 is less soluble with increasing temperature, calcite may precipitate due to this effect alone. However, even more important is the temperature-related increase of photosynthetic activities in the water column through phytoplankton blooms. As a result of enhanced photosynthesis, CO_2 is withdrawn from the lake water and thus the pH rises up to pH 9 with a consequent reduction in CaCO_3 solubility. This combination of temperature increase and phytoplankton activity contributes to additional precipitation of calcite crystals. Under such conditions, the shells of calcifying organisms (e.g., ostracods, mollusks) may also be a significant sediment constituent.

Evaporitic lacustrine sediments

Under arid or semiarid climatic conditions, evaporitic sediments are formed as the salinity and the pH of a lake increase through enhanced evaporation of the lake water. This results in the saturation of specific mineral compounds (salts), which then precipitate out of the lake's water column. In addition to calcite, which can precipitate either biogeochemically in mid-latitudes or physicochemically under semi-arid climatic conditions, evaporitic sediments are also composed of calcium sulfate (gypsum) and sodium chloride (halite), both precipitating only under arid climates.

Modification of lacustrine sedimentation

Several processes may alter lacustrine sedimentary records:

- Especially in deep lakes with steep sidewalls, turbidity currents may transport large amounts of sediment from the lake-shores into the central basin. Turbidites may be associated with erosion at their base, which causes a hiatus in the sedimentary record.
- In shallow parts of lake basins or if strong winds induce deep-reaching water movements, currents can cause resuspension of fine-grained sediments and redeposition somewhere else.
- Bioturbation caused by the burrowing activities of benthic fauna mixes the uppermost sediment layers. The effects of bioturbation are reduced if anoxic conditions prevent the presence of higher organisms at the lake floor. For example, organic rich muds (sapropels) cause anoxic conditions near the sediment/water interface due to oxygen consumption during the decomposition of organic matter.
- In the course of early diagenesis the growth of iron- and manganese-minerals like vivianite, siderite, pyrite, or rhodochrosite may also disturb the original layering of the soft sediments.

If one or more of these processes are or have been present in a lake, they can introduce hiatuses and mixing into the record and make high-resolution investigations difficult or impossible.

Sedimentation rates

The rapid reaction of the local hydrological regime to environmental change is coupled with changes in sedimentation rates (mm yr^{-1}) and accumulation rates ($\text{g cm}^{-2} \text{yr}^{-1}$). Lacustrine sedimentation rates are in the range of 0.3 mm to several mm per year, which is up to three magnitudes higher than in marine

sediment records. As a consequence, this high sedimentation rate reduces the length of the time window that might be studied to ca. 10^4 years, whereas marine records reach up to 10^8 years.

Therefore, lacustrine sediments facilitate stratigraphic studies with centennial to decadal resolution. If annually laminated (varved) sediments are preserved, annual to even seasonal time resolution is possible (Zolitschka, 2003). Thus, different kinds of abrupt changes can be detected by the wide variety of applicable sedimentological, geochemical, geophysical, and biological analytical methods (Last and Smol, 2001). Lately, multi-proxy investigations of lake sediments became more and more important because they provide several independent lines of evidence for a common observation – environmental change as the response to climate change and human impact – and therefore improve the reliability of the interpretation.

Dating

Time control is one of the most important issues in the study of lacustrine sediments. Without an accurate timescale a comparison of the sample proxy data with historical and archaeological data and with other lacustrine archives as well as with other proxy records on a local, regional, or global scale is impossible. Among all sedimentary records, lake sediments provide the best time control, as different dating methods can be applied to the same cores. Usually, radiometric dating methods are carried out depending on the decay rates of radiogenic isotopes, e.g., ^{14}C dating for the last ca. 50,000 years and ^{137}Cs and ^{210}Pb for the last 50 and 200 years, respectively. Radiometric measurements are related to time by the half-life of the isotope and through models of production and deposition of radiogenic isotopes. The time is provided in isotopic years and needs to be calibrated into calendar years by comparison with monitoring data of radioactive fallout (^{137}Cs), by using depositional models (^{210}Pb), or with the help of dendrochronology (^{14}C).

In many regions, the annual climatic cycle represents the strongest observed cyclicity. Under permanent or seasonal anoxic conditions near the lake bottom, this cyclicity can be preserved as annually laminated or varved sediments. However, varved sediments are not the rule because processes like bioturbation in well-oxygenated lakes disturb this cyclical layering. Incremental dating can be applied (Zolitschka, 2003) to well-preserved annually laminated sediments. This method is based on cyclical accumulation of biological or lithological material with time, leading to the formation of organic (biogenic) or clastic varves. The major control mechanisms of this cyclicity are the seasonal climatic variations that produce an “internal clock.” Such a varve chronology provides either an absolute chronology in calendar years, if the varves continue to the present, or a floating chronology, if the record is not annually laminated to the top of the sequence.

In addition to these “absolute” dating methods, stratigraphic methods are often applied to provide further time control and to facilitate correlation between neighboring sites of investigation. Most common is the biostratigraphic method of pollen analysis (palynology) where distinct changes in the regional pattern of vegetation are used. For a larger regional scale, paleomagnetic studies are also sensible and might even reveal global variations of inclination and declination changes of the Earth's magnetic field. For very long records, reversals or event-like excursions of the polarity of the Earth's magnetic field can be used as a stratigraphic tool (magnetostratigraphy). If a lake is situated in a volcanic region, tephra layers are another possibility to elaborate an independent time-frame through tephrochronology. Lacustrine

sediments have the advantage that one record provides several different dating methods, which allows significant improvement of the overall dating accuracy.

Proxy data recorded in lacustrine sediments

Since meteorological parameters are not directly recorded in lacustrine sediments, indirect information has to be used for climatic reconstruction. These so-called proxy data are either quantitative or descriptive information about sedimentological, geophysical, geochemical, or biological processes that are dominantly controlled by climatic conditions and thus provide a good approximation of climatic variability. Three major groups of proxy data are used with lake sediments to reconstruct past climatic and related environmental changes:

- Biological proxies (e.g., pollen, diatoms, chironomids) are calibrated using regional training sets, which are statistically transformed into quantitatively reconstructed values of temperature, pH, salinity, or total phosphorus concentration.
- Physicochemical proxies (e.g., isotopes) can be analyzed relatively fast and easily compared with biological proxies. Carbon isotopes of bulk organic matter provide information about changes in the trophic condition of a lake while oxygen isotopes of authigenic carbonates or calcareous skeletons of microfossils like ostracods provide quantitative information that can be linked to temperature and precipitation on a global scale. Furthermore, as water residence times in lakes are rather short, isotope records provide data about climatic changes almost without any time lags whereas lag effects of decades or more are typical for biological systems.
- Sedimentary proxies (e.g., flux rates, grain sizes, elemental composition, magnetic properties, clay minerals) provide qualitative information about major environmental changes in the lake and the catchment basin. These data are usually more complex than biological proxies and therefore much more difficult to interpret.

If several different proxy data are used for a combined interpretation (multi-proxy approach), the overall significance of the results is improved considerably.

Modern calibration

The key to an improved interpretation of lacustrine sediment records is a proper understanding of present-day processes leading to the formation of such deposits. The primary climatic signal can be modified and transformed in several ways. For this reason it is necessary to establish correlations between run-off events, sediment sources, and sediment deposition as well as between climatic parameters and biological sedimentary proxies, e.g., vegetation (pollen), diatoms, or chironomids. Correlations need also to be established between climatic parameters and stable isotopes or between sediment texture, structure, and composition. The period of monitoring should ideally exceed several years to obtain site-specific calibration data sets and transfer functions valid for larger regions. These can then be used to reconstruct quantitative variations of climatic variables like temperature or precipitation, which are crucial for the evaluation and refining of global to regional climate models.

Conclusions

Evidence of past and present climate variability as well as more recent anthropogenic influences on lakes and their catchment basins are recorded in lacustrine sediments. The major difficulties

in employing these natural archives for paleoenvironmental and paleoclimatic reconstructions are in establishing a precise and reliable timescale and interpreting the record properly. Ideally, both obstacles can be circumvented if lake sediments are studied, obtaining multi-proxy data on multiple-dated timescales. Successfully applied, lacustrine sedimentary archives provide a unique opportunity to study the past dynamics of environmental systems on local, regional, and even global scales. This geological perspective is necessary in order to generate realistic projections of future environmental changes that might, at least in part, result from human activities.

LAKE-LEVEL FLUCTUATIONS

Introduction

Lake-level changes can occur as a consequence of climatic change, tectonic activity, erosion at the outlet, or human activity. Water-level fluctuations associated with climate changes are a response to variations in precipitation-evaporation (P-E) over the watershed. A particular lake's sensitivity to P-E variations is primarily related to basin hydrology, or whether inflow exits the lake basin via a surface outflow (overflowing, open) or is confined to the lake basin (non-overflowing, closed). The water level of a closed lake system, in the absence of tectonic activity, erosion at the outlet, or human influence, represents an equilibrium state between: (a) input (catchment runoff and groundwater inflow), and (b) output (evaporation and sub-surface seepage). In a closed-basin system, changes in effective moisture will cause the volume of the lake to either increase or decrease until a new equilibrium is achieved. In overflowing lakes, climatically driven lake-level changes are limited to P-E decreases, because further increases are compensated by greater outflow (Harrison and Digerfeldt, 1993). The magnitude of lake-level response to climate change can be calculated from known or estimated hydrological budgets if the geomorphic characteristics of the lake and its watershed are known, including bathymetry, catchment and shoreline topography, soil type, and vegetation (Hostetler, 1995). Various combinations of precipitation and evaporation can produce the same effective moisture, but if other climate proxy data can be used to constrain one of the variables, then the range of the other can be determined (e.g., Barber and Finney, 2000).

A lake's water-level history is the result of its response to climate over a range of timescales ($1-10^5$ years). Large water-level fluctuations at 10^3 to 10^5 -year timescales correspond to global climate changes associated with glacial-interglacial periods and global ice volume (e.g., Benson et al., 1989; Finney et al., 1996). Lake-level data can provide important Pleistocene and Holocene P-E information at $<10^3$ -year timescales or better when chronological control for water-level variations can be established (Abbott et al., 1997). Historical gauge and climate observational records are available that document lake-level variations and climate fluctuations at 10^2 -year timescales for the last 50–100 years (Street-Perrott and Harrison, 1985).

Lakes are distributed globally, providing regional paleoclimatic information for low latitudes (Kutzbach and Street-Perrott, 1985; Street-Perrott and Perrott, 1990; Abbott et al., 1997; Seltzer et al., 1998) and semi-arid regions at middle to high-latitudes (Benson, 1981; Benson et al., 1989; Harrison and Digerfeldt, 1993; Thompson et al., 1993; Yu et al., 1997; Abbott et al., 2000; Anderson et al., 2005). In many tropical and sub-tropical locations, lake-level variations are of particular paleoclimatic significance. Region-wide changes in drought patterns have been identified as coincident with significant cultural change or collapse (e.g., Binford et al., 1997; Bookman et al., 2004). Well-dated lake-level data have also been used to identify feedbacks between tropical rainfall and global heat transport by thermohaline circulation (e.g., Street-Perrott and Perrott, 1990). In the middle latitudes, lake levels have been used to determine quantitative estimates of paleoprecipitation (e.g., Benson, 1981; Hastenrath and Kutzbach, 1983, 1985), and to verify paleoclimate model simulations (e.g., Webb et al., 1993).

Lake-level reconstructions

Past lake-level variations may be indicated by geomorphic evidence within a lake basin. Raised shoreline features and wave-cut platforms indicate higher lake levels (e.g., Gilbert, 1890; Oviatt et al., 1994). Evidence for past lake-level variations is also found within the stratigraphy of lacustrine deposits. It is difficult to identify basin-wide sedimentary changes from observations of a single core with a small cross section of 2–10 cm. Multiple cores collected on a shallow to deep water transect provide more reliable lake-level information for quantification of lake-level changes (e.g., Digerfeldt, 1986). Sediment stratigraphy and facies changes may record water-level shifts in several ways because lake-level fluctuations affect numerous limnological and sedimentological processes. Consequently, evidence from core studies may be subject to more than one interpretation. However, consensus developed from multiple lines of evidence can be used to build a compelling lake-level reconstruction. Sedimentary changes can be identified by visual stratigraphy, changes in color, pollen, grain size distribution, and organic matter concentration. Multiple lines of evidence commonly include physical, chemical, paleolimnological, and paleoecological analyses and studies of these are known as “multi-proxy” studies, with age control determined by high precision geochronological techniques, such as accelerator mass spectrometer (AMS) radiocarbon dating in combination with ^{210}Pb and ^{137}Cs assays for the youngest sediments. Correlation of multiple cores recovered from different water depths can be used to detect unconformities that form hiatuses in the sediment record and determine the timing of these events.

Stratigraphically-based multi-proxy lake-level reconstructions increase the ability to identify links between lake-level reconstructions and climate fluctuations (Digerfeldt, 1986; Dearing, 1997). Although the most useful combination of multi-proxy studies varies from lake to lake, the three major categories of sedimentary evidence are: (a) the distribution and pattern of littoral vegetation, (b) sediment compositional variations with varying depths, and (c) the shallowest depth where fine-grained, organic-rich sediment accumulates (i.e., the sediment limit). Lundqvist (1925, 1927) pioneered the use of core transects from shallow to deep water to investigate how macrofossil content, pollen concentration, and sediment composition varied with changing depth. Digerfeldt (1986) and Dearing (1997) further modified these methods. The use of core transects to investigate lake-level change is most commonly applied to lakes with small catchment to lake surface-area ratios that have relatively shallow underwater slopes.

The distribution of shoreline (littoral zone) macrophyte vegetation is largely determined by lake-water depth for many closed-basin lakes. Characteristic zonation of emergent, floating-leaved, and submerged vegetation extends outwards from the shoreline. A decrease in water depth (lower lake level) will commonly result in macrophyte vegetation migrating toward the lake. However, such a vegetation response may also occur over time because of progressive sedimentary infilling. In contrast, an increase in water depth (higher lake level) will result in landward macrophyte vegetation migration away from the lake. It is more difficult to find alternative explanations for landward expansion of shoreline vegetation than higher lake level.

Depending on the character of shoreline deposits, littoral zone sediments may contain higher proportions of reworked

mineral particles than offshore zones. This is caused by wave action or wind-induced currents that winnow fine-grained sediments from shoreline deposits and transport them into deeper water, toward the center of the lake. Generally, grain size decreases gradually away from shore, forming a fining outward facies. Lowstands lead to displacement of the shore towards the center of the lake and may be recognized by an increase in grain size and mineral quantity. Lake highstands, in turn, are recognized by a decrease in grain size. Similarly, the level below which fine organic or fine-grained mineral sediments accumulate is usually determined by location with respect to the shoreline. This level represents the limit between dominantly erosional and depositional sedimentary processes. Lake highstands will often be recorded as an increase in the sediment limit and lowstands as a lowering of the sediment limit. However, lower lake levels are accompanied by erosion and redeposition of older sediments away from shore, these would previously have accumulated in near-shore sedimentary environments.

The most appropriate location and group of lake-level proxies to investigate must be determined from the limnological and sedimentological properties of each individual watershed and lake basin. Additionally, geomorphic processes and basin bathymetry are important factors to consider when investigating lake-level changes using core transect studies. Variations of shore character and lake basin bathymetry will dictate whether sediment accumulation is continuous or interrupted by periods of erosion or non-deposition with considerable variability in sediment thickness and composition in shallow-water environments. For example, vegetation changes can be easily recognized in eutrophic lakes with high macrophyte production and diversity, but in oligotrophic lakes, coarse minerogenic material is often a more dominant signal. Lake-level variations will most likely be recorded by changes in the fine-grained sediment limit in lakes with sandy shorelines. In stratified marl lakes, changes in the location of marl sediment accumulation are often the dominant water-level indicator. Yu et al. (1997) used sediment hiatuses, detritus layers, and terrestrial moss layers from five cores with calcium-carbonate oxygen isotopes to identify lake-level changes. Anderson et al. (2005) used palynology, calcium carbonate proportions, and bulk organic carbon and nitrogen isotopes on four cores from Marcella Lake, Yukon Territory. Numerous studies have also investigated relationships between changes in lake level and variation in diatoms, ostracods and chironomids (Hoffman, 1998; Alin and Cohen, 2003; Yang et al., 2003).

Another approach is to use seismic surveys to identify lake-level changes and determine where to collect sediment cores. The seismic profiles allow for the identification of erosion surfaces and on-lap and off-lap sedimentary structures, and provide information regarding changes in sediment thickness across the lake basin. Abbott et al. (2000) used seismic profiling and multi-proxy sedimentary analyses including bulk sedimentology and palynology on Birch Lake, Alaska to determine the sediment limit. Keely et al. (2005) used seismic profiling on Lake Bosumtwi, Ghana. These seismic investigations improved the determination of coring locations that yielded optimal information on water-level changes.

Resolving the timing and rate of lake-level variations requires an accurate and precise chronology. Early lake-level reconstructions, prior to the advent of AMS radiocarbon dating, were commonly based on beta-counting analytical techniques using bulk sediment samples. Bulk sedimentary material is typically composed of organic matter derived from aquatic

organisms and can be older than the true age of the deposit because of a reservoir or hardwater effect. This reservoir effect is the result of either a long lake-water residence time or the presence of limestone in the drainage basin, which is a source of ancient carbon. AMS radiocarbon dating requires samples containing around 1 milligram of organic material for accurate and precise ages. Furthermore, the technique eliminates uncertainty regarding the source of the organic material because terrestrial macrofossils (as little as 0.5 mg) can be identified and dated. However, it is still possible that terrestrial macrofossils can be reworked from older sediments during water-level changes. High resolution lake-level studies based on AMS radiocarbon measurements of identified macrofossils have been conducted on Lake Titicaca, Bolivia (see case study below); Birch Lake, Alaska (Abbott et al., 1997, 2000); Marcella Lake, Yukon, Canada (Anderson et al., 2005); and the Dead Sea (Bookman et al., 2004).

Lake level variations are important for studying the mechanisms of climate change if both the spatial and temporal resolution of the data is sufficiently extensive and detailed to describe patterns on the scale of the climate process. For example, Brenner et al., (2001) used a synthesis of finely resolved lake-level reconstructions from the circum-Caribbean and Andean altiplano to evaluate paleoclimatic variations during the period when the Mayan and Tiwanaku cultures arose. Additionally, Kutzbach and Street-Perrott (1985) and Street-Perrott and Harrison (1985) verified paleoclimatic model simulations since 15,000 yBP at 3,000 year intervals by comparing the model-based closed-lake area estimates in the Northern Hemisphere tropics with the geologically-based lake-level evidence. Holocene lake-level variations in Europe and Central and North America are explained in other studies by the direct effects of sea-level, solar insolation, and atmospheric circulation changes (Hodell et al., 1991; Harrison and Digerfeldt, 1993; Wright et al., 1993; Yu et al., 1997; Abbott et al., 2000; Anderson et al., 2005). The sensitivity of lake systems to climate is evident by the distribution, size, and thermal structure of lakes throughout the world (Hostetler, 1995). Lake-level variations, by providing effective moisture balance information unavailable from temperature-sensitive paleoclimatic sources, are indispensable archives of paleoclimatic information with which to study climate change.

Case study: Lake Titicaca, Bolivia/Peru

A multi-proxy high-resolution lake-level study of Lake Titicaca documented periods of severe drought during the last 4,000 years in the central Andean altiplano in order to investigate relationships between climatic and cultural change during the late Holocene (Abbott et al., 1997). Fifteen sediment cores were collected on a transect from shallow (1.9 m) to deep (20.2 m) water from Lago Wiñaymarka, an isolated section of the larger Lake Titicaca basin, connected by a 21 m-deep channel through the Tiquina Strait (Binford et al., 1997). Lake Titicaca is a large (8,300 km²), deep (280 m) water body located on the border of Bolivia and Peru. During the late Pleistocene and Holocene, the lake alternated between an open and closed hydrological system. It is in the upper reaches of a much larger endorheic system that includes Lago Poopo and the salares of central and southern Bolivia. Today, water drains out of Lake Titicaca over a bathymetric sill at 3,804 m a.s.l. down the Río Desaguadero from the southwest corner of Lago Wiñaymarka (Wirmann, 1992). The lake has undergone

measurable water-level changes during the historic period (AD 1914 to present), ranging from 3,806.2 m a.s.l. in 1943 to 3,812.6 m a.s.l. in 1986, with an average annual fluctuation of 0.8 m (Roche et al., 1992). The Lake Titicaca basin is particularly sensitive to drought because even with the overflowing conditions that prevail today, only 1 to 3% of the lake water is lost by surficial overflow. The majority of the balance is lost to evaporation in the high altitude semi-arid environment.

The water-level history of Lake Titicaca was reconstructed from the lithostratigraphy and 60 radiocarbon measurements. First, the dated cores were used to identify stratigraphic levels where erosion surfaces occurred, indicating that the lake level was below that point (Figure L2). Second, for the periods with erosional surfaces, the transect of cores was used to identify the highest stratigraphic level where lacustrine sediments were preserved, indicating that water level was above that point. Using this twofold stratigraphic approach, five periods of significant lake-level depression forming five erosion surfaces were defined by the following criteria: (a) scour marks, (b) mud cracks, (c) abrupt transitions (<1 cm) characterized by coarser-grained (fine-sand) sediments with high bulk density (>1 g cm⁻³) overlying fine-grained organic-rich mud (>20% organic matter), (d) an abrupt increase in both iron and potassium concentration associated with the reducing conditions

in water-saturated soils, and (e) highly fragmented shell material in the overlying mud. The presence of one or more of these characteristics combined with an abrupt change in the radiocarbon age of adjacent strata indicates erosion or non-deposition. Detailed core descriptions, smear-slide mineralogy, and radiocarbon stratigraphy were used to delimit water-saturated soils and erosion surfaces formed during low water stands and sub-aerial exposure. Shallow-water subfacies (<2 m water depth) were identified by: (a) the presence of high concentrations of achenes (seeds) of the littoral sedge *Schoenoplectus tatora* in a coarse-grained matrix (silt to sand), (b) large amounts of aquatic plant macrofossils (*Myriophyllum*, *Chara*, and *Potamogeton*), and (c) sediments containing >90% CaCO₃ composed of calcified macrophyte coatings and fragmented mollusk shells.

This study demonstrated the presence of middle to late Holocene hydrological fluctuations on the South American altiplano as shown by five periods of low water stands in Lake Titicaca. The water level of Lake Titicaca fluctuated >22 m during the past 3,500 years. Four of the lowstands were profound (indicated water lowering depth) and occurred abruptly over a period of 100–200 years. The earliest occurred during a prolonged middle Holocene dry phase that ended after 3,500 BP. All of the cores collected in Lago Wiñaymarka

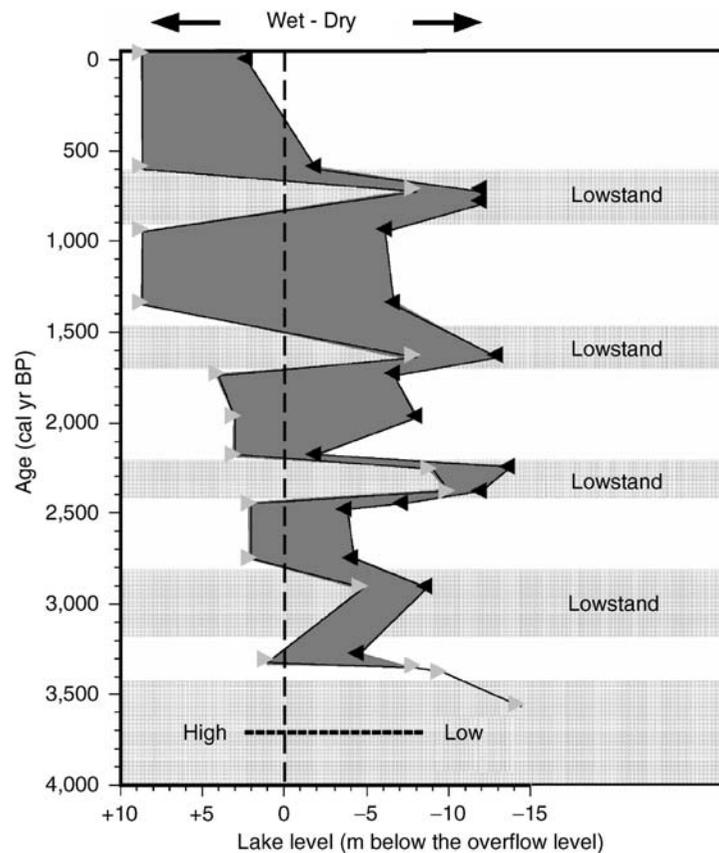

Figure L2 Lake-level reconstruction from Lake Titicaca based on lithostratigraphy from four cores and 60 AMS ¹⁴C measurements. The Gray Triangle symbol signifies the lowest stratigraphic level in cores A-D where an erosion surface occurs, indicating that lake level was below this point at the time indicated. Likewise, the Black Triangle symbol indicates the highest stratigraphic level where lacustrine sediments are preserved, implying water level was above this level.

for this study penetrate into previously sub-aerially exposed sediments, indicating that Lake Titicaca was >15 m below overflow level (BOL) prior to 3,500 BP. A second lowstand of 5–8 m BOL occurred between 3,200 and 2,800 BP. Shallow-water sub-facies between 3,500 and 2,800 BP suggest the lake remained below the overflow stage during this period. The third lowstand of 10–12 m BOL ended after 2,200 BP. The duration of this dry phase is estimated at 200 years. The fourth lowstand of 10–12 m BOL ended after 1,450 BP. The duration of this phase remains unknown, but is likely to have been near 250 years based on sediment accumulation rates. The final low lake level of 7–12 m BOL began prior to 900 BP and ended after 600 BP. Shallow-water subfacies suggests that water level probably remained low until 500 BP. The final lowstand is coincident with the decline of raised-field agriculture and collapse of Tiwanaku culture.

LAST GLACIAL MAXIMUM

Introduction

The Last Glacial Maximum (LGM) occurred when ice sheets and glaciers throughout the world were at their maximum extent during the last ice age. Once dated as 18,000 radiocarbon (21,500 calibrated/sidereal/“calendar”) years ago, the LGM is now believed to have occurred between 23,000 and 19,000 (cal) years ago (Clark and Mix, 2002). However, debate continues regarding its extent, timing and the nature of its ice sheets (below). The LGM is believed to have resulted from climate change caused by changes in the orbital configuration of the Earth. However, the LGM was synchronous in both hemispheres, suggesting that poorly understood feedback factors probably operated. Somehow, they provided sources of precipitation for ice growth and maximum expansion at the LGM.

The LGM is an important “time-slice” for paleogeographic reconstruction and computer simulation because the configuration of the Earth differed so greatly from that of the present. Extensive mid-latitude ice sheets existed in North America, northwest Europe and, controversially, in northern Russia and Siberia. The shape of ocean basins and coastlines was different because water abstracted from the ocean and locked in the ice sheets lowered sea level by between 120 and 130 m. This altered the chemistry of the ocean, which became more saline and isotopically ($\delta^{18}\text{O}$) heavier. Atmospheric circulation was modified by the large ice sheets: for example, the LGM Laurentide Ice Sheet (LIS) split the jet stream into two arms. Thick ice sheets caused the Earth’s crust to subside glacio-isostatically, the extent of which is partly revealed by raised shorelines fashioned as the crust recovered and sea level rose during and after deglaciation. Modeling these effects has provided constraints on the rheology of the Earth’s mantle and crust. The concentration of greenhouse gases in the atmosphere (CO_2 and CH_4) was lower than at present, at a time of reduced ocean and continental temperatures throughout the world. Vegetational zones were compressed by latitude and altitude. General aridity prevailed as deserts expanded and extensive dust storms deposited sand and silt (loess) deposits. However, in some regions that are arid today, extensive lakes occurred, such as Lake Bonneville and Lake Lahontan in America (Benson, 2004).

History

The term “Last Glacial Maximum” is relatively recent and refers to the time of maximum global ice volume inferred from the oxygen isotope stratigraphy ($\delta^{18}\text{O}$) of ocean sediments (CLIMAP, 1976, 1981). While the $\delta^{18}\text{O}$ signal is a global one, it conceals a wide variety of temporal responses by different ice masses caused by regional climate variation as well as the glaciological and environmental characteristics of individual ice sheets and glaciers. This was recognized when the LGM was re-defined as having occurred between 23,000 and 19,000 (cal) years ago (Clark and Mix, 2002).

The LGM concept has older antecedents that identified the maximum extent of continental ice sheets during the “latest” or “last” glaciation (Flint, 1971; Sibrava et al., 1986). This was based on field mapping of “fresh” and relatively unmodified glacial and glaciofluvial landforms, such as moraines, drumlins and eskers. First developed in the midwestern USA,

where the ice maximum became known as the “Classical Wisconsin” (Flint, 1971), this method was also applied to Great Britain and Ireland where a “newer drift” (LGM) was distinguished from an older one. However, this criterion is not always reliable: the “fresh” moraines of the Warthe glaciation in Germany were once thought to be LGM, but are older than the Eemian (“last interglacial”). Only the late Weichselian glaciation is of LGM age.

Techniques

Glacial geology in the field provides evidence regarding ice source regions, ice movement and the extent of LGM ice. Estimating the precise age of the glaciation is essential for determining its timing and regional variability. Since 1950, radiocarbon dating has been used to accomplish this essential task, with ^{14}C accelerator mass spectrometry (AMS) providing greater precision and accuracy. Where ^{14}C dating of organic samples is impossible, cosmogenic rock exposure ages can now date glacial boulders and glaciated rock surfaces (Gosse and Phillips, 2001). Uranium series dating of corals provides information on the LGM sea level – a means of estimating continental ice volume. Within this dating framework, a whole range of environmental disciplines use data from continents and oceans to complete the picture beyond the LGM ice sheets. These data form the basis of computer simulations of the LGM climate and, reciprocally, provide validation or question such simulations (Ruddiman, 2000). LGM ice sheets have also been simulated as three-dimensional thermodynamic ice-sheet models.

Extent of glaciation

Two versions of the possible extent of ice in the Northern Hemisphere at the LGM were assembled by Denton and Hughes (1981) and CLIMAP (1981): a minimum and a maximum reconstruction (Figure L3). The main differences involve the extent of glaciation in northern Russia and Siberia and Arctic Canada (below). In the Southern Hemisphere, the Antarctic ice sheet extended across the continental shelf to its edge and large ice caps expanded in the Himalayas, South America and New Zealand. High altitude small ice caps and glaciers at lower latitudes expanded in East Africa, the Andes, New Guinea and Hawaii. However, the greatest expansion occurred in the mid- to higher-latitudes of North America and Europe, for which there is no present-day analogue.

The extent of ice at the LGM is well established on the southern margins of Northern Hemisphere mid-latitude ice sheets. The LIS, which was coextensive with the Cordilleran Ice Sheet of the Rocky Mountains, advanced to Long Island, Ohio, Illinois, Iowa and South Dakota. In Europe, the Fennoscandian Ice Sheet advanced to Berlin and Warsaw. However, the northern margins of LGM ice continue to be the subject of debate (Andrews, 1987). Ongoing controversy continues regarding northwestern Russia and eastern Siberia, where a major expansion of the Barents Sea and Kara Sea ice sheets may predate the LGM. Much of the evidence is submarine and insufficient reliable age estimates are available on land.

Ice sheet reconstructions

The LGM reconstructions of CLIMAP were based to a large extent on a “marine-based” ice sheet model from Antarctica (Denton and Hughes, 1981). For example, in North America, the LIS reconstruction was a high-elevation, over 4 km thick, single ice dome centered over Hudson’s Bay. Similarly, the

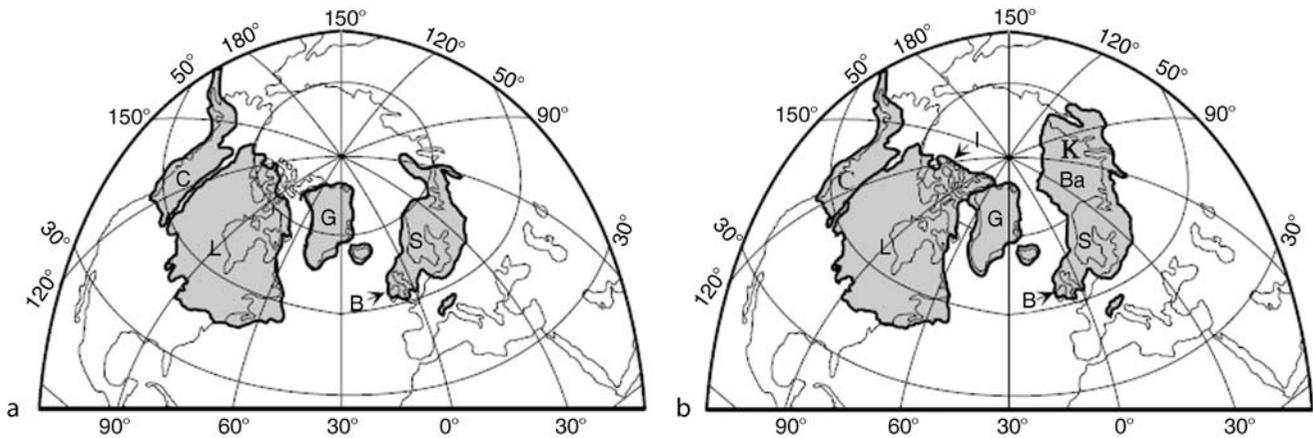

Figure L3 (a) The CLIMAP minimum reconstruction of Northern Hemisphere LGM ice sheets; (b) The CLIMAP maximum reconstruction of Northern Hemisphere ice sheets. L: Laurentide Ice Sheet; C: Cordilleran Ice Sheet; I: Innuitian Ice Sheet; G: Greenland Ice Sheet; B: Great Britain and Ireland Ice Sheet; S: Scandinavian (Fenno-Scandian) Ice Sheet; Ba: Barents Sea Ice Sheet; K: Kara Sea Ice Sheet. This does not show smaller ice caps: for example, in the western USA or the Pyrenees. See text for the location of the smaller Southern Hemisphere ice sheets and ice caps.

Fenno-Scandian ice sheet was centered over the Gulf of Bothnia, where it exceeded 3 km in thickness. These became standard ice-sheet boundary conditions for computer simulations of the LGM climate. More recent ice sheet modeling suggests an ice thickness of over 3.8 km for the LIS, with mean volumetric estimates of 10^{15} m^3 (Marshall et al., 2002).

Glacial geology in the field, however, especially indicators of ice movement from glacial erratics, is not consistent with the CLIMAP reconstruction. Instead the field evidence points to a multi-domed and thinner LIS. The LIS was less extensive in the Canadian Arctic and, as such, supports the minimum view of LGM glaciation (Andrews, 1987; Dyke et al., 2002). A thinner, multi-domed ice sheet is believed to have responded more rapidly to changes in climate: for example, Heinrich events, massive ice discharges into the ocean once thought to have lasted about 2,000 years, are now believed to have lasted only 250 years. Such rapid changes are consistent with climate events inferred from ice core records in Greenland.

Timing of the LGM

Table L1 shows estimates of ice volume and the amount of sea lowering at the LGM. Recent estimates based on hundreds of AMS ^{14}C and uranium series ages from corals in Barbados suggest that the lowest sea level occurred 26,000 years ago (Fairbanks and Peltier, 2004).

Radiocarbon dating indicates that the LIS may have advanced rapidly to its maximum extent as early as 27–29 cal ka BP, well before the LGM, and remained near that limit until 17 ka (cal). However, the Cordilleran Ice Sheet in the Puget Sound region did not reach its maximum extent until 4,000 years later. Similarly, the Antarctic Ice Sheet reached its maximum extent at different times in different sectors. The Scandinavian and British ice sheets were not joined at the LGM (compare with Figure L3), but may have been joined somewhat earlier. They reached their maximum extent about >26 (cal) ka along western margins, but about 23–22 (cal) ka on their southern margins.

The age of the LGM on the northern margin of the LIS is unknown and may be much younger than on its southern margin. All that is known is that deglaciation commenced about 15,000 years ago, an age probably close to maximum expansion

Table L1 Estimates of ice equivalent sea level (m) for LGM ice sheets (adapted from Clark and Mix, 2002)

Ice sheet	CLIMAP min.	CLIMAP max.	Model min.	Model max.
Antarctica	24.5	24.5	14	21
North America	77	92	82.4	82.4
Greenland	1	6.5	2	3
Eurasia	20	34	13.8	18
All Others	5	6	6	6
TOTAL	127.5	163	118.2	130.4

(Andrews, 1987; Dyke et al., 2002). Uncertainty in establishing the age of the LGM in some regions arises because suitable samples are unavailable for radiocarbon dating, a deficiency now being addressed by cosmogenic rock exposure ages.

LAST GLACIAL TERMINATION

Late Quaternary climates are characterized by successive glacial and interglacial periods. While glacial inceptions are usually progressive, the transitions from full glacial conditions to full interglacial ones occur within about 10 kyr or less. During these remarkable time periods, named terminations, the climate system experiences considerable reorganizations. The Last Glacial Termination, between approximately 20 and 8 kyBP, is of particular interest since it can be studied in detail and can be dated with good accuracy using radiocarbon methods. If, by definition, the major event is the disappearance of the large Northern Hemisphere ice sheets (Laurentide and Fennoscandian) with a resulting sea-level rise of about 120 m, this is associated with many other important changes. First, the warming recorded in Greenland ice cores or in marine cores at high northern latitudes does not smoothly follow the decreasing size of continental ice areas. On the contrary, abrupt warmings and coolings, associated with changes in ocean circulation punctuate the transition. Second, many well-dated climatic proxies suggest that some generalized warming that was recorded in tropical or southern marine cores occurred before any major reduction of northern ice sheets. Third, the rise in atmospheric carbon dioxide concentration from glacial levels around 180–200 ppm towards interglacial levels around 260–280 ppm also occurred several thousands of years before the continental ice volume decrease. All these facts are not

easily explained in the context of the Milankovitch theory, which claims that astronomical changes affect the mass balance of ice sheets, and consequently lead to global climatic changes. Understanding the dynamics of the Last Glacial Termination is therefore a critical step both for the theory of glacial-interglacial cycles as well as for understanding millennial scale climatic variability.

Astronomical forcing and ice volume changes

Terminations attracted the attention of paleoclimatologists when they examined the first continuous marine isotopic records. The characteristic sawtooth character of climatic changes was first outlined by Emiliani (1966). The notion of terminations was introduced by Broecker and van Donk (1970) and it was already clear at this time that the astronomical theory would not easily explain this structure (Broecker and van Donk, 1970): “... the cause of the primary sawtoothed cycle is still an open question.”

Though this early definition of terminations was descriptive, it is interesting to note that terminations do systematically correspond to deviations that would be predicted by a linear astronomical theory of Quaternary climate, as illustrated in Figure L4. If the origin of these sawtoothed 100 kyr glacial-interglacial cycles is linked to astronomical parameters, it remains to be explained what amplifying feedbacks are involved during terminations. When examining the last five or ten terminations, there is no direct correspondence between the timing or intensity of terminations and the insolation forcing. On the contrary, termination V, between isotopic stages 12 and 11, was one of the largest transitions, although it occurred about 425 kyBP when insolation changes were quite small. Conversely, termination III, between stages 8 and 9, was not a large transition although seasonal insolation changes were considerable about 243 kyBP.

Probably the simplest way to explain terminations is to envision the sawtooth-like 100 kyr cycles as relaxation oscillations. In this concept, the ultimate cause of terminations would be found in the preceding glacial maximum, and the insolation forcing only acts as a favorable external influencing factor. This can quite successfully explain the timing of events (Paillard, 1998) as well as the amplitude and phase of terminations (Parrenin and Paillard, 2003). However, a mechanistic understanding of terminations needs a closer inspection of the evolution of different climatic parameters like temperatures at different Earth locations, deep oceanographic properties, sea level, or greenhouse gas concentrations. A detailed sequential chronology of these changes is available for the last termination.

The sequence of events during the Last Glacial Termination

The summer insolation forcing at high northern latitudes (taken at the summer solstice) steadily increased from the Last Glacial Maximum (LGM) about 21 kyBP up to 11 kyBP, in the middle of the termination, at the peak insolation time. However, the mid-transition actually occurred around 12 kyBP, while the maximum insolation forcing happened later, around 11 kyBP for June insolation, around 8 kyBP for August insolation, and around 9 kyBP for the averaged summer forcing. This highlights the fact that the phase relationship between astronomical forcing and global ice sheet volume is poorly understood on a millennial time scale. However, as shown in Figure L5, the temperature variations have a much more complex history.

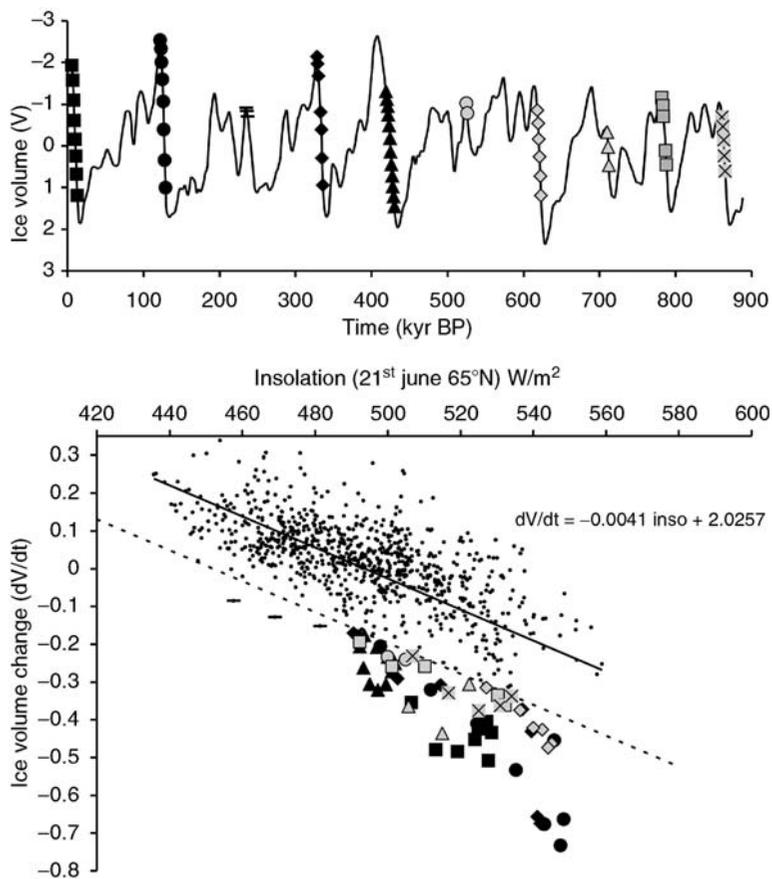

Figure L4 The *top curve* is a classical reconstruction of glacial-interglacial cycles, based on the $\delta^{18}\text{O}$ of foraminifera, and interpreted here as normalized ice volume V (Bassinot et al., 1994). On the *diagram below*, the derivative (dV/dt) is plotted as a function of the insolation forcing. A clear linear relationship is obtained, in large part due to the tuning methodology used to build a timescale for the ice volume data. However, marked points are significantly below the regression line (*heavy line*). It is then possible to define terminations as time periods during which ice volume decreases much faster than a linear astronomical theory could predict (*below the dotted line*). They occur about every 100 kyr, as can be seen on the *top panel* where the same marked points are represented.

At high northern latitudes, an abrupt warming was observed in Greenland around 14 kyrBP, as well as in many other locations in Europe and in the North Atlantic. The following warm interval (Bølling-Allerød) only lasted about two thousand years and ended with an abrupt cooling event into the Younger Dryas time interval. This cold period was shorter than a thousand years and also ended abruptly with a warm period that progressively led into the Holocene and the present-day climate. The same pattern is also visible in the atmospheric methane (CH_4) concentration recorded in Greenland ice cores. However, records from Antarctica or from the Southern Ocean have almost the opposite pattern, with a cooling occurring in the middle of the transition, the Antarctic Cold Reversal, during the northern warm Bølling-Allerød interval. The explanation for such rapid climatic changes, as shown for example by $^{231}\text{Pa}/^{230}\text{Th}$ records, involves major changes in the Atlantic deep circulation, which transports heat from one hemisphere to the other. This opposition has been named the “bipolar-seesaw” (Stocker, 1998). These abrupt changes recorded during the last termination are a clear indication that the internal variability of our climate is of primary importance in accounting for the dynamics of glacial-interglacial transitions.

The atmospheric CO_2 concentration closely follows the evolution of Antarctic temperatures, although some secondary features are probably linked to the northern climate (Monnin et al., 2001). Interestingly, this southern temperature rise started around 18 kyrBP, when the northern ice sheets were still close to their maximum volume. Explaining this southern warming with an astronomical forcing appears quite problematic, although the annual mean insolation and the obliquity forcing may have some importance (Loutre et al., 2004). More than half of the glacial-interglacial pCO_2 increase, from 180 to 240 ppm, occurred during this early phase, between 18 kyrBP and 14 kyrBP, while sea level rose by about only 20 m above glacial levels. Furthermore, an early warming has also been found in many other locations, like the tropics (Lea et al., 2000). It is therefore reasonable to assume that this early atmospheric CO_2 rise and the associated warming had a critical role in the triggering of the deglaciation. In this context, the key to understanding the terminations probably lies in the carbon cycle (Paillard, 2001), and the fundamental question is not in understanding why pCO_2 was low during LGM, but why it rose rapidly just afterwards. If maximum global ice volume was a trigger for some Southern Ocean warming and pCO_2

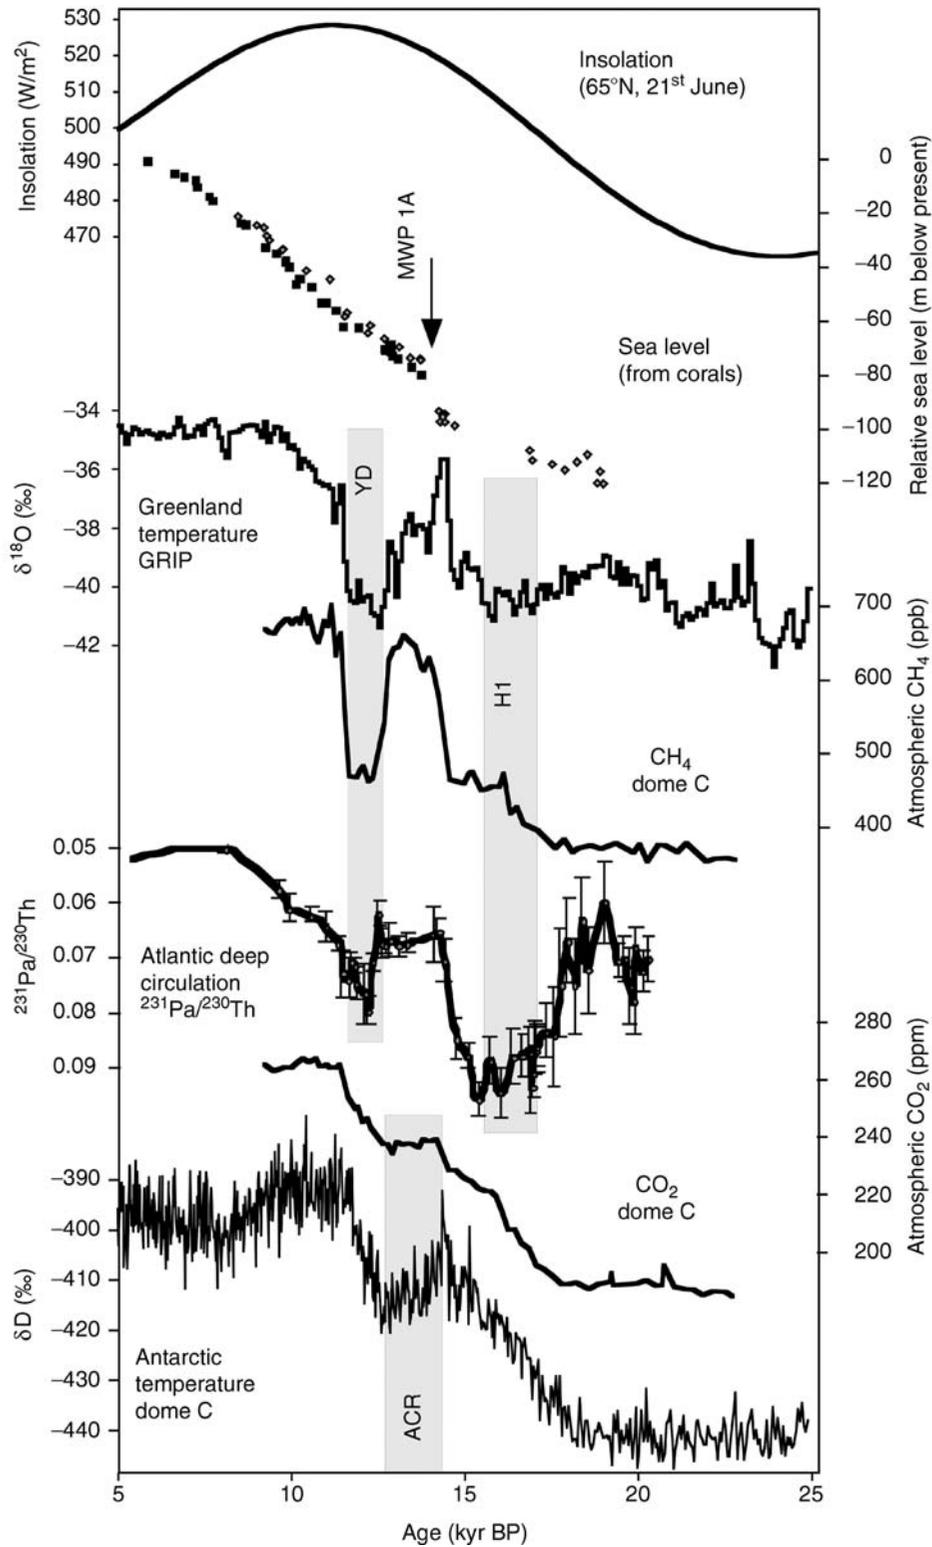

Figure L5 From top to bottom, daily insolation forcing at the summer solstice at $65^\circ N$ (Berger, 1978); sea level reconstructed from corals (Fairbanks, 1989; Bard et al., 1996); Greenland temperature based on oxygen isotopes (Dansgaard et al., 1993); atmospheric CH_4 concentration recorded at Dome C (Monnin et al., 2001); intensity of the deep oceanic circulation based on $^{231}Pa/^{230}Th$ ratio (McManus et al., 2004); atmospheric CO_2 concentration (Monnin et al., 2001); Antarctic temperature based on deuterium measured at Dome C (Stenni et al., 2001). Cold events are highlighted: Heinrich event 1 (H1), Younger Dryas (YD), Antarctic Cold Reversal (ACR).

increase, as required by the relaxation oscillation paradigm, it is natural to look at the evolution of the Antarctic Ice Sheet at this time. Since it is largely driven by sea-level changes, the Antarctic continental ice reached its maximum by entirely covering the continental shelves several thousands of years after the LGM (Denton and Hughes, 2002). A possible scenario is to assume that this could affect sea ice formation and bottom water formation around Antarctica. If we furthermore hypothesize that low CO₂ levels during glacial times are linked to Southern Ocean bottom water characteristics, then expansion of the Antarctic Ice Sheet could lead to the atmospheric pCO₂ increase. This would account both for the triggering of terminations and for the observed sequence of events (Paillard and Parrenin, 2004).

Millennial scale variability and terminations

The role of the millennial-scale climatic variability on the dynamics of the last termination remains an open question. As shown in Figure L5, the southern warming and pCO₂ increase are associated with a major decrease in the deep Atlantic Ocean circulation. This oceanic slowdown is traditionally explained by the massive iceberg discharge from the Laurentide Ice Sheet, known as Heinrich event 1, which occurred around 17 kyBP. A reasonable hypothesis would be to put these millennial scale changes at the center of the dynamics of terminations, but many questions still need to be resolved: What triggers Heinrich events? Are deep circulation slowdowns caused solely by iceberg discharges? What is the role and dynamics of the Younger Dryas and, more generally, of Dansgaard-Oeschger events? How can a Southern Ocean warming explain a rapid pCO₂ increase by 40–60 ppm in only 3 or 4 thousand years? All these questions are currently being closely examined by paleoclimatologists, and their answers should lead to a new understanding of the Last Glacial Termination. They also highlight how far we have come from the traditional Milankovitch theory in which Quaternary ice volume changes were tentatively explained only by insolation and ice sheet mass balance. If Dansgaard-Oeschger events, the Younger Dryas, Heinrich events, associated Antarctic warmings, and finally glacial-interglacial cycles appear today to be rather different topics, the detailed history of the Last Glacial Termination suggests that understanding the links between these different aspects of climatic variability could provide the clue to a revised and a more integrated theory of Quaternary climates.

LATE PALEOZOIC PALEOCLIMATES

Introduction

The climate of the late Paleozoic, particularly the Pennsylvanian and Early Permian, was very similar to the present-day climate. During both intervals, the South Pole experienced significant glaciation and the North Pole experienced intermittent glaciation (Hambrey and Harland, 1981; Zachos et al., 2001). Because of this, the term “ice house” has been used to describe the climate of both intervals. Paradoxically, although the poles were frigid, warm, wet climates prevailed at the equator during both intervals. In both intervals, glaciation occurred in the context of a major continental collision: between Laurussia and Gondwana to form Pangaea in the late Paleozoic; and between India and Asia to form Eurasia in the Cenozoic. Finally, in both intervals, an extended period of “hot-house” climate, with warm poles and shallow pole-to-equator temperature gradients, preceded glaciation (Ziegler et al., 1981; Zachos et al., 2001; Raymond and Metz, 2004).

Late Devonian glaciation (Glacial I) and paleoclimate

The onset of Southern Hemisphere glaciation in the Late Devonian is a logical place to begin our consideration of late Paleozoic paleoclimates. Although this glaciation was relatively short, perhaps less than 0.5 million years (McGhee, 1996; Streele et al., 2000), it signals the beginning of the transition between the early Paleozoic “hot-house” and the late Paleozoic “ice-house” or glacial climates. Isbell et al. (2003) referred to this glaciation as Glacial I (Figure L6). Late Famennian (Glacial I) sediments appear in a number of South American basins (Bolivia, Madre de Dios, Solimoes, Amazonas, Paranaiba) and possibly in Libya (Isaacson et al., 1999; Streele et al., 2000). This glaciation coincided with the deposition of the Hangenberg Shale, a black, organic-rich shale deposited on top of ramp and platform carbonates in low and mid-latitudes (Caplan and Bustin, 1999). The

Hangenberg is one of a series of organic-rich shales and limestones deposited on Devonian and early Mississippian continental shelves, termed “Kellwasser event beds” after the extensive Kellwasser Horizon that marks the Frasnian-Famennian boundary (House, 1985). During Kellwasser events, anoxic or dysoxic water flooded continental shelves and the burial rate of organic carbon increased (Buggisch, 1991).

The terrestrial floras and marine faunas of the Late Devonian and Mississippian were extremely cosmopolitan (Ziegler et al., 1981; McGhee, 1996; Streele et al., 2000; Raymond and Metz, 2004), suggesting a shallow pole-to-equator temperature gradient. In the Mesozoic and early Cenozoic, shallow latitudinal temperature gradients reflect extremely warm poles (Valdes, 2000). In the Late Devonian, however, cosmopolitan floral and faunal assemblages may reflect equatorial cooling. Evidence for cool equatorial temperatures associated with Late Devonian glaciation includes contraction of the ranges of calcareous foraminifera toward the equator (Kalvoda, 1986) and the increasing diversity of deep-water siliceous sponges in the latest Devonian (McGhee, 1996).

Late Devonian glaciation was preceded by mass extinction at the Frasnian/Famennian boundary: 13–38% of marine families, 29–60% of marine genera and 82% of marine species became extinct (Sepkoski, 1986; McGhee, 1996). This mass extinction appears to have been related to equatorial cooling and flooding of continental shelves with anoxic or dysoxic water, although other mechanisms have been proposed (see Raymond and Metz, 2004 and references therein). In the Late Devonian mass extinction, equatorial taxa suffered higher percentages of extinction than southern cold-temperate and polar taxa; and, shallow water, presumably warm-adapted corals suffered greater percentages of extinction than deep water, presumably cold-adapted, corals (Scrutton, 1988; McGhee, 1996).

Late Devonian glaciation coincided with a second interval of increased extinction at the Devonian-Carboniferous boundary: approximately 16% of marine families and 21% of marine genera became extinct (Sepkoski, 1986). However, these extinctions show no clear latitudinal pattern.

Witzke (1990) reviewed the use of sedimentological indicators (coals, bauxite, kaolinite, evaporites and calcretes) to define climate zones. Based on sedimentological indicators, we can identify the following Late Devonian climate zones: (a) a wet, equatorial zone, coincident or slightly to the north of the paleoequator; (b) two arid, subtropical zones to the north and south of the equatorial zone and a southern wet, warm temperate zone; and (c) a southern cool temperate zone associated with South Polar glaciation (Figure L7).

Mississippian paleoclimate

Late Devonian glaciation may have persisted into the earliest Mississippian (Isaacson et al., 1999; Isbell et al., 2003), although earliest Mississippian glacial sediments are poorly dated (Streele et al., 2000). Aside from these putative earliest Mississippian glacial deposits, the first two stages of the Mississippian, the Tournaisian and Viséan, were apparently free of significant glacial ice.

Based on sedimentary indicators, the following climate zones can be identified: (a) a zone of wet “equatorial” climate, which lay to the north of the paleoequator on the northwest side of Pangaea and coincided with the paleoequator on the east side of the continent; (b) a zone of arid climate to the south; (c) a southern warm temperate zone to the south of the arid zone; (d) a southern cool temperate zone to the

(1992), and Crowell (1999). While glaciation may have persisted until the end of the Permian (Frakes et al., 1992; Crowell, 1999; Isbell et al., 2003); others have suggested that glaciation ended in the mid-Permian (Veevers and Powell, 1987; Gibbs et al., 2002; Rees et al., 2002).

south of the arid zone; and (e) a northern warm temperate zone to the north of the equatorial wet zone (Figure L8).

Rowley et al. (1985) reviewed the phytogeography of Tournaisian and Visean floras. In both intervals, northern warm temperate floras from Siberia are distinct. In both, wet tropical assemblages from Europe and South China appear distinct from arid tropical assemblages found in the Canadian Maritimes. Few Tournaisian Gondwanan assemblages were included in their study; however, Visean Gondwanan assemblages from the warm temperate zone have a distinct floral assemblage (Iannuzzi and Pfefferkom, 2002).

The migration patterns of marine invertebrates allow us to trace the relative climate of the Mississippian. In the mid-to-late Visean, a statistically significant percentage of articulate brachiopod genera expanded their range toward the poles,

suggesting that both poles became warmer in the late Visean. Although the biostratigraphic resolution of land plant migrations is not as precise as that of brachiopods, Northern Hemisphere land plants show a similar range expansion toward the pole in the Visean (Raymond, 1985; Raymond et al., 1990; Kelley and Raymond, 1991).

Late Mississippian-Permian glaciation (Glacial II and III) and paleoclimate

Marine invertebrate migration patterns suggest that the North Pole remained warm into the Sepukhovian (Raymond et al., 1990). In the Southern Hemisphere, however, a significant percentage of genera migrated away from the South Pole in the late Visean to Sepukhovian, suggesting South Polar cooling during the Serpukovian (Kelley and Raymond, 1991). A growing

body of evidence suggests that this migration away from the South Pole was related to the onset of significant glaciation in the Southern Hemisphere (Isbell et al., 2003). Global regression in the late Serpukhovian has been linked to the onset of Southern Hemisphere glaciation (Bourotz et al., 1978; Ross and Ross, 1988). Glacial sedimentary deposits of Namurian through earliest Westphalian age occur in South America and Australia (Isbell et al., 2003). In addition, shifts in the isotopic composition ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) of marine carbonates from North America, Europe, and the Russian Platform in the Serpukhovian may signal the onset of significant glaciation (Bruckschen et al., 1999; Mii et al., 2001).

Although many lines of evidence suggest that glaciation began in the Serpukhovian, the nature of this glaciation remains uncertain. Isbell et al. (2003) argued that Glacial II sediments resulted from alpine rather than continental glaciation. Others (Veevers and Powell, 1987; Crowell, 1999) argued for continental glaciation during this interval. Resolution of this controversy will require additional data; nonetheless, the biogeographic patterns discussed below indicate that the onset of glaciation in the Serpukhovian had a profound effect on Carboniferous biotas. The biotic response to Serpukhovian glaciation was similar to the biotic response to continental glaciation in the late Tertiary-Recent and very different from the biotic response to Late Devonian glaciation.

The biogeographic differentiation of land plants and marine invertebrates increased dramatically in the early Pennsylvanian (Ziegler et al., 1981). This increase in biogeographic differentiation reflected the biotic response to the establishment of a steep pole-to-equator temperature gradient as a result of glaciation. Crame and Rosen (2002) noted a similar biogeographic response to late Cenozoic glaciation. Late Devonian glaciation occurred during an interval of low biogeographic differentiation, which persisted into the early Mississippian (Raymond and Metz, 2004).

As the poles became frigid, the equatorial climates of the Pennsylvanian became wetter and perhaps warmer as well. Late Visean "equatorial" coal deposits have a broad latitudinal distribution, ranging from 20° S paleolatitude to 30° N paleolatitude on a variety of paleogeographic reconstructions (Raymond, 1996).

A pronounced paleoequatorial coal belt, centered on the paleo-equator, became established in the Serpukhovian and continued throughout the Pennsylvanian and into the Permian (Figures L8–L10). As the equatorial coal belt became established, the diversity of equatorial land plants rose relative to the diversity of mid-latitude and high-latitude land plants (Raymond, 1996). The presence of a pronounced paleoequatorial coal belt and the increased diversity of paleoequatorial land plants during this interval suggest that equatorial climates became wetter during glacial onset. Bande and Prakash (1986) noted a similar increase in the diversity of equatorial land plants between the early and late Cenozoic, which may be tied to late Cenozoic glaciation.

Coal distribution data suggest that the paleo-equator became wetter during glacial onset. Marine invertebrate migration patterns suggest that it may have become warmer as well. A small, but statistically significant percentage of Northern Hemisphere brachiopod genera vacated the equatorial zone in the Serpukhovian by moving their southern boundary away from the equator (Raymond et al., 1989; Raymond et al., 1990). Valentine (1984) noted similar migration patterns for marine invertebrates associated with late Cenozoic glaciation, which he interpreted as evidence for equatorial warming. During Late Devonian glaciation, calcareous foraminifera contracted their ranges toward the pole (Kalvoda, 1986). This migrational pattern is exactly opposite from that of Carboniferous brachiopods and late Tertiary marine invertebrates, and suggests that the low-latitudes became cooler during Late Devonian glaciation.

Ziegler et al. (1987) linked the presence of equatorial coal to cold or glaciated poles. Otto-Bliesner (1993) attributed Pennsylvanian paleoequatorial coal to the orientation and latitudinal placement of the Ouachita and Alleghany Mountains, along an east to west trend, close to the paleo-equator. Paleoclimate models suggested that east-west trending equatorial mountain belts might constrain the position of the inter-tropical convergence zone (the zone of ever-wet, ever-warm climate) to a narrow latitudinal belt, centered on the equator. In the latest Mississippian and early Pennsylvanian, glacial onset and continental collision were so closely spaced in time that it is impossible to distinguish the contribution of mountain building and glaciation from the formation of the paleoequatorial coal belt.

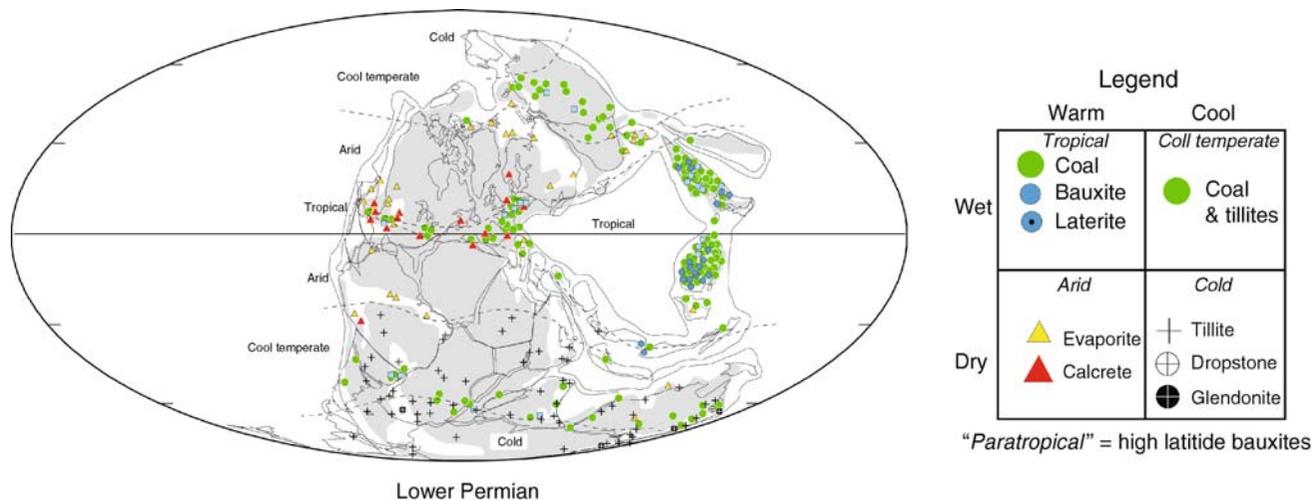

Figure L10 Lower Permian paleogeographic reconstruction showing climate zones and the distribution of sedimentary indicators of early Permian climate (unpublished data, A. J. Boucot, C. Xu, and C.R. Scotese).

The continuity of glaciation during the rest of the Pennsylvanian and into the Permian remains controversial. Isbell et al. (2003) argued for substantially ice-free poles during most of the Westphalian, followed by renewed glaciation in the late Pennsylvanian (Stephanian). Other workers suggested that Gondwana remained glaciated from the Namurian into the Permian and argued for peak glaciation in the Westphalian (Veevers and Powell, 1987; Frakes et al., 1992; Crowell, 1999). Isotopic studies, which suggest warming rather than cooling at the Westphalian/Stephanian boundary (Bruckschen et al., 1999; Mii et al., 2001), appear to contradict Isbell et al. (2003).

The abundance of 4th and 5th order transgressive-regressive cycles, known as cyclothem, in Carboniferous and Permian strata from the Paleo-Northern Hemisphere has been interpreted as evidence for continental glaciation (Ross and Ross, 1988; Heckel, 1994). According to Heckel and others (see Heckel, 1994 and references therein), Milankovitch orbital cycles caused late Paleozoic continental glaciers to advance and retreat, which resulted in the deposition of repeated transgressive-regressive sedimentary cycles in equatorial and low latitudes. Cyclothem are usually linked to continental glaciation because only continental glaciers contain enough water to affect global sea level (Isbell et al., 2003). If cyclothem reflect glacial-eustasy, the presence of Westphalian cyclothem in North America, Europe, the Russian Platform, the Moscow Basin, and the Urals argues for significant Westphalian glaciation. Conversely, Isbell et al. (2003), who felt that the middle and late Westphalian were ice-free, suggested that Carboniferous and Permian cyclothem could have other causes aside from glaciation.

A full understanding of the significance of 4th and 5th order transgressive-regressive cycles known as cyclothem requires more research. The earliest reported cyclothem occur in the early Visean of Great Britain (Wright and Vanstone, 2001), before other signs of significant glaciation, such as increased biogeographic differentiation, the development of the paleoequatorial coal belt, and isotopic shifts indicating global cooling and the growth of glaciers (Bruckschen et al., 1999; Mii et al., 2001; Raymond and Metz, 2004). Some Carboniferous 4th and 5th order transgressive-regressive cycles attributed to glacial-eustasy

may have a different cause. However, glacial-eustasy appears to be a reasonable explanation for repeated 4th and 5th order transgressive-regressive cycles that can be correlated across North America (Heckel, 1994).

Widespread glaciation may have ended in the Middle Permian (Veevers and Powell, 1987; Gibbs et al., 2002; Rees et al., 2002) (Figures L10 and L11). Others (Frakes et al., 1992; Crowell, 1999; Isbell et al., 2003) suggest that Gondwanan glaciers may have persisted to the end of the Permian. Pennsylvanian and Permian marine and terrestrial biotas retained a high amount of biogeographic differentiation, suggesting a relatively steep pole to equator temperature gradient throughout the Pennsylvanian and Permian (Ziegler et al., 1981; Rees et al., 2002). Nonetheless, the presence of fossil forests, reconstructed as cool-temperate deciduous vegetation, in Late Permian sediments from Antarctica, suggests that the Late Permian South Pole was warmer than it was during the Pennsylvanian and Early Permian (Rees et al., 2002). Compared to Pennsylvanian and Early Permian climate, the climate of the Middle and Late Permian was more influenced by monsoonal circulation patterns (Parrish, 1993). As a result, the equatorial zone of the supercontinent Pangea was relatively arid in the Middle and Late Permian and the paleotropical coal belt was confined to island continents, such as South China, which straddled the paleoequator to the east of Pangea at that time.

Summary

In summary, the late Paleozoic was a time of dramatic climatic shifts, punctuated by glaciation events. Clues to these climate changes can be found in sediments, the stable isotopic composition of marine carbonates, and the biogeographic distribution of land plants and marine animals. Late Devonian glaciation (Glacial I of Isbell et al., 2003), which started the interval, appears more similar to Late Ordovician "hot-house" glaciation than subsequent ice-house glaciations in the mid-Carboniferous-to-Permian and late Cenozoic (Raymond and Metz, 2004). The glaciation event that began in the late Serpukhovian or at the Mississippian-Pennsylvanian boundary (Glacial II of Isbell et al., 2003) appears very similar to late Cenozoic glaciation. During both intervals, the poles were cold,

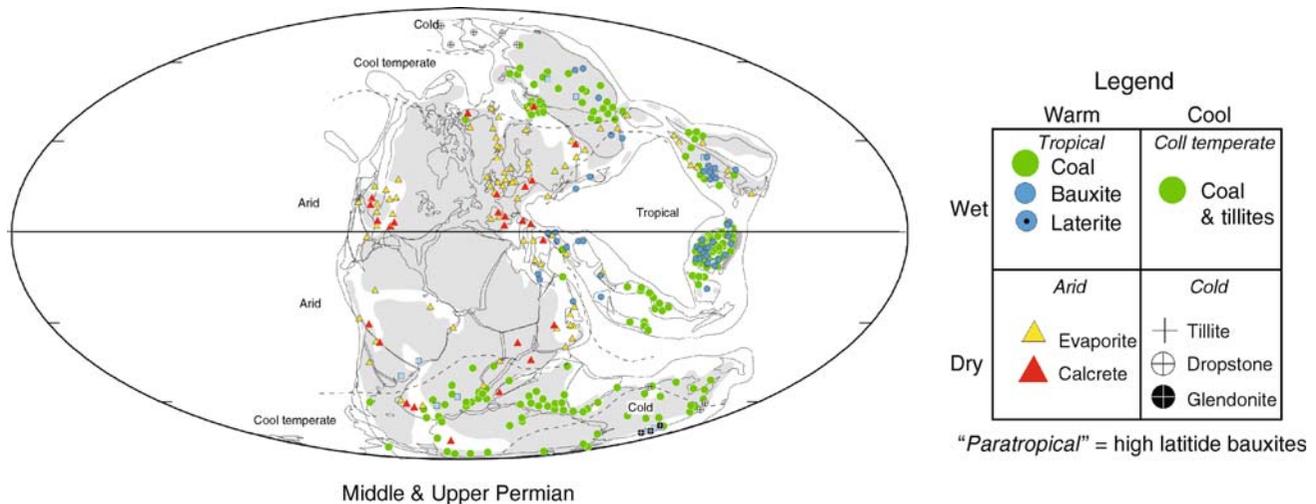

Figure L11 Middle and Upper Permian paleogeographic reconstruction showing climate zones and the distribution of sedimentary indicators of middle and late Permian climate (unpublished data, A. J. Boucot, C. Xu, and C.R. Scotese).

the equator was warm, and there was abundant biogeographic differentiation. Unlike the hot-house glaciations of the Late Ordovician and Late Devonian, Pennsylvanian-Permian glaciation was not marked by mass extinction. Sources differ on the continuity of glaciation in the mid-to-late Pennsylvanian (mid Westphalian through Stephanian) and after the Middle Permian (Veevers and Powell, 1987; Frakes et al., 1992; Bruckschen et al., 1999; Crowell, 1999; Isbell et al., 2003). However, the persistence of biogeographic differentiation throughout the Pennsylvanian to the end of the Permian argues for steep latitudinal temperature gradients, cold poles, and warm, wet equatorial climates until the end of the Paleozoic (Ziegler et al., 1981; Rees et al., 2002).

LATE QUATERNARY MEGAFLOODS

The last major deglaciation of planet Earth (the last portion of Marine Isotope Stage 2, from about 20,000 to 11,000 calendar years ago) involved huge fluxes of water from the wasting continental ice sheets. It has become increasingly apparent that much of this water was delivered as floods of immense magnitude and relatively short duration. These late Quaternary megafloods had short-term peak flows, comparable in discharge to the more prolonged fluxes of ocean currents (The unit of discharge for both ocean currents and megafloods is the Sverdrup, equivalent to 1 million cubic meters per second). Some outburst floods likely induced very rapid, short-term effects on Quaternary climates. The late Quaternary superfloods also greatly altered drainage evolution and the planetary patterns of water and sediment movement to the oceans.

Historical context

During the eighteenth and early nineteenth centuries there were many studies of landscape phenomena that posited the action of phenomenally large floods. Some of these studies invoked a kind of biblical catastrophism, but other studies merely employed hypotheses of immense floods because these phenomena seemed to provide the best explanations for such features as scoured bedrock and accumulations of huge, water-transported boulders. Unfortunately, a logically flawed doctrine of uniformitarianism was promoted in the later eighteenth century (Baker, 1998), effectively retarding progress on understanding the role of cataclysmic flooding in Quaternary processes. The renaissance in catastrophic flood studies of the later twentieth century was made possible because of a long-lasting controversy over the origin of the Channeled Scabland in the northwestern United States. Extending from the 1920s to the 1960s, the great “scablands debate” eventually led to general acceptance of the cataclysmic flood origin that was championed by J Harlan Bretz, a professor at the University of Chicago.

Based on Bretz’s studies of the Channeled Scabland, the distinctive erosional and depositional features of cataclysmic flooding are well known. These include scabland bedrock erosion (Figure L12), streamlining of residual uplands, large-scale scour around obstacles, depositional bars, giant current ripples (fluvial gravel dunes), and huge sediment fans. These features can be identified by orbital remote sensing imagery and by field reconnaissance. These features could be used to discover and document cataclysmic flood effects on more river basins globally.

Megaflood landscapes

Cordilleran

The Channeled Scabland landscape developed south of the Cordilleran Ice Sheet, in the northwestern United States. The Purcell Lobe of the ice sheet extended south from British Columbia to the basin of modern Pend Oreille Lake in northern Idaho. It thereby impounded the Clark Fork River drainage to

Figure L12 Aerial view of giant potholes and butte-and-basin scabland eroded into the basalt bedrock of eastern Washington by the cataclysmic Missoula megafloods, approximately 15,000 years ago. These potholes measure about 15 m in depth and 40 in width. They are in Lenore Canyon, a part of the lower Grand Coulee. Lake Lenore is visible at the upper right.

the east, forming glacial Lake Missoula in western Montana. At maximum extent, this ice-dammed lake held a water volume of about 2,500 km³ with a depth of 600 m at the dam. Repeated failures through subglacial tunnels are inferred to have occurred between about 18,000 and 15,000 years ago (Waitt, 1985). However, these multiple outburst events were of greatly differing magnitudes. About 15 events exceeded 3 Sverdrups, and at least one of these reached about 10 Sverdrups in discharge (Benito and O'Connor, 2003). The largest failure or failures probably involved a different source mechanism than that envisioned by Waitt (1985).

Upon reaching the Pacific Ocean, the Missoula floodwaters continued flowing down the continental slope as hyperpycnally-generated turbidity currents (Normark and Reid, 2003). The sediment-charged floodwaters followed the Cascadia submarine channel into and through the Blanco Fracture Zone and out onto the abyssal plain of the Pacific. As much as 5,000 km³ of sediment may have been carried and distributed as turbidites over a distance of 2,000 km west of the Columbia River mouth.

Laurentide

As the Laurentide Ice Sheet of central and eastern Canada retreated from its late Quaternary maximum extent, it was bounded to the south and west by immense meltwater lakes, which developed in the troughs that surrounded the ice. As the lake levels rose, water was released as great megafloods, which carved numerous spillways into the drainages of the Mississippi, St. Lawrence, and Mackenzie Rivers (Kehew and Teller, 1994). The greatest megafloods developed from the last of the ice-marginal lakes, a union between Lake Agassiz in south-central Canada and Lake Ojibway in northern Ontario. The resulting megalake held about 160,000 km³ of water, which was released subglacially about 8,400 years ago, under the ice sheet and into the Labrador Sea via the Hudson Strait (Clarke et al., 2003).

Eurasian spillways

In the 1970s, Mikhail G. Grosswald recognized that the late Quaternary ice-sheet margins of northern Eurasia, like those

of northern North America, held huge proglacial lakes, and great spillways that developed for the diversion of drainage. Not only was meltwater diverted to the south-flowing Dnieper and Volga Rivers, but the great north-flowing Siberian rivers, the Irtysh, Ob, and Yenesei were impounded by ice sheets that covered the modern Barents and Kara Seas. Though Grosswald's reconstructions created considerable controversy, recent work shows that these impoundments did indeed occur. However, the largest diversions are now dated to about 90,000 years ago, when ice-sheet growth was enhanced by the climatic influence of the ice-dammed lakes (Krinner et al., 2004). The largest megalake, Lake Mansi, drained southward through the Turgai divide of north-central Kazakhstan to the basin of the modern Aral Sea. The Aral, in turn, drained through a spillway at its southwestern end into the Caspian, which expanded to a late Quaternary size over twice its modern extent, known as the Khvalyn paleolake. The Khvalyn paleolake spilled westward through the Manych spillway into the Don valley, then to the Sea of Azov, and through the Kerch Strait to the Euxine Abyssal Plain (the floor of the modern Black Sea). The huge size of the Manych spillway, up to 35 km wide, implies that flows may have reached a peak of 10 Sverdrups (Baker, 1996). During the last glaciation, the Black Sea was isolated from the Mediterranean Ocean, and it filled with fresh water derived from the great system of glacially augmented rivers entering it from the north. The freshwater faunal facies of the Black Sea show that the Caspian was spilling through the Manych spillway around 18,000 years ago and the Black Sea was spilling into the Sea of Marmara, which, in turn, spilled via the Hellespont into the Aegean Sea.

Central Asian uplands

A number of cataclysmic flood landscapes are now recognized in the mountain areas of central Asia. The best studied of these regions is the Altai Mountains of south-central Siberia (Carling et al., 2002). The Altai flooding derived from the Chuja-Kuray ice-dammed lake, which may have held as much as 1,000 km³ of water at a maximum depth of up to 900 m (Baker et al., 1993). Downstream of this ice dam, the Chuja and Katun River valleys are characterized by immense gravel bars, emplaced into various valley-side embayments by the flooding. The bars are up to 5 km long and 120 m in height. The bar surfaces and associated run-up layers of flood-transported gravel indicate maximum flow depths of about 320 m. Flow modeling of the associated paleoflood discharges retrodicts a peak flow of about 11 Sverdrups and mean flow velocities of about 30 m s⁻¹ (Herget and Agatz, 2003).

Another region with extensive evidence of late Quaternary megafloods is Tuva. The Tuvan paleofloods derived from an ice-dammed lake in the Darkhat depression of north-central Mongolia (Grosswald and Rudoy, 1996). The paleolake held about 250 km³ of water with a depth of 200 m at its ice dam. The paleoflooding entered the upper Yenesei River, and it was remarkable for the emplacement of spectacular trains of giant current ripples (gravel dunes) near the Tuva capital city of Kyzyl (Figure L13).

In Kirgizstan, Lake Issyk-Kul, the world's second largest modern mountain lake, was transformed into an even larger ice-dammed lake during the last glaciation. Iceberg-emplaced landforms rise to 300 m above the present lake level (Grosswald et al., 1994). Spectacular erosion at the full-glacial lake outlet, Boam Canyon, indicates that the paleolake failed by cataclysmic outburst flooding. This flood emplaced an enormous outwash fan, extending 85 km from the mouth of Boam

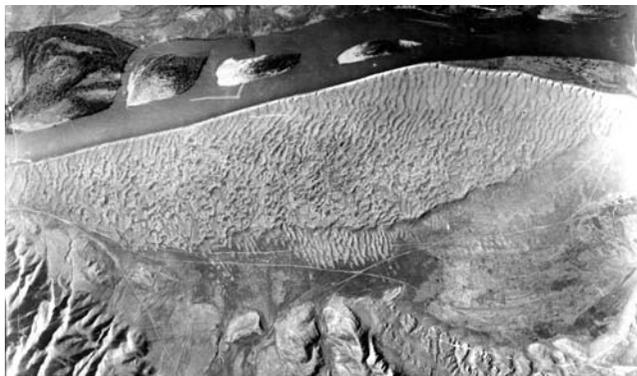

Figure L13 Aerial photograph of giant current ripples (gravel dunes) located near Kyzyl, Tuva. The ripples occur on a gravel bar just north of the Yenesei River (bottom of photograph) about 25 km southwest of Kyzyl. There are nearly 100 ripples on a bar 6 km in length. Ripple heights vary from 2 to 3 m. The photograph shows an area 6 by 4 kilometers. The paleoflood flow was moving from right (east) to left (west).

Canyon. A similar but smaller fan occurs on the upper Yenesei River, where the Tuvan floods emerged from canyons of the West Sayan Mountains and entered the Abakan Basin. Another area of probable glacial cataclysmic flooding is Lake Baikal, which may have expanded during full-glacial periods by ice blockage of its outlet, thereby raising its level of spill points.

Current controversies

Black Sea flooding

Although late Quaternary freshwater inundation of the Black Sea is well recognized, it is usually correlated with enhanced proglacial meltwater flow via the many rivers draining southward from the northern Eurasian ice sheets, as noted above. A recent controversy has arisen, however, over the marine influx to the Black Sea that occurred during rising Holocene sea level. This influx caused Mediterranean water to spill through the Hellespont and Bosphorus, reaching the Black Sea about 9,500 years ago. One view (Ryan et al., 2003) holds that the global ocean rose to the level of a relatively shallow sill of the Bosphorus outlet and catastrophically spilled into the Black Sea basin, which then was partly filled with freshwater to a level about 85 m below that of today. The resulting cataclysmic inundation presumably displaced a large human population in a calamity that is equated to the Noachian flood myth. An alternative view is that much of the Bosphorus is underlain by freshwater facies of late Pleistocene age, derived from the Black Sea. The minimal erosion of these sediments is not consistent with the idea that cataclysmic flooding led to the overlying Holocene marine facies of Mediterranean origin.

Subglacial megafloods

A variety of enigmatic landforms, involving water erosion and deposition, develop beneath very large continental ice sheets. These landforms include drumlins, Rogen moraines, large-scale bedrock erosional marks, and tunnel channels (valleys). Though commonly explained by subglacial ice deformational processes, the genesis of these features cannot be observed in modern glaciers that are much smaller than their late Quaternary counterparts. The assemblage of landforms as part of an erosional/depositional

sequence beneath continental ice sheets that precedes regional ice stagnation and esker formation was explained by Shaw (1996) as resulting from a phase of immense subglacial sheet floods, which, in turn, follow ice-sheet advances that terminate with surging, stagnation and melt-out. Shaw (1996) proposed that peak discharges of tens of Sverdrups are implied by the late Quaternary subglacial landscapes of the southern Laurentide Ice Sheet. Shoemaker (1995) provided some theoretical support for Shaw's model, though at smaller flow magnitude levels.

Global consequences

Ocean currents are integral to Earth's climate engine, distributing heat between the equator and the poles. For example, the Gulf Stream flows at discharges of up to 100 Sverdrups, involving relatively slow moving water 1 km in depth and 50–75 km wide. As this seawater evaporates and becomes more saline, it increases in density, eventually sinking in the northern Atlantic. This process forms a portion of the great thermohaline circulation, which acts as a conveyor belt for heat in the oceans. Cataclysmic megafloods can introduce relatively low-density, freshwater lids over large areas of ocean surface. Freshwater can enter the oceans very rapidly, at flow rates of up to 10 Sverdrups and volumes of thousands of km³. The resulting disruption of sea-surface temperatures and density structure can drastically alter climates, at least on time scales of decades to centuries.

The connections between Pleistocene ice sheets and the oceans are still very poorly understood. An important link is inferred from relatively brief (100- and 500-year) intervals in which thick marine layers of ice-rafted material were widely distributed across the North Atlantic. Called "Heinrich events," these layers are thought to record episodes of massive iceberg discharge from unstable ice sheets. The youngest Heinrich events date to 17,000 (H1), 24,000 (H2) and 31,000 (H3) years ago. Closely related is the Younger Dryas (YD) event, a global cooling at 12,000 years ago, which is also associated with North Atlantic ice-rafted rock fragments. There is evidence from corals in Barbados that sea level rose spectacularly, about 20 m during H1 and about 15 m just after YD. Such rises would require short-term freshwater fluxes to the oceans of about 14,000 and 9,000 km³ yr⁻¹, respectively. (Fairbanks, 1989). These events are thought to relate to ice-sheet collapse, reorganization of ocean-atmosphere circulation, and release of subglacial and proglacial meltwater, most likely during episodes of cataclysmic megaflooding.

LATE QUATERNARY-HOLOCENE VEGETATION MODELING

Introduction

Vegetation modeling is central to understanding the role that plants have played in shaping the Earth's atmospheric composition and climate in the past, and the potential responses and feedbacks of vegetation to future climate changes. Over the past decade, a series of global vegetation models have been applied to the subject of late Quaternary and Holocene climate change. Because a vegetation model provides a complete

picture of the Earth's land surface, and because it produces a diagnostic that can be directly compared to paleo-observations (e.g., plant assemblages), vegetation models have been particularly useful for evaluating the output of general circulation models (GCMs). Progress in vegetation modeling has enabled the researcher to simulate vegetation patterns with more detail, and to evaluate other variables with paleoproxies, such as dust fluxes, methane emissions, and carbon storage. Current directions in late Quaternary and Holocene vegetation modeling include the incorporation of a vegetation model directly into the land surface scheme of GCMs so that vegetation may interact in real time with the climate system through the atmosphere and oceans.

Over the past decade, a variety of process-based, global vegetation models have been developed to study a variety of problems in biogeography, biogeochemistry, and atmospheric composition. These models have been primarily applied to the present-day, but are increasingly being used to study the recent geological past. For paleo-applications, global vegetation models play an important role, because other methods of inferring past vegetation patterns and processes leave the investigator with information gaps, either spatially, temporally, or both. Paleoproxy data from a variety of sources (e.g., pollen, packrat middens) can be used to infer vegetation history and biogeography at a point, but extrapolation is difficult given the sensitivity of vegetation to climatic and edaphic factors beyond the catchment area of the pollen source. The composition of trace gases measured in gas bubbles from ice cores contains some signal of the biogeochemical processes active in the terrestrial biosphere, such as vegetation productivity, methane emissions from wetlands, and compounds produced during biomass burning. However, these ice core records integrate the climatic or environmental signals over entire hemispheres, and thus provide little information about their spatial distribution, which is important in understanding the influence of the biosphere on the climate system and interactions between vegetation and the animal world. Furthermore, the land surface signal in ice cores must often be separated from oceanic activity. For some radiatively important trace gases, including CO₂, this is a difficult task. Thus, to study late Quaternary and Holocene vegetation history, a global vegetation model is an essential tool: as an integrator over both space and time and as a method to estimate the contribution of the land surface to the budgets of greenhouse gases, an important quantity not only at present but also in the past.

Vegetation model structure and processes

The past decade has seen great progress in the development and application of global vegetation models. The latest vegetation models incorporate both biogeographical and biogeochemical processes to simulate vegetation distribution and the fluxes of carbon, water, nutrients, and other trace gases through the terrestrial biosphere. This capability makes current vegetation models a powerful tool for investigating the Earth's surface during the late Quaternary and Holocene, as a variety of problems may be addressed.

Methods

The Plant Functional Type (PFT) is the basic unit of calculation in most global-scale vegetation models. Each PFT is defined to be a generic representation of all plant taxa that share specific characteristics such as growth form (e.g., tree or grass), phenological habit (e.g., deciduous or evergreen; summergreen or raingreen), leaf morphology (e.g., broadleaf or needleleaf),

and other parameters such as root depth distribution and maximum photosynthetic rate. At the computational core of a vegetation model is a scheme that determines the combination of PFTs that make up the vegetation at a certain location. PFT combinations are often combined into assemblages, termed “biomes”; these biomes represent the major vegetation types found on earth (Table L2).

The simplest form of vegetation model (e.g., BIOME1; Prentice et al., 1992) uses a set of rules based on absolute bioclimatic limits to determine the presence or absence of PFTs and then assigns a biome based on a simple hierarchy of these PFTs. More advanced vegetation models, e.g., BIOME4 (Kaplan, 2001), use a coupled carbon and water flux scheme to determine the leaf area index (LAI) that maximizes net primary productivity (NPP) for any given PFT. The PFT hierarchy, and thus the resulting biome, is determined by the list of PFTs ranked by LAI and NPP. Additional rules or climate-based indices may also be used to further refine the biome classification. An advantage of this type of coupled biogeography-biogeochemistry model is that both vegetation structure and the impact of vegetation on global biogeochemistry may be simultaneously investigated. Finally, dynamic vegetation models, e.g., LPJ or IBIS, explicitly simulate the competition among PFTs as they evolve through time.

In the most recent global vegetation models (e.g., BIOME4, LPJ), model operation is based on 12 or 13 PFTs representing physiologically distinct classes from arctic/alpine cushion forbs to tropical evergreen trees. Each PFT is assigned bioclimatic limits that determine whether its net primary productivity (NPP) is calculated for a given grid cell.

Equilibrium versus dynamic global vegetation models

Despite the recent focus on developing dynamic global vegetation models (DGVMs) for carbon cycle research (Cox et al., 2000; Sitch et al., 2003), equilibrium vegetation models that provide a “snapshot” view of the Earth’s surface at a given time remain important for late Quaternary and Holocene vegetation modeling. Equilibrium vegetation models are currently far more detailed and precise than DGVMs in their ability to simulate biogeographic patterns. Additionally, operation of a DGVM requires 10 to 100 times more overhead than an equilibrium vegetation model in terms of the size of input and output datasets and computing power. As such, a DGVM is neither necessary nor appropriate for addressing every research problem. Equilibrium vegetation models provide an efficient method to investigate global ecosystem theory and a required test-bed for developing methods for simulating the behavior of vegetation that may later be applied in a DGVM context. A DGVM is required to study periods of rapidly changing climate where ecosystem “memory” is important, e.g., biogeochemical feedbacks in the anthropogenically-modified environment of the present and the near future. Equilibrium models are more suited to “time slice” analyses where an equilibrium approximation is adequate and interest focuses on regional phenomena that are not as well simulated with current DGVMs.

On time scales greater than ca. 10^2 years, vegetation dynamics are controlled by two main factors: shifts in absolute limits of tolerance for certain plant types and competition among coexisting plant taxa due to shifts in disturbance regime or optimum climate. Thus, most modeling to date for late Quaternary and Holocene studies focuses on simulating the potential, natural equilibrium vegetation at an instant in time (i.e., a time slice). A major reason for choosing time slices for vegetation reconstructions is that paleodata have been assembled for particular time slices, which may be used to evaluate the performance of the model. Furthermore, the computational requirements of producing a time slice simulation of vegetation are much simpler than for a dynamic scenario.

Paleovegetation simulation

For simulation of vegetation of the past, a vegetation model requires paleoclimatology data, which are usually generated from one or an ensemble of paleoclimate simulations from a GCM. Vegetation models can be coupled to the GCM climatology in a variety of ways (Figure L14). In the simplest case, the vegetation model is run “offline” through one-way forward coupling to the GCM climatology. This method has the advantage of being computationally efficient and enables a great deal of flexibility in the choice of GCM output and particular vegetation model used.

To investigate certain phenomena where particular feedbacks between the terrestrial biosphere and the climate system are thought to be important, forms of coupling that are more complicated have been applied. Asynchronous coupling uses a GCM simulation to drive an offline vegetation model, which then provides the land surface conditions (primarily the distribution of the major biomes) to make a subsequent run of the GCM. After three or four iterations, the GCM climatology is usually in equilibrium with the vegetation model. Asynchronous coupling is particularly useful for simulating long-timescale climate changes, such as those that occur on millennial scales, and has been successfully applied to the problem of glacial inception and late Pleistocene deglaciation. Finally, a vegetation model

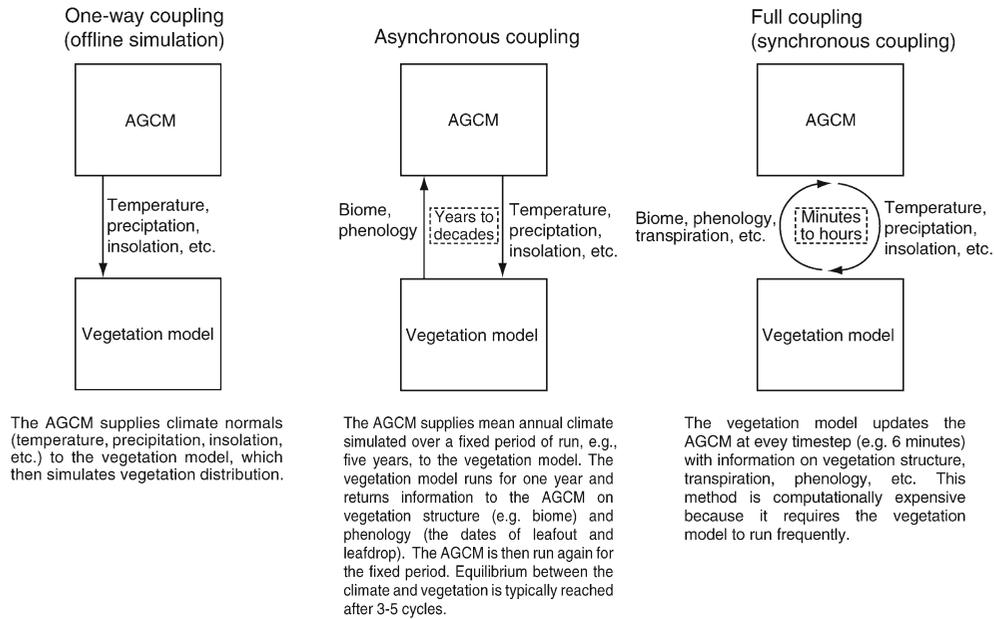

Figure L14 Types of atmosphere model (AGCM)-vegetation model coupling.

with prognostic biogeography may be fully incorporated within the land surface scheme of a GCM. This is the most computationally expensive method of making paleovegetation simulations and has been applied much less often than the other methods. The vegetation model is coded directly into the land surface scheme of the GCM, and vegetation dynamics are typically updated on an annual time-step. This configuration is particularly useful for studying rapid climate changes where changes in land surface conditions are suspected to have had a strong physical or biogeochemical feedback to the climate system. Such situations are frequent in the paleorecord, but uncertainties about the external forcing that drives the rapid climate change event have limited the application of such coupled models. Moreover, the biogeography component of a coupled atmosphere-vegetation GCM is usually a very small part of the total computational demand of the model; coupled atmosphere-vegetation models could be applied more widely.

Except in the case of fully coupled vegetation atmosphere models, paleovegetation simulation typically involves the preparation of an anomaly climatology, where the GCM paleoclimate simulation is subtracted from a control run simulation for the GCM. These anomalies are then applied to a gridded dataset of present-day observed climatology. The anomaly technique is used to avoid biases inherent in the GCM's control climatology, which is often in disagreement with observed climatology over large regions. The anomaly technique also offers a degree of standardization among GCM climatologies when it is desired to analyze the differences in the major features of the climate simulated by different GCMs.

Vegetation history

Most late Quaternary and Holocene vegetation modeling has focused on two key times in the past: the Last Glacial Maximum (LGM, ca, 21 ka) and the mid-Holocene (ca 6 ka; Figure L15). These two periods have been a major focus for paleoclimate simulations (e.g., Jousaume and Taylor, 1995;

Jousaume and Taylor, 2000; Kohfeld and Harrison, 2000) because they represent two extremes in climate forcing. At the LGM, the Earth's orbital configuration was fairly similar to today but greenhouse gas concentrations were low (Raynaud et al., 1993), Northern Hemisphere ice sheets were expanded (Denton and Hughes, 1981), and sea level was therefore lower (Fairbanks, 1989). In addition to the large changes in terrestrial geography, the ocean surface was significantly colder and the distribution of sea ice was expanded (CLIMAP, 1981). The configuration of the Earth's orbit around the Sun was, however, substantially different to that of today (and the LGM) during the early to mid-Holocene. The phasing of the precession (23 kyr) and obliquity (41 kyr) cycles of the orbit were such that the high latitudes of the Northern Hemisphere received a maximum in insolation (incoming solar radiation), both during boreal summer and annually, at ca. 11,000 calendar yBP. This anomaly decayed gradually towards the present. As a direct result of the changes in orbital forcing, many regions of the Arctic experienced summer temperatures considerably higher than at present during the early Holocene (see e.g., Ritchie et al., 1983; Bradley, 2000; MacDonald et al., 2000; Elias, 2001). Increased heating of the northern continents also influenced tropical climates; paleodata indicate that much wetter conditions existed in the Sahara and in south Asia in the early to mid-Holocene as compared to the present. However, at the time of the Northern Hemisphere insolation maximum, the Laurentide Ice Sheet, although substantially reduced from the LGM, was still sufficiently large to have a major downwind cooling effect (Mitchell et al., 1988; Harrison et al., 1992). Northern Europe and eastern North America therefore experienced a thermal maximum several thousand years after the insolation maximum (Wright et al., 1993). For this reason, investigations of the impact of insolation changes on climate have conventionally focused on 6,000 yBP, when the difference in orbital configuration was still large but the impact of the residual Laurentide Ice Sheet was small and essentially local.

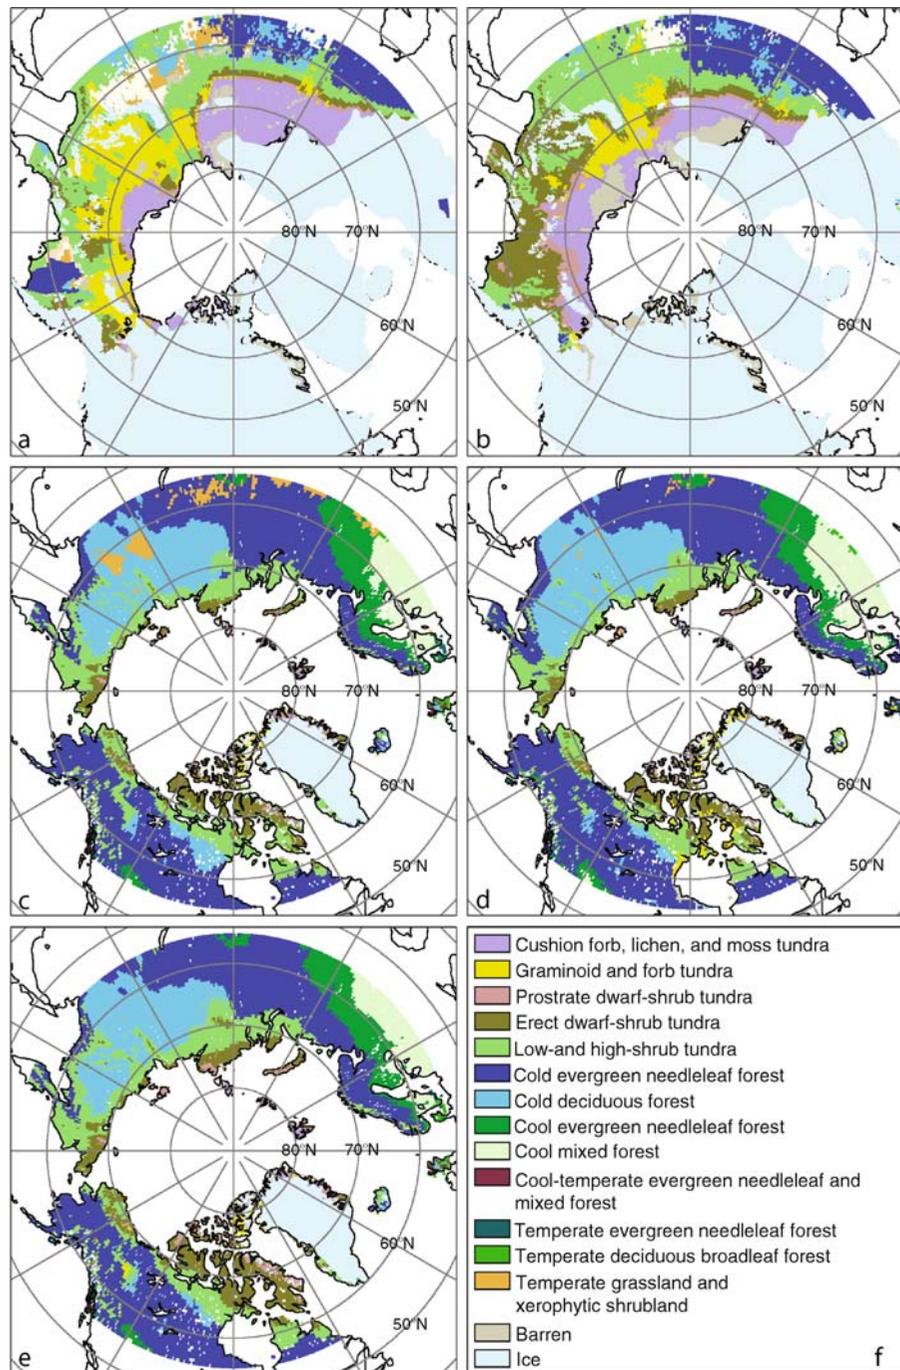

Figure L15 Paleovegetation simulations for the late Quaternary and Holocene. Offline simulation of the biomes of the Northern Hemisphere north of 55° N simulated by BIOME4: for the LGM using AGCM output from the (a) MRI2 and (b) LMDH models; for 6 ka using AOGCM output from (c) IPSL-CM1 and (d) HADCM2 models; and (e) for the present-day potential natural state using observed, gridded climatology; (f) legend for all panels. For a further explanation of these experiments see Kaplan et al. (2003).

The Last Glacial Maximum

A wide range of vegetation modeling has been performed for the LGM. This research has been motivated by the desire to understand the effect of the radically different climate on the Earth's surface at present. Major climate-driven changes in

the Earth's vegetation have implications for climate feedbacks, the distribution of animals and humans, and for the behavior of the biogeochemical Earth system. Studies in LGM vegetation modeling qualitatively describe changes in biogeography, the physiological effects of climate and low CO₂ levels on

vegetation structure and composition, implications of carbon storage on the global carbon cycle, and sources of radiatively active aerosols and trace gases. While most studies used simple one-way vegetation simulations based on a GCM climatology, a few studies have used asynchronous or fully interactive coupling between vegetation and atmosphere to investigate the role of vegetation in shaping the glacial climate. Finally, one study uses a vegetation model in “inverse” mode to estimate changes in climate variables using observed paleovegetation. This method allows accounting for the effect of CO₂ concentration on the observed vegetation.

Biogeography. LGM vegetation was dominated by grasses and shrubland in the tropics, tundra, and deserts in higher latitudes. The area of forest biomes was reduced as compared to present levels on all continents. Low CO₂ concentrations contributed to the expansion of C₄ grasses. The vegetation models simulate large, continuous areas of rainforest in the Amazon lowlands and on the exposed Sunda shelf, but do not display a high degree of fragmentation in rainforest biomes as has been suggested by some interpretations of the paleodata. Despite using an anomaly-based technique for developing the paleoclimate, the models are still somewhat sensitive to the GCM-simulated paleoclimate. No analog biomes – notably graminoid and forb tundra in the Arctic – are widespread, and the potential for more to appear is possible especially if they were defined in the models (Prentice et al., 1993; Kaplan et al., 2003).

Biogeography/plant physiology. Model simulations of LGM vegetation have been used to illustrate the effect of low CO₂ concentrations on vegetation structure and plant physiology. Jolly and Haxeltine (1997) showed that LAI and vegetation productivity in the mountains of tropical Africa result in the simulation of shrub and grassland and biomes in areas that might otherwise climatically support forests. These results indicate that attempts to use observed paleovegetation assemblages to reconstruct climate may be wrong if the direct effect of changes in atmospheric CO₂ concentrations on the vegetation was not taken into account. Furthermore, the low CO₂ concentrations may be responsible for thinner forests, such as the observed forest-parklands of North America that were abundant at the LGM but have no modern analog (Cowling, 1999).

Carbon storage/carbon cycle. A great deal of vegetation modeling has been done to estimate the role of the terrestrial biosphere in long-term oscillations in the global carbon cycle (Friedlingstein et al., 1992; Friedlingstein et al., 1995; François et al., 1999; François et al., 2000; Kaplan et al., 2002; Otto et al., 2002). All modeling studies indicate that the land biosphere stored considerably less carbon at the LGM as compared to the present; models predict a reduction in carbon storage from 200 to 1,000 Pg C. The general reduction in forest area, expansion of tundra and desert, and the effect of low atmospheric CO₂ concentrations on ecosystems were the main reasons for the reduction in carbon storage. In any reconciliation of the global glacial carbon budget, the low LGM terrestrial carbon storage must be accounted for with increases in carbon stored in the oceans.

Dust sources. Ice core measurements indicate that atmospheric dust concentrations at the LGM were up to 20 times greater than at present. These dramatic increases may be due to changes in climate and land surface conditions. A modeling study (Harrison et al., 2001) found that dust sources are highly sensitive to land surface conditions, where potential as a dust source increases exponentially as vegetation cover becomes sparser. Under LGM conditions, the vegetation model indicates

that large areas of the land surface were covered by very sparse vegetation or were completely barren, conditions ideal for dust deflation. The effect of the cold climate and low CO₂ concentrations on terrestrial vegetation may have increased global atmospheric dust loading significantly, with further feedbacks to the climate system through direct radiative effects and the export of nutrients to the ocean.

Methane. In contrast to the pattern shown in the dust record, atmospheric methane concentrations were less than half of those measured in the late Holocene, before strong anthropogenic influence. Earlier studies hypothesized that the reduction in atmospheric methane concentrations could be due to a reduction in global wetland area and productivity (Chappellaz et al., 1993). However, a detailed vegetation model study (Kaplan, 2002) demonstrated that wetland area did not change significantly between the LGM and the pre-industrial period, and therefore the reduction in methane source from wetlands was probably not responsible for the majority of the observed reduction in atmospheric methane concentrations. Lower vegetation productivity was responsible for a ca. 20% reduction in the wetland methane source. This conclusion remains robust even when the vegetation/wetland-methane model is driven by a number of different GCMs, each of which exhibited a wide range of change in global and regional climates in the LGM paleoclimate simulation (Pinot et al., 1999).

Asynchronous coupled modeling. Initial evaluation of vegetation model output from one-way coupling experiments regarding a GCM paleoclimate simulation indicated that in some areas, simulated vegetation could not be corroborated by paleovegetation observations. This was particularly true for the mid-latitude zone of unglaciated Eurasia, where vegetation models overpredicted the amount of forest. Asynchronous coupling of a vegetation model to an atmosphere model (Kubatzki and Claussen, 1998) improved on the result of the vegetation simulation, particularly in Siberia where the inclusion of vegetation-snow-albedo interaction proved to be the key in reducing forest area in the model results. The study also showed that vegetation-atmosphere interactions through albedo effects were important in other areas: a “bright” parameterization for the initial albedo of deserts resulted in the simulation of extensive subtropical deserts worldwide, whereas a “darker” model for desert albedo led to extensive colonization of the glacial western Sahara by plants and an intensification of the monsoon over India.

Interactive coupled modeling. A fully coupled atmosphere-vegetation model study of the LGM resulted in similar conclusions, most notably that the biophysical effect of changing vegetation cover resulted in grasslands and tundra largely replacing forests in Eurasia (Levis et al., 1999). This coupled model study had the benefit of being able to investigate the effect of the change in CO₂ concentrations on leaf stomatal conductance. Physiological studies have shown that plants at low ambient CO₂ concentrations and under well-watered conditions will lose more water for a given unit carbon gain; over large scales this could have an effect on atmospheric humidity and regional hydrology. Further sensitivity studies established that the effect of low CO₂ concentrations manifest themselves in the climate system much more strongly through direct changes in vegetation cover and density rather than through this potential enhancement in vegetation transpiration.

Inverse modeling. Guiot et al. (1999) used the novel technique of applying a vegetation model in inverse mode to investigate the changes in two climate variables (temperature of the

coldest month and total annual precipitation) given an observed vegetation distribution. By using a process-based vegetation model instead of the traditional response surface or regression methods for determining climate variables from observed vegetation, the authors were able to account for the changes in vegetation structure due to low CO₂ concentrations that have no modern analog. Applied to the Mediterranean basin and Eurasia, the technique showed that many GCMs might underestimate the extent of cooling and drying in the LGM climate.

The mid-Holocene

While climate change between the mid-Holocene and present was considerably smaller than the LGM-present difference, a decade of paleoclimate simulation work indicates that capturing these subtle changes in a climate model probably requires interactive simulation of the atmosphere with the land surface. Vegetation modeling efforts for the mid-Holocene have focused on land surface changes in the Sahara and the circumpolar north, where the expansion of vegetation as indicated by paleodata was greatest. Both of these regions have been shown to have important biophysical feedbacks to the climate system and the observed extent of vegetation change cannot usually be reproduced without some form of interactive coupling between the land surface and the atmosphere. In the case of the Sahara, even the most sophisticated coupled models still fail to reproduce the observed extent of vegetation change. Global vegetation response to mid-Holocene climate also has implications for the carbon cycle and the global budgets of radiatively active trace gases.

Biogeography. Initial simulations of mid-Holocene vegetation were performed in an offline experiment with paleoclimate simulation from the CCM1 GCM using prescribed present-day sea surface temperatures and preindustrial CO₂ concentrations (Prentice et al., 1998). These vegetation simulations were evaluated for Europe, where a dense network of paleodata allowed detailed model-data intercomparisons. Results indicated that the model could capture only few of the major vegetation changes observed in the data. The simulation did agree with data in that forest cover extended further north and to higher elevations as compared to the present, and excluded boreal conifers from central and eastern Europe. But the model simulation generally disagreed with observations, importantly in not simulating the observed extent of vegetation change in southern Europe and the extent of temperate forest types in the Fennoscandia, and by simulating a greatly expanded area of steppe in southeastern Europe that is not observed in the paleoecological record. In a series of similar offline experiments, Harrison et al. (1998) further demonstrated an ensemble of vegetation model simulations for the mid-Holocene driven by ten different GCMs showed quantitatively similar vegetation changes in the intertropical zone and the northern and southern extratropics, with drier equatorial forests and an increase in vegetation cover in the subtropical desert regions, and an expansion of forests to the north. An underestimate, relative to paleodata observations, of the magnitude of subtropical vegetation change was also a feature common to all models. The small differences among models were related to the simulation of features in the regional climate. Another recent study used a coupled atmosphere-ocean GCM with an offline vegetation model that focused specifically on vegetation change in northern latitudes of the Northern Hemisphere (Kaplan et al., 2003). This study found that both simulated and observed changes at the northern forest limit were small, but that significant changes probably occurred in the type

of tundra covering the area north of the forest boundary. While most vegetation models treat tundra as a single vegetation class with uniform physical properties, this study emphasized that the height, density, and phenology of tundra vegetation may be as important as the forest-tundra boundary itself as a biophysical feedback to the atmosphere. All of these uncoupled offline experiments emphasized the need for interactive coupling, both between the atmosphere and oceans and the atmosphere and land surface, to reproduce realistically the climate and vegetation of the mid-Holocene.

Biogeography / carbon storage. Another offline vegetation modeling study (Foley, 1994) attempted to estimate the change in global terrestrial carbon storage at the mid-Holocene compared with the present, taking into account the changes in vegetation distribution under a simulated mid-Holocene climate. Though significant changes in global biogeography were simulated in this experiment, including the northward expansion of the northern limit of forests and the expansion of grasslands area in the Sahara desert, the patterns were not in particularly good agreement with the paleobotanical record. Regionally, NPP and vegetation carbon storage increased significantly (up to 15%), but global carbon storage did not change significantly between the simulated present and mid-Holocene conditions.

Asynchronous coupling. In an effort to better capture the climate and biogeography of the mid-Holocene, a series of experiments used the asynchronous coupling technique (Kutzbach et al., 1996a; Kutzbach et al., 1996b; Texier et al., 1997; de Noblet-Ducoudré et al., 2000). All of these studies focused on the areas of greatest climate and vegetation change since the mid-Holocene, i.e., the Sahara region and the northern forest-tundra boundary. Texier et al. (1997) found that after the fourth iteration of an asynchronous coupling, global tundra area was reduced by 25% and the savanna-desert boundary in west Africa shifted 2.5 degrees north, as compared to the present. Finally, de Noblet-Ducoudré et al. (2000) concluded that vegetation conditions in the Sahara were dependent on both sea surface temperature and the simulation of atmospheric circulation, and that the observed changes in vegetation distribution could not be explained by including vegetation feedback alone. While no asynchronous coupling experiment was fully successful in reproducing the observed conditions of vegetation at the mid-Holocene, these experiments did show that interaction between the land surface and the atmosphere had an important influence on mid-Holocene climate.

Interactive coupling. Two recent studies used fully coupled atmosphere-vegetation models to study the mid-Holocene climate and biogeography (Ganopolski et al., 1998; Doherty et al., 2000). Doherty et al. (2000) showed that vegetation-atmosphere feedbacks had the effect of not only modifying the climate over the Sahara in general, but also the seasonal pattern of rainfall in North Africa, particularly by extending the length of the rainy season. This had the effect of producing an increase in vegetation over the Sahara region, but was still not consistent with the vegetation change observed in the data. A limitation of this study was that it used a GCM with fixed, present-day sea surface temperatures. Ganopolski et al. (1998) used an Earth system model of intermediate complexity (EMIC) to perform a study of mid-Holocene climate and vegetation that included fully coupled atmosphere, ocean, sea ice, and vegetation components at coarse spatial resolution. While analysis was possible only over large regions, the results indicated that ocean circulation, sea ice, and vegetation feedbacks were important controls on high latitude vegetation at the mid-Holocene. Alternatively, the response of North African climate was dominated by the land

surface feedback alone. Both studies showed importantly that only with the complex interaction of atmosphere and land surface can we begin to approach a realistic simulation of mid-Holocene climate and vegetation.

Conclusions

Late Quaternary and Holocene vegetation modeling experiments have, for the first time, allowed a complete picture of the Earth's land surface in the past to be presented in a systematic way. These experiments have also provided an important evaluation of climate model output, through the ability to make quantitative comparison of simulated to observed vegetation from proxy data. These model-data intercomparisons have highlighted deficiencies in both climate and vegetation models and led to improvements in modeling technique and a general trend towards full integration of vegetation models within GCMs. As both GCMs and vegetation models improve, we may expect to see more realistic paleoclimate simulations, and a clearer picture of the face of the Earth. These vegetation simulations will also see a wide range of new application to problems in archaeology and anthropology, biogeochemistry, and climate change research, all of which will present a clearer picture of the behavior of the earth system and help researchers reach a better understanding of the potential for future climate change.

LATERITE

Laterite is an iron-rich, sub-aerial, weathering product, commonly believed to evolve as a result of intense, in situ substrate alteration under tropical or sub-tropical climatic conditions. It comprises an important subset of a wider range of ferruginous and related aluminous (i.e., bauxitic) weathering products, which include ferricretes and various iron-rich paleosols. Laterite weathering profiles often develop an indurated surface layer of resistant duricrust, forming laterally extensive sheets ca. 1–20 m in thickness (Figure L16). These lateritized surfaces are both chemically and physically resistant and may extend over areas of a few, to hundreds, or even thousands, of square kilometers.

Historical background and definitions

The term laterite (literally “brick rock”) was first used by Buchanan (1807) to describe a naturally occurring material from

Figure L16 Laterite profile (ca. 40 m) exposed at the edge of a mesa (i.e., table-land) at Panchgani (17°55'N, 73°48'E), Maharashtra, India. Mechanically resistant upper layers of the laterite profile typically form a protective capping overlying less altered materials below, producing a characteristic cliff-like morphology.

Angadipuram (10°58'N, 76°13'E), Kerala state, south-western India. Once cut and allowed to harden, laterite was used as building material (Figure L17). Since this first description, the term has had a long history of geological and geomorphological usage. However, the unfortunate early adoption of Buchanan's casual field description as a type definition has since caused considerable confusion. A more comprehensive and geologically rigorous description was provided by Newbold (1844) from studies of laterite-capped plateaux near Bidar, India (17°54'N, 77°32'E). He was the first to suggest that laterite developed in situ (in this instance upon Deccan flood basalt lavas), by segregation and subsequent rearrangement of minerals and elements that originally comprised the parent rock (Newbold, 1846). Despite this attempt to better define laterite and the lateritization process, the term “laterite” (sensu lato) was used throughout the nineteenth and twentieth centuries to describe a wide range of iron-rich, terrigenous weathering products and duricrusts. Unfortunately, many of these materials were often products of fundamentally different element enrichment and depletion processes (Schellmann, 1986; Ollier and Galloway, 1990; Bourman and Ollier, 2002; Schellmann, 2003).

Modern field studies make evident that the majority of examples of iron-rich duricrust typically occur as two genetically

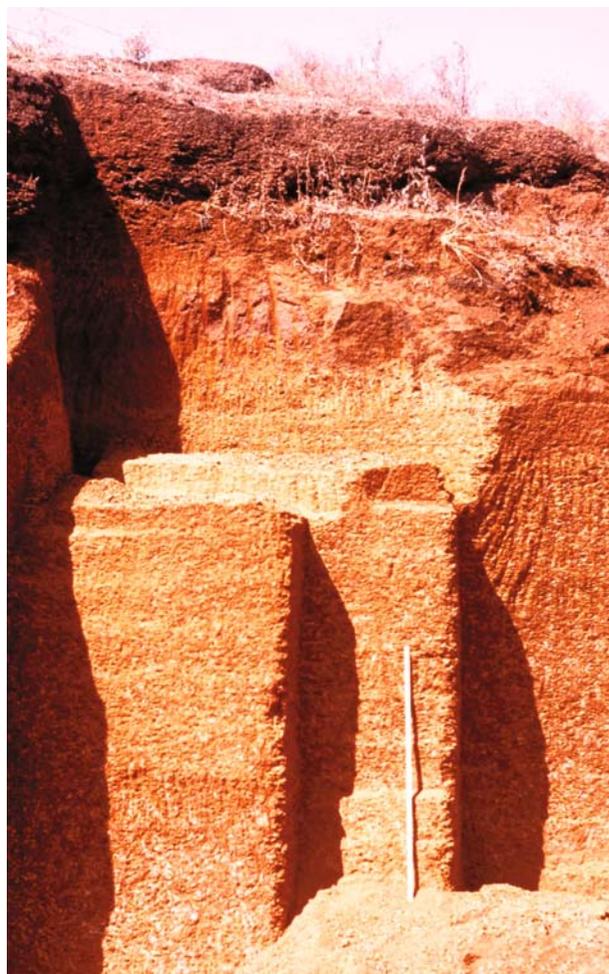

Figure L17 Laterite quarrying at Bidar, India, showing recently cut sections (with 1 meter scale rule) where material from the upper parts of the profile (Zone IV) has been extracted for laterite bricks. Bidar localities were used by Newbold (1846) to argue for laterite as an “in situ” (i.e., autochthonous) weathering product.

distinct types. Aleva (1994) distinguishes between *laterites*, which attain elevated iron contents entirely through autochthonous residual enrichment within the weathering profile (i.e., no net input of iron), and *ferricretes*, in which an absolute iron enrichment occurs (i.e., alteration profiles that receive an allochthonous net input of iron). This division represents a useful process-based distinction, but the practicality of determining allochthony or autochthony of the iron component is often problematic (e.g., Thomas, 1994). In practice, many lateritic weathering profiles are modified by the introduction of allochthonous materials. For instance, many elements (e.g., Fe, Al and some trace metals) can be introduced either in solution or as chelates by groundwaters passing through the evolving weathering profile. These elements can then be re-deposited at specific levels within the profile by redox reactions associated with variations in groundwater chemistry and water table fluctuation. Alternatively, allochthonous material (e.g., eolian dust) may also be introduced by mechanical accumulation through the exposed surface of the profile (e.g., Chadwick et al.,

Table L3 Geochemical analysis of the Bidar weathering profile illustrated in Figure L18

Chemical variations show an up-profile increase in the degree of alteration from basaltic bedrock (BB1) to indurated laterite cap (BB9). Note the enrichment of Fe and Al oxides, also metals like Cr, Cu, and V toward the surface, with concomitant depletion of silica, alkalis and alkali earths. (Establishment of a water table or fluvial and eolian inputs may modify these patterns).

1990; Brimhall et al., 1991). Nevertheless, the distinction between dominantly autochthonous or allochthonous weathering profiles remains important because it places constraints upon processes operating during duricrust evolution, and upon contemporaneous paleoclimatic and geomorphological conditions.

Characteristic properties

Laterites (*sensu stricto*) are, primarily, residual materials formed directly by in situ rock breakdown, and should not contain any significant allochthonous component. They owe their chief compositional characteristics to the relative enrichment of iron (and often aluminum), and the other less mobile parent rock (i.e., protolith) constituents. This enrichment occurs under aggressive weathering conditions as a consequence of the greater mobility, and hence loss, of constituent silica, alkalis, and alkaline earths from the protolith (Table L3). Since protolith materials nearer the surface are more subject to weathering, the degree of alteration will diminish with depth, thereby producing a weathering profile (Figure L18). Where such profiles are exposed, they typically consist of an uninterrupted progression from unaltered bedrock, through increasingly

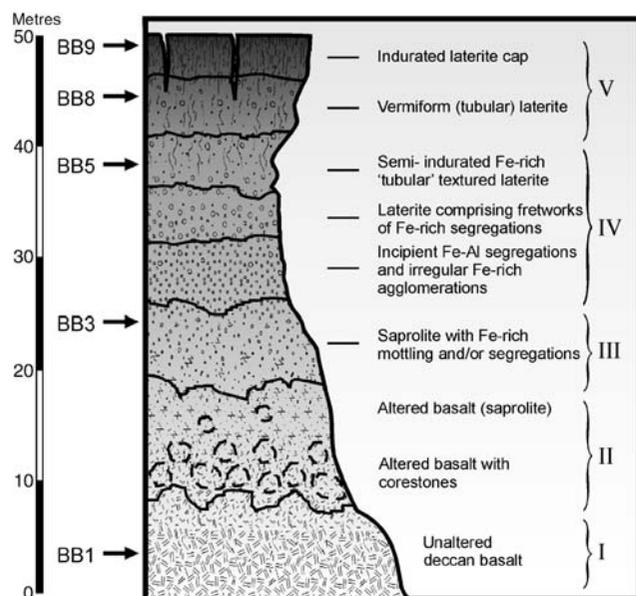

Figure L18 Generalized vertical section through the autochthonous Bidar laterite weathering profile (17°55'N, 77°32'E), illustrating the compositional (Table L3) and textural progression from unaltered basalt protolith to indurated laterite (after Borger and Widdowson, 2001). (I) unaltered basalt progressing up-profile to material displaying limited alteration of primary minerals; (II) altered basalt containing “unaltered” corestones within a soft saprolitic matrix, progressing upward into (III), a saprolitic to weakly-lateritized zone with residual lithological characteristics, increasingly obscured up-profile with increasing Fe-mottling and segregations; (IV) moderately lateritized zone comprising iron segregations and vermiform textures, and becoming increasingly indurated up-profile; (V) strongly lateritized, indurated laterite with vermiform textures, becoming highly ferruginous in the uppermost levels of the profile. (N.B. A similar alteration progression is commonly observed on other protolith substrates).

altered and iron enriched zones, to culminate in laterite at the top. Lateritic duricrusts typically form the uppermost layers of in situ weathering profiles, and crop out at the surface as a massive, interlocking fretwork of iron (and aluminum) oxides and hydroxides (i.e., sesquioxides, Figure L19).

Conditions of formation

The conditions under which lateritic profiles form include:

- (i) Favorable geomorphological environments characterized by limited runoff and lack of aggressive erosion. Ingress of rainfall and/or establishment of a water table serve to promote evacuation of the more mobile constituents.
- (ii) Favorable climatic conditions typified by seasonal, high annual rainfall (e.g., a monsoon-type climate). High humidity and high mean annual temperatures further promote alteration.
- (iii) Regions of relative tectonic stability, characterized by minimal uplift, crustal deformation, or erosion.

The chemical and mechanical durability of laterite confers a prominent role in tropical and sub-tropical landscape evolution. Studies of occurrences in India, Africa, and Australia have proved crucial in advancing tropical geomorphology (e.g., McFarlane, 1976; Summerfield, 1991; Thomas, 1994; Widdowson, 1997a, b). However, disturbance, by uplift, climate change,

Figure L19 Close-up of the uppermost, indurated layer (Zone V) of a lateritic duricrust revealing the massive, interlocking fretwork of iron and aluminum oxides and hydroxides (i.e., sesquioxides), and their associated ‘vermiform’ texture.

or both, is likely to terminate the lateritization process and lead to rapid erosion and stripping of the lateritic weathering profile (Borger and Widdowson, 2001). Consequently, laterite formation and preservation has been episodic throughout the geological record (Bardossy, 1981; McFarlane, 1983) with, for instance, acmes occurring within cratonic regions during the late Cretaceous “greenhouse climate,” and during the Tertiary thermal maxima.

Wider importance

Recently, ferricrete and laterite duricrusts, together with Fe-rich paleosols, have acquired renewed importance as paleoclimatic indicators because preservation of these materials records the occurrence of wet, tropical conditions during the geological past (e.g., Tsekhovskii et al., 1995; Tardy and Roquin, 1998). Such information is crucial in documenting changing regional and global climates (e.g., Bardossy, 1981; Thomas, 1994) and, together with other key climate proxies, aids in identifying periods of climatic perturbation arising either rapidly through volcanic and impact events or due to longer-term climate controls (i.e., Mikankovich-Croll cycles). Importantly, the presence of lateritic profiles in the geological record also confers wider

paleoenvironmental information, such as that concerning paleogeographic setting and the nature of paleolandscapes. For instance, laterite formation is likely to have always been restricted to humid tropical regions (or their climatic equivalents), and to those areas characterized by low runoff, ingress of precipitation, and the long-term establishment of a stable water table. Reconstruction of ancient lateritized paleosurfaces can also provide a useful tool for quantifying the degree of neotectonic deformation, since post-lateritization uplift can lead to the distortion of originally low-lying peneplains, and measurable increases in surface elevation (Widdowson and Cox, 1996).

Furthermore, appropriate mineralogical, geochemical, and isotopic studies on laterites are also beginning to reveal detailed information regarding past climatic and atmospheric conditions. Carbon, oxygen, uranium-thorium, and, most recently, lithium isotope systematics of weathering products offer the opportunity to investigate paleoatmospheric, paleoclimatic, and paleo-weathering conditions throughout the geological record (e.g., Bird and Chivas, 1989, 1993; DeQuincey et al., 2002; Pistiner and Henderson, 2003; Kisakurek et al., 2004). For instance, geochemical and isotopic analyses of Proterozoic laterites from South Africa (Gutzmer and Beukes, 1998), suggest not only an ancient oxidizing atmosphere, but also a hot and humid climate at ca. 2 Ga. Moreover, carbon isotope signatures preserved within these laterites may actually indicate the presence of early, terrestrially-based, photosynthesizing organisms. Finally, other isotopic systems, such as samarium–neodymium (Sm–Nd), have been successfully employed to identify and quantify allochthonous dust input into ancient weathering profiles, and as a proxy for monitoring the long-term chemical and isotopic balance between the evolving weathering profile and its associated hydrological characteristics (Viers and Wasserburg, 2004).

LAURENTIDE ICE SHEET

The Laurentide Ice Sheet is that part of the North American ice sheet complex that was centered on the Canadian (Laurentian) Shield during Quaternary glaciations. Its configuration and history are fairly well known only for the Wisconsinan (last) Glaciation, and are known in outline only for preceding glaciations.

The late Wisconsinan (25–10 ka BP [ka = thousands of radiocarbon years]) North American ice sheet complex consisted of

three major ice sheets: the Laurentide Ice Sheet, which was centered on the Canadian Shield but also expanded across the Interior Plains to the west and south; the Cordilleran Ice Sheet, which inundated the western mountain belt between the northernmost coterminous United States and Beringia (unglaciated Yukon Territory and Alaska); and the Innuitian Ice Sheet, which covered most of the Canadian Arctic Archipelago north of about 75° N latitude (Figure L20). The ice cover over Newfoundland and the Maritime Provinces of Canada during this interval is usually referred to as the Appalachian Ice Complex, because ice flowed out from local centers within the region rather than from the Canadian Shield. All of the peripheral ice sheets were broadly confluent with the Laurentide Ice Sheet at the Last Glacial Maximum (LGM), and the Greenland Ice Sheet was confluent with the Innuitian Ice Sheet. The term Laurentide Ice Sheet is sometimes applied to this contiguous North American ice mass, though rarely in glacial geology. The North American ice sheet complex was by far the largest of former late Pleistocene ice sheets, with an area of about 15 million square kilometers (17.4 million, including Greenland ice). Its growth and decay thus accounts for more than half, possibly as much as three quarters, of global sea-level change during the last glacial cycle. Its presence profoundly affected the global climate system and the isostatic deformation of the planet.

The nucleus of this complex, the Laurentide, comprised three major sectors, the Labrador Sector, the Keewatin Sector, and the Baffin Sector. These sectors are named for areas of ice sheet inception and probable areas of outflow at the LGM. They were located respectively east, west, and north of Hudson Bay. Continental scale syntheses of ice recession following the LGM are given by Prest (1969), Bryson et al. (1969), Denton and Hughes (1981), Dyke and Prest (1987), and Dyke et al. (2003).

Wisconsinan history

Because the Laurentide Ice Sheet accounts for such a large proportion of global sea-level change, the oceanic record of global ice volume is a good proxy of its history for the period beyond the range of reliable radiocarbon dating (>30,000 yBP). On this basis, the ice sheet started to nucleate about 120,000 years ago, following marine isotopic stage 5e, and attained sequentially greater maxima at about 115,000, 70,000, and 20,000 years ago. It is generally agreed, though poorly demonstrated, that ice sheet nucleation resulted from snowline lowering to the point where snow persisted through the summers on the large plateau areas of the Canadian Arctic Archipelago, Quebec-Labrador, and the Arctic mainland west of Hudson Bay, formerly known as Keewatin. In the far north and possibly in Hudson Bay, formation and thickening of perennial sea ice may have assisted the process of englacialiation by eliminating iceberg calving when the ice caps advanced to shorelines. The outlines of early Wisconsinan ice sheets are poorly known because no moraines are now securely assigned to the maxima at 115 ka and 70 ka (Dyke et al., 2002). If interpretations of putative glaciolacustrine sediments (Scarborough Formation) and till in Sunnybrook Drift at Toronto and the ages of tills below and above the St. Pierre nonglacial sediments in the St. Lawrence River are accepted, ice sheets reached southernmost central Canada at these times but may not have extended into the United States. Similarly, the extent of ice at the middle Wisconsinan minimum (stage 3) is poorly known and has been variously portrayed. During the ice volume minimum at about 30 ka BP, ice cover approximately coincided with the Canadian Shield, leaving ice cover similar to present in the Cordillera and in the Canadian Arctic Archipelago (Dyke et al., 2002).

Late Wisconsinan glacial history is better known because it is based on well-mapped surface glacial features, such as end

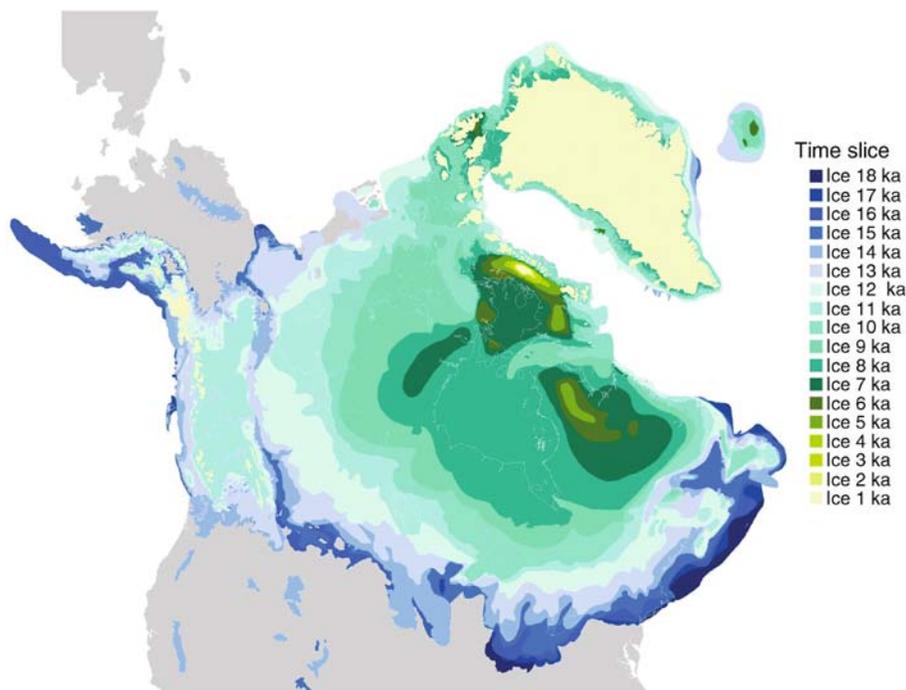

Figure L20 Isochrone map of deglaciation of North America, derived from Dyke et al. (2003).

moraines and ice-flow features (e.g., drumlins), and it is more abundantly constrained by radiocarbon dates. From its 30 ka BP position, Laurentide ice expanded to its late Wisconsinan maximum position in the northwest, south, and northeast about 23–24 ka BP and in the southwest and far north about 20–21 ka BP (Dyke et al., 2002). Hence, the general limit of glaciation expanded by 500–1,000 km in 7,000–10,000 years, including the inception and growth of the Innuitian and Cordilleran Ice Sheets. Relatively little recession occurred prior to 14 ka BP except in deep water on the continental shelf off New England and Atlantic Canada (Figure L20). Indeed, the southwestern margin of the Cordilleran Ice Sheet continued to advance through the Puget Lowland of Washington State until 14.5 ka BP. Thus, the period of generally maximum ice cover in North America spanned from about 22 to 14 ka BP, which is broader than the interval of the global sea-level minimum by several millennia on either side. This fact suggests that North America is more susceptible to glaciation than are the other large, periodically glaciated regions.

The recession of ice from the LGM is portrayed in Figure L20 at 1,000-year intervals in radiocarbon years, assembled from Dyke et al. (2003). The glacial geomorphology of the continent is the fundamental constraint on any interpretation of North American deglaciation. Two specific patterns, those of end moraines and other ice marginal features and those of ice flow features, are of primary importance. These broad patterns have been known for decades from large-scale compilations such as the Glacial Map of Canada (Prest et al., 1968; Dyke and Prest, 1987) and the Glacial Map of the United States east of the Rockies (Flint et al., 1959). The fundamental assumption in interpreting these patterns, in common with present and previous efforts, is that where moraines or other ice marginal features do not record specific ice margins, the margins tended to follow normal ice flow directions. This common assumption accounts for the fundamentally similar patterns seen in most reconstructions of Laurentide deglaciation over the decades, namely recession back to the three major centers of Keewatin, Quebec-Labrador, and Baffin Island.

The second major constraint in interpreting the history of deglaciation is the set of relevant numerical age determinations. New “exposure dating” studies have provided important tests of models of terrain age in the “weathering zones” along the mountainous eastern seaboard (e.g., Steig et al., 1998) and have reaffirmed the late Wisconsinan age of final coalescence of the Laurentide and Cordilleran Ice Sheets in Alberta (Jackson et al., 1997). However, only radiocarbon age determinations are sufficiently precise at this time to allow mapping of the deglaciation sequence at centennial resolution. The radiocarbon database of Dyke et al. (2003) provides direct and minimum-limiting dates on ice recession as well as maximum-limiting dates on readvances, including the advance to the late Wisconsinan glacial limit.

Most direct dates on ice marginal positions are from sites where moraines or meltwater features have been followed into shell-bearing marine deposits, such as commonly occur in ice-contact deltas. Opportunities to date ice marginal features landward of the limit of postglacial marine incursion directly are exceedingly rare, being limited to those few localities where ice readvanced across living or recently dead vegetation or where the varve chronologies of proglacial lakes can be tied into the radiocarbon time scale. The remaining age control is entirely in the form of minimum-limiting dates on lake sediments, peat, wood, plant macrofossils, foraminifera, and mammal bones. Reservoir corrections are applied to radiocarbon dates on foraminifera as they are to marine mollusks.

In summary, ages of deglaciation are reasonably well established in most coastal areas. Varve chronologies and dated readvances provide control at key inland sites. Elsewhere, minimum-limiting dates are valuable constraints. Recent improvements in age control and more detailed mapping of deglacial patterns have brought the North American deglaciation sequence more evidently into correlation with the major climatic events recognized in the North Atlantic region and in the Greenland ice cores. Thus, the acceleration of retreat at 14 ka BP corresponds to the sudden warming evident in the Summit, Greenland ice core record. More significantly, the Younger Dryas cooling now emerges as an important control of ice marginal behavior of the North American ice sheets, similar to that shown by the Scandinavian Ice Sheet, a result commensurate with growing recognition of this event in North American pollen records. Similarly, the prominent 8.2 cal ka BP cold event (7.5 ^{14}C ka BP) is now firmly correlated with the deglaciation of Hudson Bay and drainage of glacial lakes Agassiz and Ojibway (Barber et al., 1999).

The world’s largest ice sheet complex lost < 10% of its area prior to 14 ka BP. It then retreated nearly linearly until 7 ka BP, by which time only 10% of the area remained more glaciated than it is today. This linear reduction of area, as currently understood, was interrupted by two events: a reduced rate of recession during the later half of the Younger Dryas, and an increased rate as ice cleared from Hudson Bay (Figure L21). These events are clearer when plotted on the calendar time

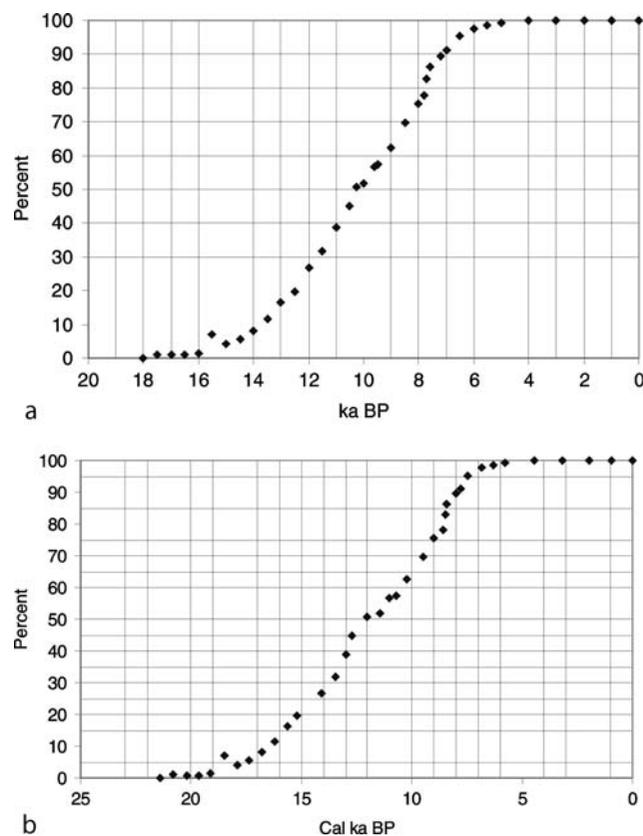

Figure L21 Percent area deglaciated in North America and Greenland, plotted on radiocarbon (a) and calendar (b) time scales.

scale, because the radiocarbon time scale abbreviates the duration of the Younger Dryas (Figure L21b).

The deglacial chronology accords reasonably well with the record of global sea-level rise (Fairbanks, 1989), which features two meltwater pulses separated by reduced melting during the Younger Dryas interval. During meltwater pulse IA (13–11 ka BP), the North American ice sheet complex decreased from about $14.9 \times 10^6 \text{ km}^2$ to $11.5 \times 10^6 \text{ km}^2$. During meltwater pulse IB (10.5–8.5 ka BP), ice area decreased from $10.5 \times 10^6 \text{ km}^2$ to $4.2 \times 10^6 \text{ km}^2$. These area reductions correspond approximately to volume losses of $10.8 \times 10^6 \text{ km}^3$ ($5,400 \text{ km}^3 \text{ a}^{-1}$) and $11.7 \times 10^6 \text{ km}^3$ ($5,600 \text{ km}^3 \text{ a}^{-1}$). These rates account for 40% of meltwater pulse IA and 60% of meltwater pulse IB. The relatively early demise of the Eurasian ice sheets accounts for their greater contribution to meltwater pulse IA.

LITTLE ICE AGE

General description

The period known as the “Little Ice Age” spans roughly the sixteenth through the mid-nineteenth centuries. During this time, temperatures over much of Europe were frequently unusually cold, Alpine glaciers advanced, and European rivers froze much more often than during medieval times or during the past century and a half. Cold climates also prevailed over several other areas, especially those adjacent to the North Atlantic. The combination of cold conditions over both Europe and eastern North America, the two areas with the greatest amount of western record-keeping, led many to consider the period as one of global cooling, resulting in the label “Little Ice Age.”

Modern science has shown, however, that there is considerable regional variation in the extent of the cooling, with some areas even warming during this period. It now appears that the Northern Hemisphere as a whole cooled only moderately (Briffa et al., 1998; Jones et al., 1998; Mann et al., 1999; Crowley, 2000), by several tenths of a degree. However, not enough data exists to establish a reliable estimate for the Southern Hemisphere as a whole. Furthermore, even in the areas that cooled, there is a great deal of variability in the timing of the cooling. This latter fact has led to a proliferation of time-periods that are called the Little Ice Age, with some extending it to the fourteenth century (Fagan, 2000).

Despite the inhomogeneous cooling during the Little Ice Age, it remains important as it is the most reliably documented, relatively large climate anomaly during the last millennium (prior to the industrial revolution). Understanding the Little Ice Age is therefore an important test of our comprehension of natural climate variability.

Evidence

Based on early thermometer measurements, documentary evidence, and proxies for past temperatures (such as tree rings and glacier extents), it is believed that annually averaged European temperatures were roughly 1–1.5 °C colder during the Little Ice Age relative to preceding or subsequent periods (Pfister, 1995; Shindell et al., 2001). However, many winters appear to have been much colder (e.g., see Fagan, 2000). Dutch masterpieces from that time by Brueghel, van der Neer and others show people skating on canals and rivers that almost never freeze today. Ice was so prevalent in northern seas that Inuit fisherman were seen as far south as Scotland. Glaciers advanced in the Alps, Scandinavia and Iceland, destroying outlying farms and threatening to crush whole villages. Snow lay on the ground in Britain and the Netherlands an average of 20–30 days during the winter between 1680 and 1730, as opposed to an average of 2–10 days every winter during the twentieth century (Fagan, 2000). In North America, native tribes banded together to form the League of the Iroquois in the face of declining food supplies and other natural hardships during those cold years. During the American Revolutionary War, British soldiers were able to drag massive cannons across a frozen New York Harbor.

It is often claimed that the Viking settlements in Greenland and the New World were wiped out by the severe drop in

temperatures. Local climate conditions likely changed in these locations, but not necessarily in concert with those elsewhere. Additionally, it seems that the cutting off of trade routes back to Europe played a primary role in the settlements' demise. An increase in North Atlantic sea ice due to climatic changes may therefore have been more important than altered local conditions. Weather in Iceland illustrates the complexity of relating climate change to habitability. Iceland was locked in by sea ice for several months during most years of the Little Ice Age, but seldom after 1880. Barley was grown effectively in Iceland from the ninth century through the twelfth, after which this crop failed until the warming of the late 1900s. While conditions were certainly harsher in Iceland during the Little Ice Age, the cold weather there may have actually begun much earlier.

Causes of cooling

It has long been speculated that the drop in temperatures was due to a dimmer Sun. Galileo's development of the telescope for astronomy in the early 1600s allowed early observers to chart the behavior of the Sun. They regularly noticed dark spots, which cycled over a period of about 11 years, as they do today. After 1645, the spots largely vanished. They reappeared around 1715, and the sunspot cycle has been present ever since. The intervening years are now known as the Maunder Minimum, the most prolonged and dramatic of several decadal timescale reductions in solar irradiance during the last millennium. This period coincides with the coldest European temperatures. Modern satellite measurements have confirmed the early assumption that the number of sunspots is related to the total brightness of the Sun, though the exact relationship is not yet well quantified. The Maunder Minimum period, with almost no sunspots recorded by European astronomers, represents the extreme low of a multi-century period that appears to have been marked by generally lower solar output. Evidence from cosmogenic isotopes (atomic isotopes produced only by cosmic rays whose ability to reach the Earth depends on the sun) obtained from ice cores matches the general pattern of sunspot variability during past centuries, including the Little Ice Age (Stuiver and Braziunas, 1989). The reduction in solar output during the Maunder Minimum is estimated at about one-quarter of one percent (Lean et al., 1995). Though this is a very small change, the output of the Sun is so large that this can still have a sizeable impact. However, it is not enough to plunge the whole Earth into much colder conditions, and even to account for the modern view of the Little Ice Age as a regional phenomenon requires some amplification.

The other major factor in the cooling during this period was an increase in volcanic eruption frequency and size (Free and Robock, 1999; Crowley, 2000). Limited historical information is supplemented by the signature volcanic ash layers preserved in ice cores. Eruptions injected a larger number of aerosol particles into the atmosphere during the seventeenth century than during the period immediately following the Little Ice Age or during the Medieval Warm Period, which preceded it. These particles reflect solar radiation, and it is estimated that the additional eruptions of the seventeenth century would have reduced the radiation reaching the Earth by an amount comparable to the reduced solar output at that time (Crowley, 2000). The global average surface temperature response is proportional to this energy change; therefore,

volcanism could have played a role in the global or hemispheric mean response although the global effects lasted only 1–3 years. A combination of solar and volcanic influences seems the most likely explanation for the hemispheric-scale cooling of the Little Ice Age.

Regional climate change

Studies have shown that changes in stratospheric ozone in response to solar variations amplify the climate impact of those irradiance variations (Haigh, 1996; Shindell et al., 1999; Shindell et al., 2001). Incorporating those ozone changes, the most recent climate model simulations have found that the reduced brightness of the Sun during the Maunder Minimum causes global annual average surface temperature changes of only a few tenths of a degree, in line with the small hemispheric average cooling seen in the proxy data. However, regional wintertime cooling over Europe and North America is 5–10 times larger due to a shift in atmospheric winds (Shindell et al., 2001). Both the climate model and proxy data show that surface temperature changes associated with solar output variations exhibit alternating warm oceans and cold continents at mid-latitudes of the Northern Hemisphere (Figure L22). These seem to occur primarily through a slowdown in the speed of westerly winds at the Earth's surface associated with the North Atlantic Oscillation (NAO). Greater heating by the Sun in the tropics relative to high latitudes causes an equator-to-pole flow of air, which is turned towards the east by the Earth's rotation. A reduction in the amount of sunlight reaching the planet leads to a weaker equator-to-pole heating difference, and therefore slower winds. Ozone changes in the stratosphere amplify this effect.

Impacts on surface temperatures are particularly large in winter. Because the oceans are relatively warm during the winter due to their large heat storage, the diminished flow creates a cold-land/warm-ocean pattern (as shown in Figure L22) by reducing the transport of warm oceanic air to the continents, and vice versa. Changes in this wind flow have only a small impact on global temperatures as the warm and cold regions average out. However, they have a large regional effect and increase the frequency of extreme events, such that a reduction in winds would lead to many more extremely cold days over Europe and eastern North America (which may stand out in the historical record). The shift in circulation thus appears to be the solution to the apparent paradox of extreme cold with only a marginally dimmer sun. Ocean circulation may have also responded to solar irradiance fluctuations. Volcanic eruptions are known to induce a positive bias in the NAO during the winter following the eruption, but this is opposite to the pattern seen during the Little Ice Age. Their long-term impact is likely to be relatively minor, as the particles injected into the upper atmosphere typically remain there in sufficient numbers to affect climate for only a year or two.

Though early records of wind flow are extremely limited, historical data associates the European seventeenth century winter cooling with enhanced northeasterly advection of continental air, consistent with an anomalous negative phase of the NAO (Slonosky et al., 2001). Reconstructions of the strength of the NAO from instrumental and proxy data suggest that there may have been a long-term weakening during the Little Ice Age (Luterbacher et al., 1999). Ocean sediments show a decreased sea surface temperature of 1–2°C in the Sargasso Sea during the sixteenth to nineteenth centuries, and warmer

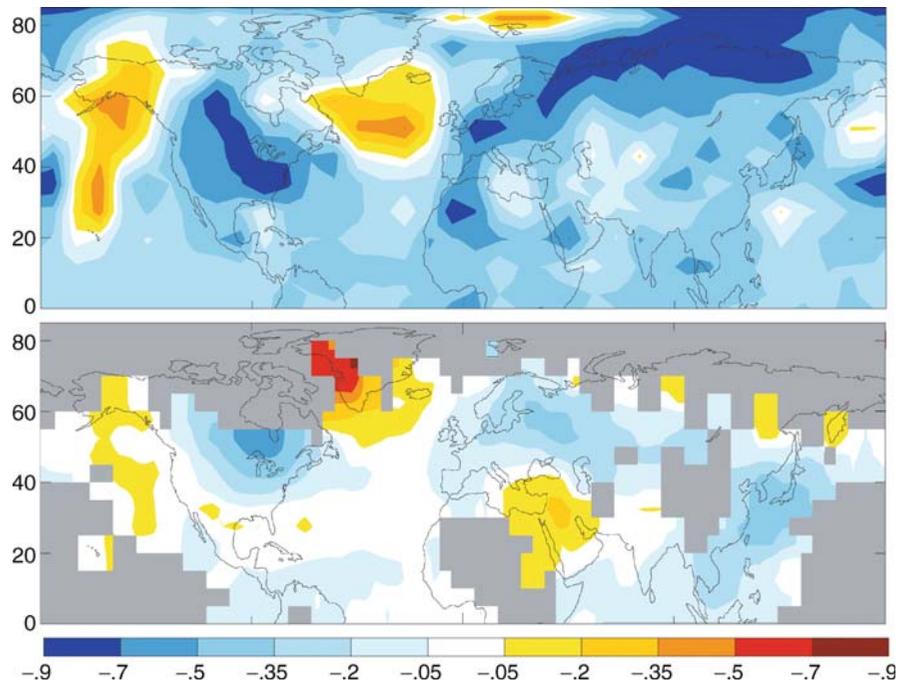

Figure L22 Annual average surface temperature change (C) due to solar irradiance change between the Maunder Minimum (late seventeenth century) and a century later, when solar output had returned to relatively large values, in the NASA Goddard Institute for Space Studies climate model (*top*) and in the historical temperature reconstructions (*bottom*).

Atlantic temperatures north of 44°N latitude, extending to the area off Newfoundland (Kiegwin and Pickart, 1999), consistent with a reduced NAO, but not with uniform basin-wide cooling.

LOESS DEPOSITS

Definition

Loess can be defined simply as a terrestrial clastic sediment, composed predominantly of silt-sized particles, which is formed essentially by the accumulation of wind-blown dust. Initially, von Leonhard (1823–1824) used the word “*Loeß*” for friable silty deposits near Heidelberg, based on the word “*Loesch*” for loose soil, which was the term used by the local people of the Rhine Valley. Lyell (1834–1845) brought the

term into widespread usage and was responsible for stimulating interest in similar deposits. However, the eolian origin of loess did not become widely accepted until the publications of von Richthofen (1870–1885). Several genetic and descriptive definitions of loess have been discussed since that time. Although the sub-aerial wind-fall origin, as well as silt-sized quartz particles domination, are the leading criteria of loess sediments, other additional definitive features (e.g., loose, unstratified, porous, calcareous, pale yellow, occurring in mantle form, etc.) are advocated by many scientists. In a historical perspective, the definition's use was controlled by its application.

Composition and features

Loess is relatively well-sorted clastic sediment that is homogeneous, porous and slightly altered. *Typical loess* (so called “*primary loess*”) usually has a yellow or pale yellow color. Coarse silt particles (10–50 μm in diameter) make 40–70% of typical loess by weight. This size fraction of particles is characteristic of eolian dust deposits and commonly is called the “*basic*,” “*loess*” or “*loessic*” fraction. The percentage of clay and sand content in loess is subordinate in importance (5–20%). Beside the prevailing quartz grains (40–80%), it may contain feldspar, calcite and dolomite. Quartz in loess occurs as irregular, subangular and angular grains with characteristic surfaces resulting from mechanical fragmentation. Among clay minerals, either illite or montmorillonite dominates are present, although kaolinite, vermiculite and chlorite may also be present in smaller amounts. Carbonate content is variable (ranging from 1 to 20%), depending on environmental conditions. Mineral grains are slightly cemented and partly aggregated mostly by carbonate. Primary carbonates usually are dolomite particles but secondary carbonates consist of calcite coatings on silt grains, fillings in interstices and vertical tubes left from the decay of grass roots. The void ratio is usually extremely high (45–55%) in loess, and the average diameter of aggregates is 10–15 μm . Loess is permeable to water and easily collapses when saturated with water. The compression strength of loess is about 1.5 kg dm^{-2} . The collapsibility leads to eventual problems for engineering activities in loess areas. Moreover, loess is easily eroded by surface water and liable to underground piping, though under dry conditions even steep loess walls are stable (Figure L23). Remnants of terrestrial materials, mostly of cryophile fauna and flora, are typical in the loess horizons. Individual loess

Figure L23 Peoria and Roxana loess horizons of the Wisconsinian time at Crowley's Ridge, Arkansas.

horizons are usually unstratified, but loess sequences often contain intercalated loam or sand beds (Liu et al., 1985; Pécsi, 1990).

Although the above features are characteristic of typical loess, non-typical loess or “*loess-like sediments*” of similar properties and genesis is widespread. In many loess sequences there is a continuum of modified loess, which ranges from weakly developed leached layers to intensely weathered paleosols and pedocomplexes. When altered by active soil formation, loess becomes more clay-like, hardens and can be either leached of primary carbonates or enriched by secondary carbonates. When redeposited by rainwater runoff, snowmelt and other processes, loess becomes slightly stratified. The terms “*secondary loess*,” “*altered loess*,” “*degraded loess*,” “*redeposited loess*,” “*loess derivatives*” and “*reworked loess*” have been used to describe such varieties of loess.

Origin

The origin of loess has a long history of controversy. Since von Richthofen suggested the “*subaerial*” theory of loess formation in 1870, the eolian origin of loess has been the most popular and best-documented. Succeeding investigations refined the process of eolian dust sedimentation and loess feature formation. The contributions of Tutkovskii, Obruchev and Kriger (Russia), von Richthofen and Grahmann (Germany), Liu (China), Fink (Austria), Kukla (Czechoslovakia) and Pécsi (Hungary), as well as Pye and Péwé (USA), are well known (Smalley, 1975; Liu et al., 1985; Pécsi, 1990; Pye, 1995).

Three conditions are required for loess deposition: (a) a large supply of suitable dust-sized particles that is sustained, at least episodically, over a period of tens to hundreds of thousands of years; (b) adequate wind energy to transport the dust, and (c) the existence of suitable dust traps downwind of the dust source area.

Although in situ weathering products may be directly deflated, in most instances at least one intermediate stage of alluvial or glaciofluvial transport and deposition is involved before it is picked up by wind and deposited as loess. Extensive loess deposits appear to be a Quaternary phenomenon and show a clear spatial relationship with areas of Pleistocene continental glaciation. Such deposits have been referred to as “*glacial*” or “*periglacial*” loess. The constituent silt particles were formed largely by sub-glacial grinding and subsequently deflated from glaciofluvial outwash deposits. Loess cover is particularly thick (almost up to 30 m) near valleys that served as meltwater drainageways, but thins and becomes finer away from valleys. Deposits of loess also occur on the semi-arid margins of some deserts (“*peridesert loess*”). In this case, significant amounts of quartz silt are probably produced by eolian abrasion and weathering processes in deserts or in adjacent mountain ranges before being deflated and deposited as loess. As opposed to the “*cold loesses*” of periglacial zones, the peridesert loesses are called “*warm loesses*” (Smalley, 1975, Liu, 1985, Pye, 1995).

The magnitude of the dust flux and pattern of dispersion from a potential source are strongly influenced by the nature of the prevailing regional winds. Local wind systems, such as valley winds, can be important in forming proximal dust deposits, but longer-range transport and formation of distal deposits requires the involvement of regional-scale wind systems. Dry deposition is enhanced wherever there is a reduction in wind speed or an increase in surface roughness. However, if dust passes over a water body, moist ground or a vegetated surface, the particles may be trapped. Subsequently, on impact of rainwater runoff, snowmelt or other processes on the slope, grains may be moved further away

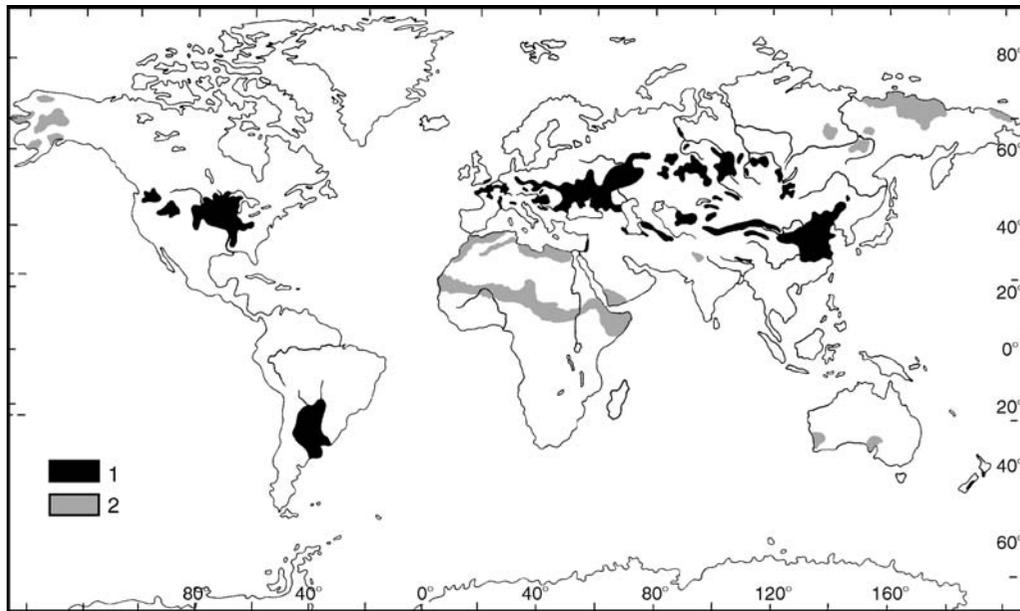

Figure L24 Distribution of loess and loess-like sediments. 1: Loess and loess-like sediments; 2: Loess derivatives and loess-like sediments (after Pécsi, 1990).

until they are stabilized by vegetation. Soil and related weathering processes are a syn- or post-depositional alteration of the primary deposit, and to some geologists are early stage diagenesis.

An alternative hypothesis (“soil-eluvial,” “in situ” or “back-swamp-loessification”) of loess formation was suggested by Berg in Russia in 1916, and then advocated by Russel and Fisk in the USA in 1944 (Smalley, 1975; Follmer, 1996). This hypothesis excludes the eolian factor and assumes most of loess sediments have a fluvial origin. According to this idea, any fine-grained deposits may be converted into typical loess as a result of weathering and soil forming processes. The in situ theory has not been well-documented or widely accepted since that time. The fundamental defect of the theory is that it creates a cascade of increasingly complex relationships that require unrealistic explanations, such as great tectonic uplift, excessive amounts of alluviation, and greater depths of valley cutting during erosion cycles. Also the characteristic angular grains of quartz are not explained by this theory.

Distribution

Loess is one of the widest-spread formations of the ice age, but it also forms on semi-arid desert margins and on foothills of mountain ranges. Loess sediments cover almost 10% of the world’s land surfaces. Extensive loess and loess-like sediments occur on plains, plateaus, pediments and major river basins (Figure L24). Loess reaches its maximum thickness (> 100 m) on the Loess Plateau of China, but usually loess series are not more than 30 m thick. In Eurasia, typical loess is also common in southern Siberia, central Asia, on the Russian Plain, in central Europe, and in isolated areas in Western Europe. Loess is widespread on the Columbia Plateau and Mississippi basin in North America and on La Plata basin in South America.

Outside the present-day temperate belt, non-typical loess varieties have developed. They vary in clay and sand content, mineral composition and color. Some loess, such as that in New Zealand and Argentina has a high content of volcanic glass and feldspars,

while loess in parts of Central Asia, the Rhine Valley and the Mississippi Valley has a high content of carbonate minerals (up to 30%). Some deposits, such as those of Nebraska, contain up to 40% sand (*sandy loess*). At the other end of the spectrum, fine-grained loesses on the southeastern and eastern margins of the Chinese Loess Plateau and Tadjikistan have more than 20% clay (*clayey loess*). Brownish-pink loess varieties are common in the Mediterranean climatic zone (Kashmir, Pakistan, Iran, Israel, North Africa and New Zealand) and non-calcareous loesses were formed under relatively humid environmental conditions in some regions. A special loess variety, the “*yedomas*” loess-ice complex, occurs in large patches in northeastern Siberia, in the permafrost tundra zone. Along Yukon River in Alaska and on the Loess Plateau of China, high rates of loess deposition continue today.

MARINE BIOGENIC SEDIMENTS

General features

Biogenic (or biogenous) sediments are ubiquitous in marine environments; the main divisions are readily classified with reference to the amount of carbonate present and the depth of water at which they are found (shallow or deep). The dominant types are (in the order of abundance): deep-sea carbonates (calcareous ooze, foraminifer ooze, nannofossil ooze); deep-sea siliceous deposits (siliceous ooze, diatom ooze, radiolarian ooze); hemipelagic silica-rich deposits (at continental margins below upwelling regions); shelf carbonate deposits (reef and platform carbonates, dominated by coral and algal debris or by foraminifer and mollusk materials, depending on circumstances; reefal debris, lagoonal carbonate muds, etc.); and various types of anaerobic deposits (rich in organic matter and with or without opal or carbonate). Because deep sea covers most of the surface of the planet, the dominant biogenic deposits are deep-sea sediments, and their dominant ingredient is pelagic plankton, reflecting the fact that production is tied to sunlight (Figure M1).

The key ingredients of biogenic sediments are therefore calcium carbonate, opaline silica, and organic matter; the first two of these ingredients are largely in the shape of microfossils on the deep-sea floor (Funnell and Riedel, 1971; H. C. Jenkyns, in Reading, 1986). Opaline fossils and organic matter tend to occur together (but not invariably so) and are generally found in high productivity regions. While carbonate is precipitated in such regions, it tends to be dissolved because a high supply of organic matter will increase carbon dioxide levels at the water-sediment interface, which produces carbonic acid. This circumstance was well understood by John Murray of the *Challenger* Expedition in the nineteenth century. Murray also provided the main subdivisions of deep-sea sediments and noted that deep-sea carbonates tend to occur in the shallower half of the deep-sea floor. The boundary is referred to as the “carbonate compensation depth” or CCD. It is the largest of the biogenic sedimentary features on Earth and reflects a balance

between rate of supply (almost all from calcareous plankton) and rates of dissolution (which increase with depth). The level of the CCD responds to the carbon chemistry of deep waters, and is quite different in the North Atlantic (deepest, below 5 km) and North Pacific (shallowest, above 4 km north of the equator). Roughly, this level runs parallel to the “apparent oxygen utilization”; that is, the amount of oxygen in deep water that has been converted to carbon dioxide. Because of this relationship, fluctuations of the CCD through time are useful in the reconstruction of the marine carbon cycle, and provide (some) clues to changes in the sharing of carbon dioxide between ocean and atmosphere. Quite generally, the deposition of biogenic sediments and the record contained therein are crucial ingredients in defining the machinery of global biogeochemical processes (e.g., Butcher et al., 1992).

Shallow-water carbonate deposits

Biogenic sediments in the sea consist of fossils or fragments of fossils. Initially, it was the study of fossils (paleontology) that dealt with their origin and applied this knowledge in biostratigraphy (the dating of sedimentary sequences and the tracing of evolution) and the reconstruction of environments of the past (paleoecology, paleoclimatology, paleoceanography). Geologists interested in these subjects studied modern shallow-water environments, beginning in the nineteenth century, with emphasis on corals, mollusks, foraminifers and other organisms producing hard parts of carbonate. Reefs provided an early focus and attractor because fossil diversity tends to be high in reefs (“bioherms”) preserved in the geologic record (for an overview, see B. W. Sellwood, in Reading, 1986). From the 1950s, developments in scuba diving opened entirely new avenues for direct observation and for experiments (Figure M2). Sampling submerged coral now routinely provides information about past conditions of growth, based on the measurement of growth bands, supplemented by chemical analysis. The study of modern environments and of the record preserved in skeletal structures has provided tools to study ancient environments as well, using fossils from the appropriate time. The information sought includes depth of water, temperature, productivity, dynamic interactions between organisms and environment and between

Haeckel); *bf*: benthic foraminifers (E. Haeckel).

the organisms themselves, the role of disturbance, and seasonal variation. Above all, fossils – whether large or small (macro- or micro- or nanno-fossils) – record their environment of growth. If they do not like the extant conditions, they may shut down and record nothing (“biased reporting”). To gather information about past climate conditions, therefore, one has to employ several lines of evidence, using paleontology, sedimentology, geochemistry, and physical principles in a best-guess approach to reconstruction.

The largest biogenic structure on the planet is the Great Barrier Reef (GBR) off the northeastern coast of Australia. Drilling (by the drilling vessel *JOIDES Resolution*, in the context of the international Ocean Drilling Program (ODP, 1985–2003)) has demonstrated that the bulk of the structure is geologically young, less than one million years old. Presumably, the origin of the great reef is tied to the large sea level fluctuations that occurred after 800,000 years ago. Reefs are rubble factories, and sea level fluctuations stimulate rubble production. In particular, the periods of rapid rise during the melting of large ice sheets would have favored survival and expansion of rapidly growing species, such as those belonging to the genus *Acropora*. In addition, sometime after

the Mid-Pleistocene Climate Shift (see below), the Western Equatorial Warm Pool expanded southward to the region of the GBR, presumably aided by the clogging of the warm-water exit into the Indian Ocean and by the reef rubble produced around Indonesian islands. The GBR is a highly irregular structure (Figure M3). Its features and those of other reefs in the South Pacific erode during low stands of sea level (especially chemical erosion; Purdy, 1974), and build up during high stands favoring shallow ground. Without sea level fluctuation and attendant erosion, the product of reef growth is a carbonate platform.

Deep-sea carbonate deposits

Calcareous ooze rich in foraminifers was first discovered as a widespread deposit on the deep-sea floor in the middle of the nineteenth century. It was not clear, initially, whether the biogenic remains evident within the ooze originated on the sea floor or in the water. John Murray showed, by comparing plankton samples with sediment samples, that the bulk of the sand-sized material consists of planktonic foraminifers (“*Globigerina* ooze”). He also realized that the preservation of these fossils deteriorates with depth in the water, such that all carbonate would be dissolved below some depth (now known as the

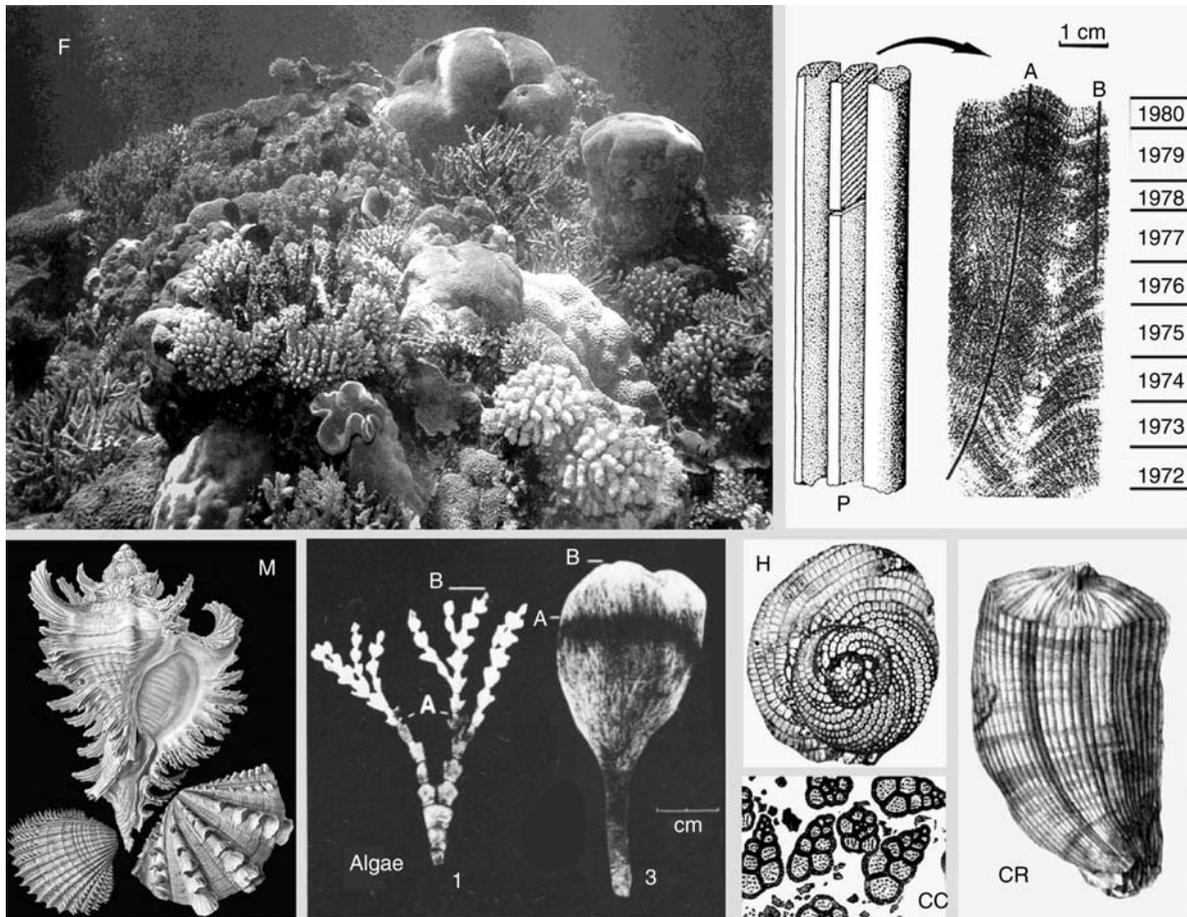

Figure M2 Shallow-water calcareous biogenic sediments originate from carbonate-secreting organisms such as corals, mollusks, algae, and foraminifers. *F*: Tropical coral reef at Fanning Island (SIO photo); *P*: core sample from a specimen of *Porites* from the western tropical Pacific (J. Pätzold, Bremen); *M*: armored mollusks (E. Haeckel); *A*: algae, in situ staining of calcareous algae in Bermuda (*Halimeda*, *Penicillus*) to determine rate of growth (G. Neumayr); *CR*: Cretaceous mollusk, reef-forming in places (rudist pelecypod, M. Neumayr).

CCD), leaving only “Red Clay.” The CCD describes the narrow depth-dependent zone where carbonate-rich sediments give way to red clay and other carbonate-poor deposits bathed by undersaturated waters. A more subtle assessment of conditions on the sea floor at the time of deposition is possible by noting the state of preservation of calcareous fossils (Figure M4). A narrow zone separating well-preserved from poorly preserved fossils within the calcareous ooze defines the level of the “lysocline.” The lysocline fluctuates through time as a result of changes in deep circulation, which affects oxygen and carbon dioxide content of deep waters. Quite generally, patterns of preservation (taphonomy) hold a large amount of information regarding the environmental conditions during deposition of biogenic sediments.

The fact that rates of carbonate accumulation change considerably in a given region of the deep-sea floor was discovered during the Swedish Deep-Sea Expedition (1947–1948). It was especially obvious in the eastern equatorial Pacific, where sediments show regular cycles of light and dark colors, associated with high and low carbonate content. Both fluctuations in carbonate production and fluctuations in the intensity of carbonate dissolution can produce such cycles. The sediment cycles were

linked to productivity fluctuations that were in turn ascribed to changing trade wind intensities and equatorial upwelling, with ice ages having the stronger winds and increased upwelling (Arrhenius, 1952). In general, these concepts were supported by later studies, although the light-dark cycles are largely a result of variations in the intensity of carbonate dissolution.

Overall, calcareous nannofossils are the dominant component of calcareous ooze, especially in the large regions of low productivity below the central gyres. Thus, the typical biogenic deposit on the planet is coccolith ooze. Study of the minute coccoliths (platelets shed from coccolithophorids, Figure M1, upper left) requires the use of powerful microscopes. The invention and spread of scanning electron microscopes greatly aided in producing inventories and detailed descriptions of these fossils (Winter and Siesser, 1994). The pioneer work was done using petrologic microscopes, and these instruments still are the preferred tools for routine shipboard analysis, i.e., for the biostratigraphic dating of sediments during drilling expeditions. The presence of easily recognized nannofossils known as “discoasters” (Figure M1, far right) indicates an age greater than Quaternary, for example. Discoasters died out at the end of the Pliocene.

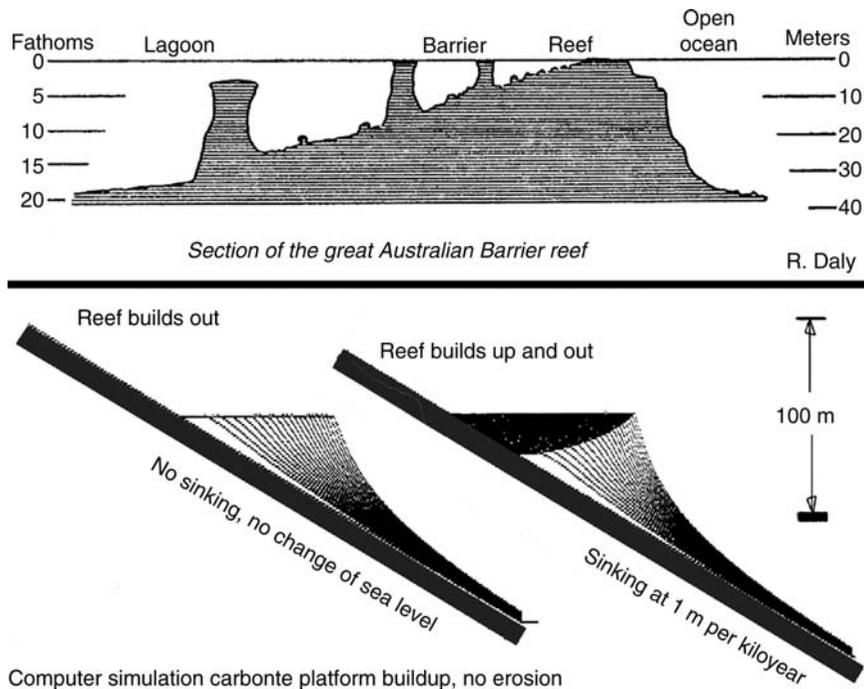

Figure M3 Nature of the Great Barrier Reef, as a product of differential buildup (during high sealevel stand) and erosion (during low stands). *Upper:* Profile through Great Barrier Reef, drawn by R. Daly (1934). *Lower:* basic structure of a carbonate platform as expected for constant sea level and slow sinking of the foundation (W.H.B., unpublished).

In places, especially on relatively shallow regions of the Atlantic, calcareous ooze contains the shells of pelagic gastropods, in varying proportions. Such shells are made of aragonite, a polymorph of calcium carbonate that is much more soluble than calcite. The shells are typically 1 cm long; where dominant (made so by bottom currents washing the sediment) they constitute "pteropod ooze."

The process of seafloor spreading slowly moves calcareous sediments to greater depth, on a million-year time scale. Thus, as a general rule, deep-sea sediments overlying basaltic basement (generated at the spreading center) should be rich in carbonate, while sediments overlying these older deposits should have less carbonate. That is, by the principles of "plate stratigraphy," sediments at the bottom of the stack were originally deposited at shallower depths above the CCD near the spreading center. As the plates moved apart and the ocean floor subsided, older sediments fell below the CCD. Reality is more complicated because of large fluctuations of the CCD through geologic time. The largest such excursion was the enormous drop of the CCD to deeper levels around 40 million years ago (Figure M5). This drop (toward the end of the Eocene) represents a large shift in carbonate accumulation patterns, from shelf to deep sea. It heralds the beginning of the great cooling that dominated the Cenozoic and illustrates the importance of mountain building (uplift on land removes shelf seas) in the course of this cooling. The marked drop of the CCD in the Atlantic since about 10 Ma marks the turning on of deepwater production there; that is, a filling of the basin with more saturated waters (said to be "young"). At the same time, opaline fossils on the sea floor dissolved more easily from that time onwards (young water bears less silicate than old) and there was an overall shift of silica deposition from the Atlantic to the Pacific.

The Auversian Facies Shift at 40 million years ago, when carbonate deposits become widespread on the deep-sea floor, is well expressed in the acoustic stratigraphy of deep-sea deposits. The shift is recognized in the western tropical Pacific as a marked change from highly reflective layers (interbedded limestones and chert) to more or less transparent (echo-lacking) chalk sequences. The fundamental reason for this development is twofold: the switch of carbonate deposition from shelves to the deep-sea floor, and the removal of opal into upwelling regions by diatom deposition, including in the belt around Antarctica. Upwelling is a function of winds, and winds are driven by temperature gradients, hence zonal winds that drive year-round upwelling increase with polar cooling.

Ocean and climate history

The study of biogenic sediments, especially those recovered from the deep-sea floor, provides the basis for reconstruction of ocean and climate history for the last 100 million years or so (paleoceanography). Information for periods before this time is difficult to obtain because seafloor subduction removes the evidence. The main tool in reconstruction is a detailed biostratigraphy (Berggren et al., 1985; Bolli and Saunders, 1985), greatly aided by coordination with the history of magnetic reversals. The main clues for reconstruction are derived from a combination of biogeography and stable isotopes, notable oxygen and carbon isotopes (Vincent and Berger, 1981; Kennett, 1985; Wefer and Berger, 1991), complemented by a large number of additional proxies for environmental conditions (Hay, 1988; Fischer and Wefer, 1999). The most detailed reconstructions have centered on the last glacial maximum (following the CLIMAP studies, 1976) and on the sequence

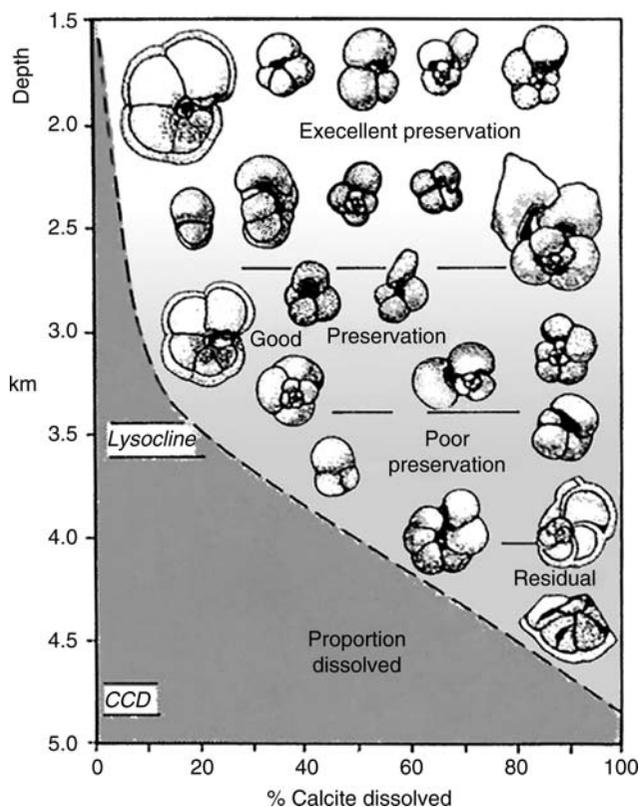

Figure M4 Deterioration of preservation of calcareous fossils (here: planktonic foraminifers) as a function of water depth, and definition of lysocline and CCD. The color of the calcareous ooze becomes darker with depth, as the proportion of carbonate decreases.

of events since that time, with some emphasis on the Younger Dryas cold spell during the period of ice melting (Fairbanks, 1989). As noted by Olausson (1965) and many since, the addition of large amounts of meltwater to the northern North Atlantic interferes with the formation of deep water and thus has many ramifications for the global thermohaline circulation (Broecker and Denton, 1989).

The pioneer work in the reconstruction of the history of the last million years was done on the cores obtained by the *Albatross* during the Swedish Deep-Sea Expedition (1947–1948, led by Hans Pettersson), by Gustaf Arrhenius, Cesare Emiliani, Eric Olausson, Frances Parker, and Fred Phleger. For the history of the last 100 million years, the pioneer studies were done by a rapidly growing community of biostratigraphers and paleoceanographers on material recovered by the drilling vessel *Glomar Challenger*, in the Deep Sea Drilling Project (1968–1983). Among the contributors to the first of the “Initial Reports on the Deep Sea Drilling Project” were M. N. Bramlette, W. R. Riedel, W. A. Berggren, E. A. Pessagno, J. D. Bukry, W. W. Hay, W. H. Blow, J. D. Hays, and A. G. Fischer. Project Chief Scientist was M. N. A. Peterson. Just as the *H.M.S. Challenger* symbolizes the beginning of modern oceanography, the *Albatross* and the *Glomar Challenger* are iconic for the beginnings of paleoceanography. A third vessel, the *JOIDES Resolution*, took over from 1985 and became the dominant tool for ocean history exploration at that time.

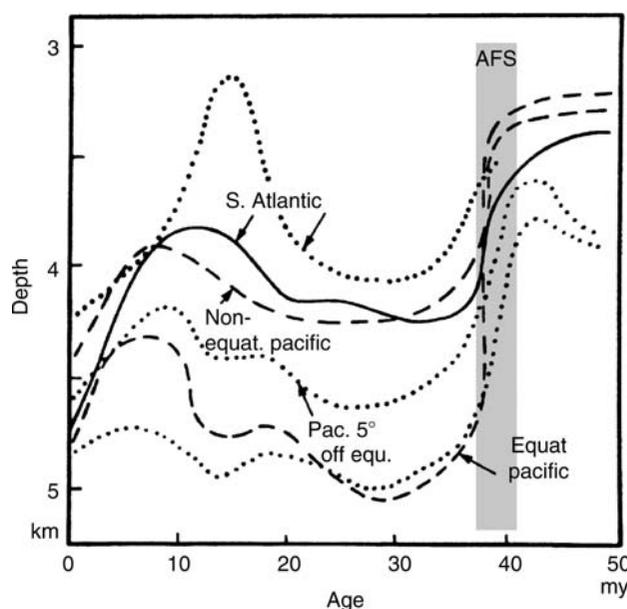

Figure M5 Reconstruction of CCD variations for various regions of the ocean. *Dotted lines*: According to Berger and Roth (1975). *Solid and dashed lines*: according to van Andel et al. (1977), as drawn in Seibold and Berger (1993). *AFS*: Auversian Facies Shift (Berger and Wefer, 1996). The AFS denotes an overall change in sedimentation patterns, whereby calcareous ooze becomes dominant in deep-sea deposits (carbonate deposition being shifted from shelf to deep sea) and opaline sediments are no longer widespread, but become concentrated below upwelling regions, including the sea around Antarctica.

The main result from the *Albatross* investigations was that biogenic deep-sea deposits show cyclic sedimentation, a finding that was linked to orbitally driven climate change and corresponding ice-age fluctuations. Much evidence has been found since to support this notion, especially from the analysis of oxygen isotopes of planktonic and benthic foraminifers, and from time series analysis using Fourier methods (Hays et al., 1976). The ice-age cycles are driven by changes in seasonal contrast, much as initially suggested by the Serbian mathematician Milutin Milankovitch (1930). The dominant cycles reflect the influence on seasonal contrast from changes in the obliquity of Earth’s axis (41,000 years) and in the eccentricity of the orbit (near 100,000 years) (Figure M6). Precession (the fact that summer solstice migrates between positions close to and far from the sun along the orbit) translates the eccentricity signal into 23,000-year amplitude variations in climate, which express themselves especially strongly in the productivity cycles of upwelling regions. A striking change in response of the climate system to the forcing occurs near 920,000 years ago: a strong long-term cycle sets in as the amplitude of the signal increases, first expressed as a doubling of the obliquity cycle, and then (near 700,000 year) moving into a 100,000-year cycle.

The main result from *Glomar Challenger* drilling concerned the evolution of a cold ocean from a warm one, with all its ramifications (Kennett, 1982). This general *leitmotif* governs the evolution of marine organisms during the Cenozoic, from nannoplankton to whales (which evolved blubber and baleen to gather krill in cold upwelling regions).

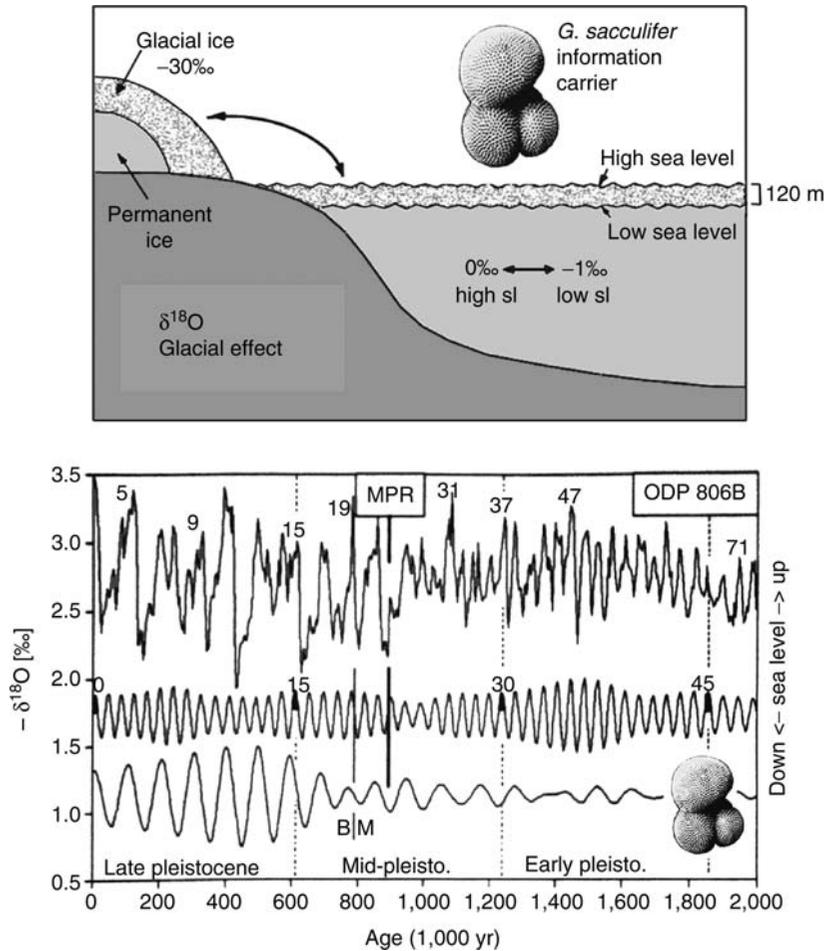

Figure M6 Oxygen isotope stratigraphy of Quaternary biogenic sediments from the western equatorial Pacific. *Upper:* Diagram showing how ice-mass changes are translated into variations of oxygen isotope composition of planktonic foraminifers (concept introduced by C. Emiliani, 1955). *Lower:* Stratigraphy of a sequence of cores from Ontong Java Plateau (modified after Berger and Wefer, 1992). *Numbers:* Emiliani isotope stages. *MPR:* Mid-Pleistocene Revolution (climate shift to long cycles with large amplitudes). *Top:* Original isotope sequence. *Below:* 41-kyr cycle contained in the series, and 100-kyr cycle, based on Fourier decomposition of the original record.

The chief drawback of early drilling was the mixing of sediment during drilling. This was largely eliminated during the Ocean Drilling Program (1985–2003), by sending a piston coring advice ahead of the drill bit. The cores allow for high-resolution studies, on a thousand-year scale, and this opened the door for “tuning” of the sedimentary record to Milankovitch forcing, which can be reconstructed rather precisely (Shackleton and Crowhurst, 1994). As a result, detailed records of climate change emerged, including the details and differences of ice-age cycles in various regions of the ocean. Other topics that have been studied in detail are Antarctic ice buildup and the response of the ocean in terms of changing productivity and deep-sea circulation, the nature of the climate change at the Eocene-Oligocene boundary (Prothero and Berggren, 1992), and the sequence of a strange carbon isotope excursion at the end of the Paleocene (thought to involve large-scale release of methane from submarine clathrates; Dickens et al., 1995). The series of events surrounding the grand extinction event 65 million years ago attracted much interest, as did many other examples of natural experiments that allow an assessment of

how the climate machine works and how the ocean responds to disturbance.

The great sustained stepwise cooling that characterizes global climate history since the late Eocene (Auversian Facies Shift, AFS, 40 million years ago) is well reflected in the oxygen isotopes of benthic foraminifers from the deep-sea floor of the Atlantic (Figure M7). The isotope index traces both ice and temperature; thus, it illustrates both the cooling of deep waters and the buildup of polar ice sheets, but at different proportions depending on the time span considered. Ice on Antarctica is thought to enter the picture around the time of the AFS, followed by major changes in circulation and associated sedimentation patterns. However, great ice sheets have presumably only covered the Antarctic continent since the middle Miocene. At the Pacific equator, the first indications for a narrowing of the zone of upwelling appear after the AFS, in the shape of a band of opaline sediments (that is, sediments rich in radiolarians and diatoms). These sediments are significant as a clue to the rise of zonal winds. An asymmetry of zonal wind activity about the equator would have been

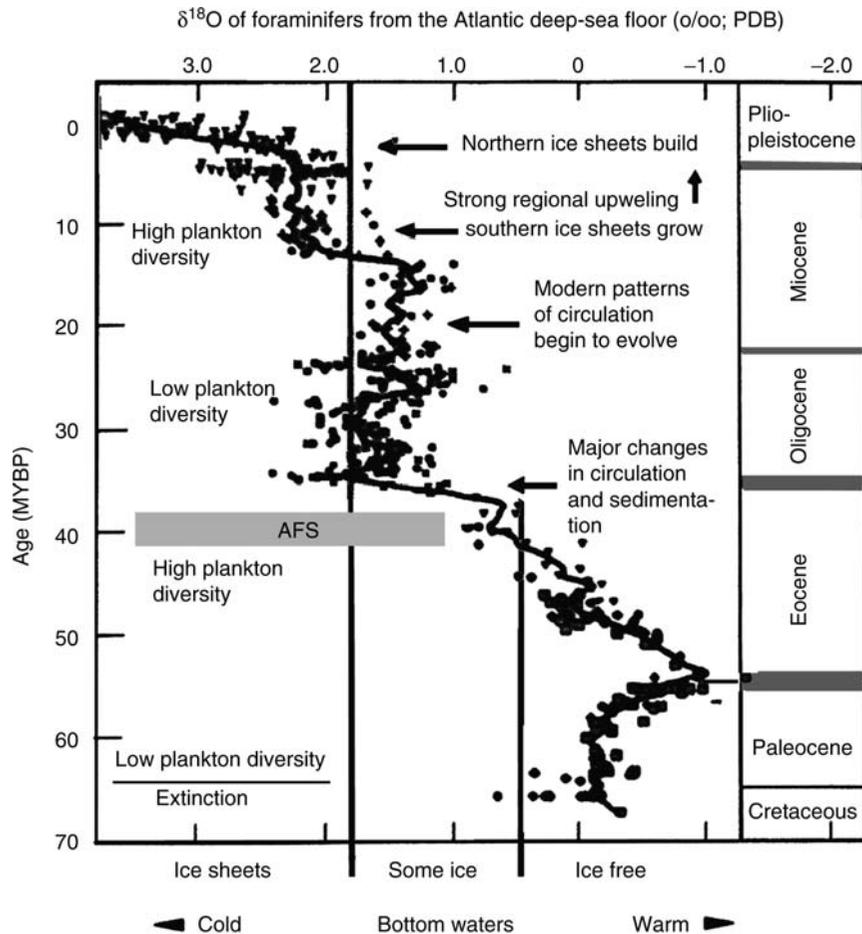

Figure M7 Stepwise cooling in the Cenozoic, since 40 million years ago (AFS, Auversian Facies Shift). The first step implies production of cold deep water (seen in the extinction of benthic foraminifers); the second, buildup of Antarctic ice caps; the third, buildup of ice in the northern polar regions (modified after a diagram in Miller et al., 1987).

present, similar to that found today but more pronounced. The southern trades helped to drive equatorial upwelling. A strong asymmetry presumably persisted until well into the late Neogene, when ice buildup in the Northern Hemisphere provided a counterweight to southern polar ice fields (Flohn, 1985).

The low plankton diversity during the Oligocene is puzzling. The rapid increase of diversity in the early Miocene, with the evolution of deep-living and shallow-living plankton, has been linked to the development of a thermocline. Certainly, the existence of a thermocline within the sunlit zone is a defining feature of the modern ocean. Photosynthesizing organisms must stay in the sunlit zone sufficiently long, on average, to produce more substance than they use up in respiration. Whenever the mixed layer is substantially thicker than the sunlit layer, this basic condition (Sverdrup's criterion of net photosynthesis) is not likely to be met. A deep and/or ill-defined thermocline will allow a thick mixed layer. This makes the pelagic realm an unfavorable habitat for production. In addition, the lack of opportunity for migrating up and down through the different environments defined by a thermocline precludes diversification. We may conclude, therefore, that in the Oligocene the thermocline was largely ineffective as an element

in structuring the pelagic environment; that is, the habitat of plankton.

Strong coastal upwelling, based on silica and organic matter content of hemipelagic sediments, is well documented for the last 10 million years or so, especially in the Southern Hemisphere (Summerhayes et al., 1992; Christensen and Giraudeau, 2002). Presumably, the resulting high abundance of plankton and associated herring-like fish favored the rapid evolution of warm-blooded predators, including sea birds, both with and without flight, and marine mammals.

A direct comparison of warm oceans (pre-AFS) and cool or cold oceans (post-AFS) is complicated by the fact that the former are associated with large shelf seas and the latter are not. Furthermore, the configuration of continents was quite different, with a broad seaway once connecting the Pacific, Indian and Atlantic Oceans in tropical latitudes – the Tethys (Barron and Peterson, 1989; Barrera and Johnson, 1999). Any efforts to relate differences or similarities in life habitat conditions and biodiversity to the warm-cold contrast may well be compromised by the presence or absence of large shelf seas and the Tethys seaway (The Tethys persisted well into the Cenozoic; Haq, 1981). There are some features of the warm ocean,

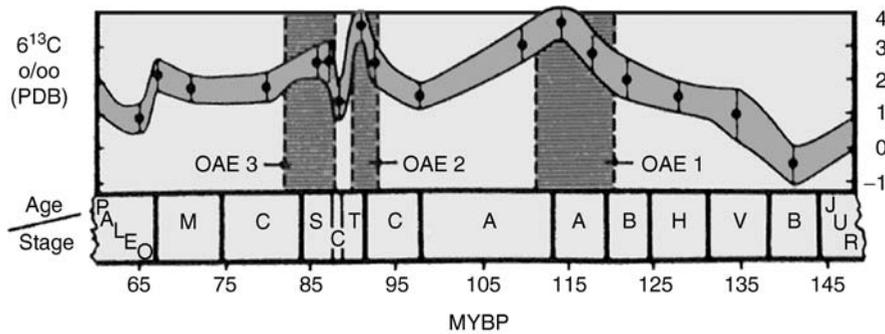

Figure M8 General trends of carbon isotope stratigraphy (pelagic marine limestones) in the Cretaceous, suggesting the removal of organic carbon during times of low oxygen availability (that is, during deposition of black mud) (modified from Arthur et al. 1985). OAE: Oceanic anoxic event.

however, that are quite different from those of a cold one on a fundamental level. Foremost among these is a dearth of oxygen in deep waters, which largely derives from the fact that oxygen is less soluble in warm water than in cold. This, presumably, greatly contributed to the fact that anaerobic conditions, reflected in the accumulation of black mud (now shale), were widespread during Cretaceous periods, and especially so during certain privileged intervals spanning the Albian-Aptian, Cenomanian-Turonian and Santonian-Campanian boundaries. The cause for extended anaerobic conditions, it is thought, is a greatly increased effusion of volcanic magma to the surface of the planet, bringing with it a corresponding increase of carbon dioxide in the atmosphere (Arthur et al., 1985). The system responds by burying organic carbon, which counteracts the geochemical imbalance. The burial of organic carbon preferentially removes C-12 from the carbon cycle, driving up the ratio between C-13 and C-12, which is then reflected in the stable isotope composition of calcareous fossils deposited at the time (Figure M8). The origin of much of the retrievable petroleum on the planet is linked to anaerobic conditions in the middle Cretaceous seas. The paleoceanographic implications of oxygen stress are vast, including widespread denitrification, which would have greatly impacted the level of productivity (For background on productivity in the sea, and reading the record of productivity in biogenic sediments, see Falkowski and Woodhead, 1992).

The great concepts of orbitally driven climate cycles during the Quaternary, of general cooling during the Cenozoic, and of warm oxygen-stressed seas in the Cretaceous, along with the revolutionary insights from plate tectonics, have fundamentally changed the way geologists look at the environmental history of the planet in the second half of the twentieth century. However, perhaps the single most important clue to the nature of Phanerozoic history, and especially regarding evolution, has been the recognition of the importance of the end-of-Cretaceous ("K-T") impact of a celestial body with Earth, producing widespread extinction (for discussions, see Berggren and van Couvering, 1984). It was within biogenic deposits that the extinction event was first clearly documented, in particular in calcareous shallow-water and pelagic deposits (e.g., Berggren, 1962; Bramlette, 1965). The evidence for impact was found in a famous pelagic carbonate section near Gubbio in Italy (Alvarez et al., 1980), where the exact horizon of extinction of planktonic foraminifers had been previously established (Luterbacher and Premoli-Silva, 1964).

Studies of the K/T boundary have greatly contributed to the reconstruction of the exact sequence of events, and especially to elucidating the early response of the system to stress (involving strange plankton blooms: Thierstein and Okada, 1979) and the course of recovery from the event in terms of biodiversity (in a time-span counted in millions of years).

MARINE CARBON GEOCHEMISTRY

Introduction

The ocean contains approximately 50 times as much dissolved CO₂ as is contained in the atmosphere, and the carbon cycle in the ocean controls the pCO₂ of the atmosphere on time scales of thousands of years. The atmospheric CO₂ concentration today is rising because of human activities, such as fossil fuel combustion and deforestation. The CO₂ rise is faster than the century-scale ocean/atmosphere equilibration time, but the ocean will ultimately absorb most of the CO₂ that is released. In the past, changes in the carbon cycle of the ocean drove changes in atmospheric pCO₂ synchronously with the glacial/interglacial climate cycles. The orbital forcing which paces the glaciations (called Milankovitch cycles, see *Astronomical Theory of Climate Change*) is asynchronous across the equator; extra warmth in the north is balanced by decreased heating in the south. However, because of the rapid mixing of the atmosphere, the glacial CO₂ cycles tend to warm or cool the entire planet synchronously, and are largely responsible for the global synchrony of the glaciations. The carbon cycle of the ocean is therefore a primary determiner of the climate of the Earth, in the past and in the future.

The carbon cycle in the ocean begins with gas fluxes across the sea surface into the atmosphere. These depend on wind speed, temperature, and the chemistry of the water at the sea surface. Seawater chemistry of CO₂ is complicated by the presence of the carbonate pH buffer system pH. Only a tiny fraction of the dissolved carbon is present as the uncharged dissolved gas that can interact with the atmosphere. Because of this chemistry, a slight change in the pH of seawater can result in an enormous change in the concentration of dissolved CO₂, and in the equilibrium pressure of CO₂ in the atmosphere. The solubility of dissolved CO₂ depends on temperature and to a lesser extent salinity, so that a warming parcel of seawater will tend to push more CO₂ into the atmosphere. The CO₂ concentration of surface ocean waters is also affected by the growth and sinking of phytoplankton in the surface ocean. The carbon cycle of the ocean is therefore determined by a

combination of chemical, physical, and biological mechanisms (see also *Carbon cycle*).

The physical chemistry of carbon in seawater

Carbon is a unique element in the biosphere, in part because of its extremely varied chemistry. The oxidized form, CO_2 , is the dominant form in the atmosphere. In seawater, oxidized carbon undergoes hydration and pH reactions leading to generation of bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) ions. These species are collectively called “dissolved inorganic carbon” or DIC. The most reduced form of carbon is methane, CH_4 , while most biological carbon exists at intermediate oxidation states analogous to carbohydrates, which follow the approximate stoichiometry CH_2O . Reduced forms of carbon are collectively called “organic carbon.” Production of organic carbon from inorganic requires an input of energy, such as the light energy used in photosynthesis, or chemical energy used in chemosynthesis.

In the air, the CO_2 abundance can be defined as a concentration (molecules per volume), a proportion or “mixing ratio” (molecules of CO_2 per molecule total), or as the proportion of the total pressure that can be attributed to CO_2 . This last quantity is called the “partial pressure,” and at sufficiently low total pressures, the ideal gas law tells us that the partial pressure of a gas like CO_2 is very close to the total pressure of the mixture multiplied by the fraction of the molecules that are CO_2 . The atmospheric CO_2 abundance is commonly expressed either as a mixing ratio in units of parts per million (ppm), or as a partial pressure in units of microatmospheres ($10^{-6} \text{ atm} = \mu\text{atm}$). The numerical value of either of these measures in the atmosphere is close to 370 in both cases (and is presently rising by approximately 1.5 ppm or μatm per year). The abbreviation “ $p\text{CO}_2$ ” stands for partial pressure (and is unfortunately easy to confuse with the meaning of pH, defined as the negative logarithm of the concentration of H^+). For a detailed discussion of the physical chemistry of inorganic carbon in seawater, see Stumm and Morgan (1981).

A convenient way to think about CO_2 equilibrium between air and water is to take the chemistry of a water sample, and calculate how much CO_2 would exist in the air above it in equilibrium. In this way, we can define the $p\text{CO}_2$ of a water sample. This tells us nothing about the real physical pressure that a diver, for example, would feel in the water, but tells us what the composition of a bubble would be after it has had a chance to equilibrate. In nature, water and gas phases are not always in equilibrium; in fact, for CO_2 at the surface of the ocean, disequilibrium is the rule. If the $p\text{CO}_2$ of a water sample is higher than the $p\text{CO}_2$ of the air it is in contact with, then CO_2 will tend to evaporate from the water into the air, lowering the $p\text{CO}_2$ of the water and raising the $p\text{CO}_2$ of the air as the system approaches equilibrium (see *Carbon dioxide, dissolved (ocean)*).

The solubility of any gas in water depends on temperature, with increasing solubility as the water cools down. CO_2 gas is no exception. At a given concentration of dissolved CO_2 , the equilibrium partial pressure in the gas phase therefore decreases as the temperature drops (increasing solubility means less remains in the gas phase). The surface ocean is warm in the tropics and cold at the poles. Therefore, one component of the carbon cycle in the ocean is a tendency for CO_2 to escape to the atmosphere in the warm tropics, where it is less soluble, and to invade the ocean in the colder high latitudes.

Partitioning of carbonate species in seawater

CO_2 gas proper is but a minor participant in a larger chemical system called the carbonate buffer system. CO_2 gas combines with water (is “hydrated”) to form carbonic acid (H_2CO_3). Carbonic acid undergoes two proton dissociation reactions (loss of H^+) to form the charged (ionic) species bicarbonate (HCO_3^-) and carbonate ion (CO_3^{2-}). The hydration reaction is

In practice, it is analytically difficult to distinguish hydrated from unhydrated CO_2 , so these two species are lumped together into a single category that for simplicity we will just call dissolved CO_2 in the discussion that follows. The equilibration time of this reaction is roughly a minute, although it can be accelerated in biological systems by the enzyme carbonic acid anhydrase.

The dissociation reactions are governed by equilibrium expressions, denoted K_1 for the loss of the first proton and K_2 for the second. The dissociation constant K_1 can be written to determine the ratio of the products to the reactants of the reaction

while the second, K_2 , applies to

The ratios are taken between the activities of each of the solutes, which can be approximated by the concentrations in moles per liter, denoted by square brackets:

$$K_1 = [\text{HCO}_3^-][\text{H}^+]/[\text{CO}_2]$$

and

$$K_2 = [\text{CO}_3^{2-}][\text{H}^+]/[\text{HCO}_3^-]$$

Values of the dissociation constants are given by Dickson and Millero (1987).

Built upon these seemingly simple relations is a chemical system of rather counter-intuitive behavior. One example is the response of $[\text{CO}_3^{2-}]$ to changes in the CO_2 concentration of the solution (Equation 1). Carbonate ions determine whether CaCO_3 from coral reefs or planktonic shells dissolves (see *Carbonate compensation depth*). The response of an equilibrium reaction to an addition of a species on one side of the equilibrium is a tendency to shift the equilibrium toward the opposite direction, to “mop up” the added species. The response of the first dissociation (Equation 2) in isolation would be an increase in HCO_3^- and H^+ (an increase in H^+ is equivalent to a decrease in pH). The response of the second dissociation reaction might seem to be another shift to the right, increasing the concentration of CO_3^{2-} (and increasing the stability of CaCO_3). We could call this the “rising tide floats all boats” response.

However, this simple expectation is wrong. The flaw in our reasoning was to ignore the protons, which exist in much lower concentration than any of the carbon species. The rightward shift in Reaction 2 above generates a much more profound change in H^+ , relative to its concentration, than the change in HCO_3^- . H^+ therefore dominates the response of Reaction 3, which shifts to the left rather than to the right as we would assume. The behavior of the system can be seen more intuitively by combining both reactions, eliminating the troublesome

protons (and thereby conceptually forbidding them from changing their concentrations at all – a better approximation). This new reaction is:

When the reaction is written in this way, an addition of carbonic acid (or, equivalently, CO_2) can be seen to consume CO_3^{2-} , provoking the dissolution of coral reefs, rather than their growth. In spite of the fact that CaCO_3 contains carbon, it cannot act as a sink for CO_2 unless a source of base is added.

The buffer chemistry of seawater has an immediate implication for the interaction of seawater with rising atmospheric $p\text{CO}_2$, even in the absence of solid CaCO_3 . For a simple unbuffered gas like oxygen, for example, the solubility of the gas is expressed by Henry's law

$$K_{\text{h},\text{O}_2} = p\text{O}_2/[\text{O}_2]$$

which tells us that the concentration of the gas in solution goes up proportionately to a rising partial pressure in the gas phase. The relation also holds for CO_2 , as

$$K_{\text{h},\text{CO}_2} = p\text{CO}_2/[\text{CO}_2]$$

but the total amount of CO_2 that the seawater can absorb is affected by the buffer chemistry as expressed in Reaction 4 above. Dissolved carbonate ion (CO_3^{2-}) reacts with added CO_2 , effectively hiding it from the atmosphere and from Henry's law. The buffer works by reacting most of the invading CO_2 with CO_3^{2-} to form HCO_3^- , so the strength of the buffer is determined by the ratio of the CO_2 and CO_3^{2-} concentrations. Globally, the average ratio of CO_3^{2-} to CO_2 in surface waters is about 10, so seawater can hold 10 times as much CO_2 as it would without the buffer system. As atmospheric CO_2 rises, however, sea surface CO_3^{2-} concentrations will drop, and the buffer capacity of seawater will decline.

When the gas concentration in the surface ocean is out of equilibrium with the atmosphere, it relaxes toward equilibrium by a process known as gas exchange. The rate of gas exchange depends on the wind speed, surface roughness, bubbles and foam, the presence or absence of a surface microlayer, or skin of oils, and the diffusivity of the gas. A typical gas exchange rate is $3\text{--}5 \text{ m d}^{-1}$, meaning that a typical mixed layer of 100 m thick at the ocean surface will approach equilibrium with an e-folding time scale of $100 \text{ m}/5 \text{ m d}^{-1} = 20$ days (see Wanninkhof, 1992). For CO_2 , the factor of 10 buffering would increase the time scale to about 200 days. For the ocean as a whole, the rate at which gases invade the deep ocean is limited by the circulation time scale of the ocean, which is about a thousand years. For CO_2 , because the ocean is the larger reservoir, the atmosphere largely responds to ocean forcing, rather than the other way around, on the time scale of ocean overturning circulation.

The balancing of the various dissolved carbon species across the equilibrium reaction makes it somewhat more complicated to think about the carbon cycle in the ocean. For example, when seawater with one set of concentrations is mixed with a different seawater sample with a different set of concentrations, the mixed carbonate buffer system adjusts to re-establish pH balance. That is to say, if we combine one solution with $10 \mu\text{M}$ CO_2 with equal parts of another that starts with $20 \mu\text{M}$ CO_2 , we do not necessarily obtain a solution that contains $15 \mu\text{M}$ CO_2 , because some of the CO_2 reacts with CO_3^{2-} in

the resulting mixture. This makes life complicated for oceanographers, who would prefer that their chemical quantities be "conservative to mixing." The solution is a pair of derived quantities for seawater that do have the required conservation properties. One is the total concentration of all of the CO_2 species; this is called the "total CO_2 ," or ΣCO_2 . If we mix a solution that contains $1,800 \mu\text{M}$ ΣCO_2 with equal parts of another that contains $2,200 \mu\text{M}$ ΣCO_2 , we will obtain a solution that contains $2,000 \mu\text{M}$ ΣCO_2 , with no tricky business.

The other derived quantity is called the alkalinity, which is defined as the sum of all charges of the salts of weak acids in solution. One way to think about alkalinity is that if we were to add H^+ in an amount equal to the alkalinity, then all of the carbon in solution would be in the form of CO_2 , free to exchange with the atmosphere. Ignoring contributions from borate and other minor species, the "carbonate alkalinity" of seawater can be written as

$$\text{alk} = \text{HCO}_3^- + 2\text{CO}_3^{2-} \quad (5)$$

where the factor of two in front of CO_3^{2-} reflects the two protons it would take to produce carbonic acid from carbonate. The crucial point is that Reaction 4, above, has the same alkalinity on both sides of the reaction. As pH equilibrium redistributes carbon species toward one side or the other of Reaction 3, the alkalinity is unchanged. Therefore, if we combine two water parcels with different alkalinites, the alkalinity of the resulting mixture is a simple combination of the two. We say that both alkalinity and total CO_2 are conservative to mixing, and this simplifies our thinking about all kinds of processes that occur in the ocean carbon cycle.

How can we relate the alkalinity and total CO_2 to the equilibrium $p\text{CO}_2$ of surface waters, and exchange of CO_2 with the atmosphere? As we have already seen, dissolved CO_2 gas itself is only a minor part of the total carbon inventory of seawater, and the fraction of carbon in the form of CO_2 depends on the pH of the solution. Together, the alkalinity and the total CO_2 concentration can tell us everything there is to know about the carbon chemistry of the seawater. At a constant alkalinity, if we increase the total CO_2 concentration, the concentration of dissolved CO_2 and the equilibrium $p\text{CO}_2$ of the water sample will go up. This is easy to imagine, as an increase in the number of carbons without any change in the number of charges must lead to an increase in the number of uncharged carbons, that is CO_2 . In a similar way, if we maintain a constant total CO_2 and increase the alkalinity, then the number of charges per carbon atom goes up, and the proportion of uncharged CO_2 molecules goes down.

A useful property of the alkalinity is that it does not care about fluxes of CO_2 gas. An invasion of CO_2 from the atmosphere will increase the total CO_2 of the seawater, and alter the proportions of the various carbon species according to Reaction 3, but since shifts along Reaction 3 have no effect on the alkalinity, the alkalinity will be unchanged in response to gas exchange. In an analogous way, if we were to add strong acid to seawater somehow, this would change alkalinity while leaving the total CO_2 unchanged. This latter is a hypothetical example; natural fluxes of strong acid such as acid rain are generally negligible in the carbon chemistry of the surface ocean.

The biological pump

The other major mechanism governing the fluxes of CO_2 across the sea surface, nearly equal in magnitude to the effect of

temperature discussed above, is the growth and sinking of phytoplankton in the surface ocean. Geochemically, the effect of phytoplankton growth is to convert dissolved carbon into particulate carbon. Particles can sink, generating a net flux of carbon downwards in the ocean. Some of the phytoplankton (plants of the sea) sink on their own, while another fraction of the sinking carbon arises from the fecal pellets excreted by zooplankton grazers. This process has been called the “biological pump” (see Broecker and Peng, 1982). The atmosphere only sees the surface ocean, so the effect of the biological pump is to change the ocean chemistry so that the atmosphere sees, and therefore changes, the chemistry of the atmosphere itself.

It is helpful to divide the biological pump into two components, because these components have opposite effects on the CO_2 concentration and $p\text{CO}_2$ of the surface ocean. The first, and dominant, component is the organic carbon pump, comprised of the proteins, lipids, and other structural biochemical machinery of the cell. This is called the “soft tissue” pump. Only a small fraction of the plankton production is exported to depth; in very productive regions, the export fraction may reach half, while in the open ocean only 5–10% of the production is exported. The rest of the biomass produced is respired in the surface ocean, returning to dissolved carbon. Organic carbon production depletes the total CO_2 concentration of the seawater, but has only a small effect on the alkalinity. Therefore, the effect of the soft tissue pump is to decrease the $p\text{CO}_2$ of surface waters.

The second component of the biological pump is the production and sinking of the calcium carbonate (CaCO_3) shells of some plankton species. This process is called the “hard tissue” pump. The formation of CaCO_3 takes place by the reaction

Because one mole of CO_3^{2-} accounts for one mole of total CO_2 but two equivalents of alkalinity (see Equation 5), the effect of the CaCO_3 pump is a 2:1 change in alkalinity versus total CO_2 . A decrease in alkalinity leaves a greater proportion of uncharged carbon (CO_2), so the net effect of the CaCO_3 pump on the $p\text{CO}_2$ of surface waters is an increase in $p\text{CO}_2$.

When these two components of the biological pump are combined in the surface ocean, the rate of the soft tissue pump exceeds that of the hard tissues, so the overall effect of biological activity in the ocean is to decrease the $p\text{CO}_2$ of the atmosphere. CaCO_3 secreting plankton are favored in tropical surface waters, but even here the rate of organic carbon sinking from the surface ocean exceeds that of CaCO_3 by a factor of up to 10. In polar waters colder than 10°C , CaCO_3 production becomes even less important. If the biota of the ocean were killed and the contents of the ocean allowed to redistribute themselves in response to this, the $p\text{CO}_2$ of the atmosphere would perhaps double.

Photosynthesis in the ocean is limited by a number of factors that determine the extent to which biology affects ocean chemistry and atmospheric $p\text{CO}_2$ (Longhurst, 1998). The first factor is light; production of biomass requires energy, which is derived by sunlight via the photosynthetic apparatus. Although open ocean waters are clearer than any freshwater lakes on Earth, the incident sunlight is absorbed and scattered by phytoplankton, other particulate and dissolved material, and by the water itself. Although the absorption of light depends on wavelength (red is absorbed most quickly, which is why undersea scapes appear blue), in general the absorption of intensity of “photosynthetically available radiation” (PAR)

decreases over a depth scale of about 100 m. Below this depth, the metabolic costs of respiration exceed the available energy from photosynthesis, and phytoplankton are unable to thrive. The surface sunlit zone, capable of supporting phytoplankton, is called the “euphotic zone.” The production of CaCO_3 does not require energy in the same way as photosynthesis does, and there is some secretion of CaCO_3 by zooplankton such as foraminifera below the euphotic zone, but most CaCO_3 production is associated with phytoplankton called coccolithophorids in the euphotic zone.

A second factor influencing the availability of light to the phytoplankton is mixing. Winds tend to mix the surface waters of the ocean into a distinct mixed layer ranging from a few to a thousand meters thick. The thickness of the mixed layer depends on the contrast between the temperature (and to a lesser extent the salinity) of the surface ocean compared with the deep ocean. In the tropics, warm surface waters are more buoyant than the colder waters below. This density difference inhibits mixing of waters across the stratification boundary, and the mixed layer tends to be thin. Phytoplankton suspended in the surface euphotic zone tends to remain in the euphotic zone. However, at high latitudes, or in subpolar winter, the cooler surface waters mix more readily with subsurface waters, allowing the wind to create a deep mixed layer. The phytoplankton spend at least some of their time at depths deeper than the euphotic zone, limiting their growth. The “spring bloom” in the North Atlantic is a clear demonstration of the effect of mixing. As soon as spring warming stabilizes a shallow mixed layer, the phytoplankton concentrations and photosynthesis rates increase dramatically.

The end of the spring bloom in the North Atlantic (and in other regions) is caused by another factor that limits phytoplankton growth: nutrient ions such as NO_3^- and PO_4^{3-} , which are essential to the manufacture of the biochemical machinery of the cell. Nitrogen is used in the amino acid building blocks of proteins, and phosphorus is used in DNA and in an energy storage molecule called ATP. The elemental ratio of C:N:P in phytoplankton is relatively constant, and has been named the “Redfield ratio.” An astonishing fact about ocean chemistry is that the ratio of N:P in seawater is close to that of phytoplankton, so that to a first approximation, both elements get used up at the same time. Carbon, in contrast, exists in much greater abundance in seawater, so that the nutrients are always depleted first. The mean concentration of PO_4^{3-} in the ocean is $2.2 \mu\text{M}$; when this value is multiplied by a revised C:P Redfield ratio of 135 we estimate that approximately $200 \mu\text{M}$ of the roughly $2,000 \mu\text{M}$ ΣCO_2 concentration in the ocean (N10%) travels with PO_4^{3-} as “metabolic” CO_2 . The metabolic CO_2 represents the maximum impact of biology on the chemistry of the surface ocean.

The effect of the soft-tissue biological pump in the ocean is to deplete NO_3^- and PO_4^{3-} in surface waters by exporting them to the deep ocean. Primary production in the ocean is therefore tied intimately to upwelling or mixing of nutrient-rich subsurface waters into the surface euphotic zone. One place where this occurs is in near-shore waters, where winds drive offshore currents, pulling subsurface waters up from below. Another such place is along the equator, where the change of direction of the Coriolis force pulls surface waters away from the equator, leaving a void that must be filled by upwelling subsurface waters. A third mechanism for bringing nutrients to the surface takes us back to the spring bloom example above; deep wintertime mixing entrains nutrient-rich deep water into the euphotic

zone, recharging it with nutrients for the next spring bloom. After the nutrients are used up by the spring bloom, phytoplankton concentrations and photosynthesis rates decrease for the rest of the summer.

In contrast to the North Atlantic, some regions of the surface oceans, such as the Equatorial Pacific, the North Atlantic, and the Southern Ocean, maintain high concentrations of nutrients in the surface euphotic zone all year round, with no spring bloom. One of the more exciting discoveries of the past decade is that the phytoplankton may be limited by the availability of another nutrient, iron (Fe) (see *Iron and climate change*). Phytoplankton require iron in the minute ratio of approximately $1:10^5$ Fe:C. The oxic form of iron, Fe^{3+} , is relatively insoluble in water, and so seawater tends to become depleted in iron relative to their stocks of NO_3^- and PO_4^{3-} . When this water upwells, it must await the delivery of iron by deposition as dust from the atmosphere. The North Atlantic, according to this theory, is rich in dust deposition, so supports a spring bloom, while the equatorial Pacific is more remote, and is dust and iron limited.

There is a general correspondence between the temperature of the surface ocean and its nutrient content, although this relationship is not absolute. In part, this is because colder surface waters mix more readily with nutrient-rich subsurface. Deeper mixing also creates a situation of light limitation for phytoplankton, as explained above. At any event, the net effect of this correspondence is to set temperature and sea surface nutrients in opposition to each other in their effects on atmospheric $p\text{CO}_2$. The cold temperatures in the Southern Ocean, for example, tend to lower the $p\text{CO}_2$ of surface water, pulling CO_2 into the ocean. However, the high concentration of nutrients in Southern Ocean surface waters indicate that the ΣCO_2 concentration is higher there than it would be if nutrients were depleted, tending to increase atmospheric $p\text{CO}_2$ in the opposite direction from the thermal forcing. On the other hand, the region of the highest CO_2 flux from the ocean to the atmosphere is the equatorial Pacific, where nutrient-rich waters are warmed by the tropical sun, in other words where both temperature and nutrient forcing are working in the same direction.

Most of the organic matter that sinks out of the euphotic zone in the surface ocean never reaches the sea floor, typically 4 km below. It is subject to microbial degradation and to grazing by zooplankton in the mid-water column. The sinking flux of particles can be measured using a device called a sediment trap, which consists of a large funnel or cylinder with a carousel of sealable sample chambers that can sequentially store the falling debris (Honjo, 1996). Several traps are typically tied to a mooring, allowing an assessment of the sinking flux of carbon as a function of depth. These fluxes are generally found to decrease drastically over the top 500 m of the water column.

Different chemical components of the debris are removed selectively as they sink. The flux of organic carbon decreases more quickly with depth than does the flux of CaCO_3 or SiO_2 (another type of shelly hard part, the mineral opal is secreted by the phytoplankton diatoms) (see *Diatoms*). Nitrogen and phosphorus are removed more quickly than carbon, as indicated by increasing C:N and C:P ratios in sediment traps. The flux of CaCO_3 appears rather uniform with depth in sediment traps, but budgets for CaCO_3 production and deposition on the sea floor, and for alkalinity in the water column, seem to indicate a substantial dissolution of CaCO_3 in the mid-water column. The discrepancy with sediment trap results may be caused by biases in trap efficiency in shallow waters (Yu et al., 2001) or by CaCO_3 dissolution (Betzer et al., 1984) within the traps.

Organic carbon by itself is not sufficiently dense to sink very quickly through seawater, if at all, and so attention has focused on the role of CaCO_3 , SiO_2 , and wind-blown continental material as “ballast” (Armstrong et al., 2002; Klaas and Archer, 2002). This theory is consistent with the sediment trap data in that while the fluxes of the various constituents vary widely in space and time, the ratio of organic carbon to ballast in the deep traps, and in particular to CaCO_3 , seems much more stable. Only a small fraction of the organic matter produced in the surface ocean makes it to the deep sea, so the ballast model predicts that the absolute flux of organic carbon to depth might be determined by the fluxes of ballast. However, the ballast model does not explain the trap data in the top kilometer of the water column, where the organic carbon to ballast ratio is higher and more variable than in the deep sea.

CaCO_3 compensation and the pH of the ocean

We have seen how the biological pump affects the $p\text{CO}_2$ of the atmosphere, by pumping carbon and nutrients from the surface ocean to the deep. In addition to this direct effect, the biological pump has an indirect effect on $p\text{CO}_2$, called carbonate compensation (Broecker and Peng, 1987). CaCO_3 is produced biologically, mostly in the surface ocean. Some fraction of this CaCO_3 reaches the sea floor, and its chemical constituents (Ca^{2+} , one ΣCO_2 , and two alkalinities) are permanently removed from the ocean as it is buried. This output is balanced by input from the dissolution of rocks, mostly sedimentary CaCO_3 , a process called weathering on land. The idea is that the pH of the ocean adjusts; acting as a stable negative feedback to insure that the output of CaCO_3 by burial balances the input from weathering. As we have seen, a change in seawater pH will have a large impact on the speciation of carbon, and therefore on $p\text{CO}_2$ (see *Paleo-ocean pH*).

The input of dissolved CaCO_3 to the ocean derives from the chemical weathering of rocks on land (see *Weathering and climate*). The saturation state for CaCO_3 dissolution is given by the reaction

If the product of the reactants, Ca^{2+} and CO_3^{2-} , is less than the value of K_{sp} then the solution is undersaturated and CaCO_3 will tend to dissolve. In practice, the CO_3^{2-} combines with CO_2 and water to yield the overall reaction

where the Ca^{2+} and HCO_3^- reflect the dominant ion pair in most river water. The reactant CO_2 is derived ultimately from the atmosphere, but CO_2 partial pressures in soil gas are elevated to an order of magnitude higher than atmospheric values by the action of plants and the microbial respiration of soil carbon. River water, reflecting its origin as soil water, is typically strongly supersaturated in CO_2 , and close to saturation with respect to CaCO_3 at that $p\text{CO}_2$. In areas where the rate of freshwater runoff is extremely high, the dissolution reaction may not have time to keep up with the flux of distilled rainwater, and the solution concentrations will drop. The lithology, or rock type, of a region also has an impact on the chemistry of rivers. To a first approximation, however, we expect that the total flux of dissolved CaCO_3 to the ocean depends primarily on the total rate of fresh water runoff to the oceans, and secondarily on temperature, soil biological activity ($p\text{CO}_2$), terrain type,

and other variables. Once the Ca^{2+} and alkalinity are delivered to the ocean, they are used to produce CaCO_3 according to the reaction

returning the atmospheric CO_2 that weathering borrowed back to the atmosphere.

CaCO_3 production occurs in shallow ocean waters and in surface waters overlying the deep sea (Milliman, 1993). In many cases, in coral reefs for example, the production rate of CaCO_3 seems to mirror the rate of organic carbon production, as though the organisms calcified in order to shift the pH balance back toward the acidic, ensuring a readily available supply of dissolved CO_2 . Some fraction, roughly half, of the CaCO_3 produced in surface waters dissolves in the water column, and the rest reaches the sea floor to be redissolved or buried.

The fate of CaCO_3 landing on the sea floor depends strongly on depth in the ocean, because the solubility of CaCO_3 increases with pressure (Archer, 1996). This is because the dissolution reaction entails a small decrease in volume as CaCO_3 dissolves; an increase in pressure encourages the system to find the volumetrically smaller, dissolved, form. In addition, there is a surface/deep contrast in the concentration of CO_3^{2-} , resulting from the biological pump. We have already seen that the effect of the biological pump, dominated by the soft-tissue pump, on the carbon chemistry of the water column is to deplete the surface waters in ΣCO_2 . As a result of the pH equilibrium reaction 3, dissolved CO_3^{2-} is increased over the mean ocean value. The concentration of CO_3^{2-} goes down with depth, but the amount of CO_3^{2-} required in equilibrium goes up with depth. These factors combine to create a "saturation horizon" in the water column, above which CaCO_3 is supersaturated, and below which it is undersaturated. Some fraction of the CaCO_3 raining to the sea floor lands on topographic highs, in sediments overlain by supersaturated water, and tends to be buried. CaCO_3 landing in abyssal sediments tends to dissolve. The distribution of CaCO_3 on the sea floor resembles snow-capped mountains, with preservation on the mountaintops and none in the valleys. The depth of the "snow line," where CaCO_3 is no longer preserved in sediments, has been called the carbonate compensation depth, or CCD. In practice, sedimentary CaCO_3 dissolution is complicated by the rate of diffusive contact of the pore water with overlying water, and by other sediment reactions such as organic carbon respiration. Not all of the CaCO_3 deposited above the saturation horizon is buried, and some of the CaCO_3 flux to undersaturated sediments may be preserved. The CCD (a property of the solid sediment) is not the same as the saturation horizon (a property of the water column). In most parts of the ocean, the CCD is 0.5–1.5 km deeper than the saturation horizon (see *Carbonate compensation depth; Carbon dioxide, dissolved (ocean)*).

The pH-determining mechanism of the ocean, called carbonate compensation (beware of the unfortunate overlap with the separate concept of the carbonate compensation depth or CCD), arises from the need for the ocean to balance the input and burial rates of CaCO_3 . The way the ocean regulates burial to balance weathering is through the pH of the ocean. The input of CaCO_3 from weathering tends to drive the ocean towards the basic, as a source of excess alkalinity. The neutralization of the primary CO_3^{2-} dissolution product by atmospheric CO_2 to produce HCO_3^- in Reaction 8 is a consumption of the acid from the atmosphere and ocean by CaCO_3 , a base. If this source of base were unbalanced by CaCO_3 burial

in sediments, the ocean would get progressively more basic over time. This would increase the proportion of the dissolved carbon that is CO_3^{2-} , increasing the depth range over which CaCO_3 is stable and increasing the burial rate of CaCO_3 , until ultimately the burial rate would balance the weathering rate. The time scale over which this relaxation takes place is 5–10 kyr (Archer et al., 1997).

Numerous factors can drive CaCO_3 compensation. An increase in chemical weathering would drive the CCD deeper, lowering atmospheric $p\text{CO}_2$. Today, a significant fraction of CaCO_3 deposition occurs on continental shelves and carbonate platforms, which may have been exposed during times of lowered sea level such as the Last Glacial Maximum (LGM). A decrease in shallow-water burial would have required an increase in deep sea burial to compensate, also lowering $p\text{CO}_2$. A decrease in the production rate of CaCO_3 , driven perhaps by ocean chemistry or climate change, would require that a greater proportion of the CaCO_3 produced be buried, requiring a deeper saturation horizon and CCD, resulting in lower $p\text{CO}_2$. Finally, a CaCO_3 compensation response in the future will ultimately neutralize much of the fossil fuel CO_2 that humankind is releasing to the atmosphere. The CO_2 invasion will acidify the ocean, lowering $[\text{CO}_3^{2-}]$ and decreasing CaCO_3 burial. Excess CaCO_3 source to the ocean will drive the ocean toward the basic, neutralizing the excess CO_2 into the form of dissolved HCO_3^- in the ocean water column.

MARINE CLAY MINERALS

Clay minerals found in the marine environment may be arbitrarily divided into two genetic groups: those forming in and those being transported into marine waters and sediments. Clay minerals forming in seawater and sediments link directly to diagenetic processes and are not examined in detail here. Detrital clay minerals can be compared to source terrain or provenance and hinterland climate, so are described here.

Clay minerals forming in the marine environment commonly display neoformal features, as they are often secondary to some precursor. Although this neoformalization can occur in the water column or within surficial sediments, this is patently a diagenetic process with links to adjacent sea and land surface conditions (such as paleoclimate) that are too tenuous for discussion here. Such links do exist; an example is given by Worden et al. (2000). Early (near-surface) diagenetic clay minerals include the group of clay minerals termed glauconite, which may replace shells (e.g. foraminifera) or clastic grains (e.g. feldspars). Deep burial diagenetic marine clay minerals are beyond the scope of this description.

Clay minerals being transported into the marine environment are detrital in origin, being transported by water, ice, air, or volcanic eruption. The types of clay minerals are thus variable, depending on the source terrain lithology, weathering characteristics during erosion and transport, transport time and method, and final depositional environment. Thus, a granitic source terrain will contain abundant feldspars; these may be weathered in humid conditions to form kaolinite which will be deposited close to shore as it flocculates and forms large clay crystals. However, at any point in this story, our assumptions may be incorrect! In an arid environment, kaolinite production will be diminished, even with the correct source lithology (granite). Clays may be deposited as floodplain soils where they become neoformal as successor clays during temporary storage prior to a second phase of erosion and marine deposition that will not reflect the hinterland lithology. The moral of this story is that caution is required during interpretation of both Recent and modern marine clay mineral assemblages, as well as the more problematic ancient materials.

The mineral structure of clays is problematic (Parker and Rae, 1998). Since clays are layer silicates, often around 2 μm in size, we are dependent on the Scanning Electron Microscope, Transmission Electron Microscope, and X-ray diffractometer in performing mineralogical analysis. This article follows the United States Geological Survey convention (<http://pubs.usgs.gov/of/of01-041/htmldocs/clay.htm>) of listing "groups" of minerals

where appropriate, roughly by overall abundance, examining the interpretation possibilities and problems in each case.

The abundant clay minerals of recent and ancient marine sediments (in no particular order)

Chlorite group

The chlorites are Mg, Al, Fe aluminosilicates of the brittle mica suite. They originate as hydrothermal minerals, but are most abundant in chlorite schists and greenschist metamorphic terrains (their most common provenance). Their occurrence in marine sediments as detrital components reflects this primary source terrain as the ultimate point of their origin and a clear association with physical weathering (as opposed to chemical weathering and thus mineral degradation). Rapid erosion by glaciers and rivers of mountain terrains are the most common "first pass" interpretation proxy for the chlorite group. The problems with chlorites stem from their widespread occurrence and robust nature. Thus, they may survive more than one cycle or erosion, being eroded out of their primary source terrain, and subsequently deposited and stored in a secondary sedimentary rock, before being re-eroded and deposited out of context from their original source. Chlorites may also form during burial diagenesis, thus potentially confusing any studies of paleoweathering or paleoclimates.

Illite. Illite comprises a K, Al aluminosilicate of the mica group. They originate as the weathering product of feldspars and other clay minerals, especially the degradation of muscovite. Illites may form hydrothermally in alkaline conditions rich in K, often as an inter-layered mineral structure with smectites ('mixed layer illite-smectites'). Thus, they have a similar, if lower, metamorphic grade origin to chlorites. A very common component of detrital marine sediments, illite is notable usually only by its absence or abundance. A common interpretation strategy is to consider illite as the ever-present "clay mineral rain" of the seas, to be used as a ratio against smectite or kaolinite in paleoweathering studies. The same interpretation problems pertain as with the chlorite group: illite is robust and may survive many sediment cycles; thus, its original provenance is rarely clear. The crystallinity of illite is often maintained during erosion, reflecting the metamorphic grade of the original hinterland.

Kaolinite group

The kaolinites comprise hydrous aluminosilicates of the serpentine-kaolin group. Their primary origin is associated with the hydrothermal alteration of feldspars and other silicates. Humid weathering also promotes similar degradation and the kaolinitization of feldspars is common under such climatic conditions and is accelerated by warm, humid conditions. Volcanic ashes often contain kaolinite. The kaolinites form one of the most abundant and useful paleoclimate proxy materials as their detrital presence always suggests humid conditions at some point in their origin. Interpretation problems are also abundant of course! A non-feldspar-bearing hinterland terrain may be humid and warm, yet produce no kaolinite. As mentioned above, kaolinite is also abundant and thus its presence is not always enough to determine changing paleoclimatic conditions. Ratios of kaolinite with other minerals have commonly been employed in determining horizons of paleoclimate change. Changing ratios, when compared favorably to other paleoclimate proxies (stable isotopes, palynomorphs) form a useful method of identifying episodes of past climate change (Chamley, 1989). The tendency of kaolinite to flocculate and settle close to shore thus means that changing ratios may also reflect variable

sea-levels, not changes in paleoweathering of the hinterland. Finally, kaolinite is a common shallow burial diagenetic mineral.

Smectite group

The smectites are variable composition Ca, Na, Al, Mg Fe aluminosilicates for which montmorillonite is a practical synonym. Smectites originate from the weathering of basic and intermediate igneous and meta-igneous rocks, as well as being a common constituent in volcanic ashes (bentonites, fuller's earths). As a result of weathering, soils forming in temperate and humid climates, especially where seasonally wet, commonly contain smectite. Thus, their proxy interpretation is similar to that of the kaolinites, if not quite as clear. Problems in interpreting the presence and changing abundance of smectites in rock successions include the inverse problem to kaolinite: commonly being a small crystal, smectite tends to stay buoyant for longer than other clays and thus is deposited offshore. For this reason, it has been associated with deep marine and transgressive conditions – the paleoclimate “signal” in its abundance may be masked by relative sea-level changes. An even greater hazard to smectite interpretation is its volcanic origin, as ash-falls can appear randomly in the sedimentary record, masking any paleoclimatic control. Detailed petrographic investigation of the presence of volcanic glass shards or ash-fall textures may resolve this interpretation hazard.

Mixed-layer clays. Many of the clay mineral crystal groups listed above and below can become interstratified. Most common are the illite-smectites and chlorite-smectites. Such clays often have a hydrothermal origin. In soils, they form when conditions are episodic, such as wetting and drying cycles. Thus, the presence of mixed-layer illite-smectites has been related to seasonal climates. Interpretation is hazardous, however, as these minerals are difficult to characterize.

The less abundant clay minerals of recent and ancient marine sediments (in no order)

For the sake of brevity, I have selected two of the many tens of rarer clay minerals to demonstrate their use in paleoclimatic interpretations.

Sepiolite and palygorskite

Sepiolite is part of the palygorskite group and possesses a Mg-bearing, hydroxide chain-like silicate structure. Palygorskite is chemically and structurally more complex. Both are of use to paleoclimatologists, especially palygorskite as it forms in near-surface arid conditions. If proven to be detrital and found in marine sediments, an arid hinterland can be assumed. The problem is its rarity and actual provenance as wind-blown dust may be transported in the stratosphere from arid zones to those of a humid nature, confusing the interpretation.

MARS: WATER AND PAST CLIMATES

Mars has long been the focus of a great deal of attention, largely due to the presence of water and the potential for harboring life, either now or in the past. Until recently the question of life on Mars has focused on whether Mars was once “warm and wet” and Earthlike or “cold and dry” and barren like the Moon. The recent orbiter and rover missions have revealed that Mars is a remarkably diverse place and these simple labels no longer fit. Mars has experienced a striking diversity of environments from extremely arid deserts, to standing water in lakes, to a planet blanketed by snow and ice. The key questions in the search for life have therefore become how warm, how wet, and most importantly, for how long?

The evidence for these past environments is contained in the rocks, minerals, and landforms of Mars. Minerals in particular contain the record of geologic processes and ancient environments in which they formed; certain minerals only form in water, whereas others are rapidly destroyed in wet environments.

Mars is a volcanic planet

The first close-up images of Mars revealed a surface dotted with massive volcanoes and provided the first hints of a planet dominated by volcanic processes (Figure M9). However, the definitive information on the composition of Martian rocks has come from the visible, infrared, neutron, and gamma ray spectrometers that have been used to map mineral and elemental compositions. Spectral data from Earth-based telescopes and early spacecraft missions provided hints of compositional differences and the presence of iron-bearing minerals (e.g., Soderblom, 1992). The first global maps of the minerals, rocks, and ice on the surface, as well as the dust and condensates in the atmosphere of Mars were made using data from the Thermal Emission Spectrometer (TES) infrared spectrometer aboard the Mars Global Surveyor (MGS) spacecraft (e.g., Christensen et al., 2001). These observations have been followed up by near-IR spectra from the Mars Express OMEGA experiment (Mustard et al., 2005).

TES infrared spectra have shown that the rocks and sands are composed almost entirely of volcanic minerals characteristic of basaltic rocks (e.g., Christensen et al., 2001). These common minerals – feldspar, pyroxene, and olivine – are found in the basaltic lavas that also cover much of the Earth, from the ocean floor to the volcanic islands of Hawaii and Iceland. OMEGA has confirmed the widespread occurrence of olivine and pyroxene over much of the surface (Mustard et al., 2005). The rocks in the ancient cratered terrains are basaltic in composition, whereas the younger rocks of northern lowlands have more glass, more silica-rich minerals, and fewer iron-bearing pyroxene and olivine minerals (Christensen, 2001; Mustard, 2005). Volcanic rocks high in silica typically form by complex processes that include remelting of existing basalts, fractional crystallization, or melting of a water-rich source region. The possible existence of higher-silica rocks on Mars may imply more water in the mantle than on Earth, or differing temperatures or pressures at which melting occurred. Alternatively, the high-silica components may have been produced by minor aqueous weathering of basalt (e.g., Wyatt et al., 2004). In either case, the vast majority of the Martian rocks is volcanic in origin.

Figure M9 Apollinaris Patera, a 200 km wide ancient volcano, is seen in this mosaic of THEMIS infrared images. Apollinaris erupted huge volumes of ash that have been carved into channels by water.

Early fluvial activity

Many of the ancient, heavily-cratered terrains of Mars contain channels that were eroded by water. Analysis of the global distribution of these channels has shown that extensive fluvial activity occurred over portions of the ancient highlands (Figure M10). These data indicate a period of erosion early in Mars history that produced extensive infilling of craters, the development of local and regionally integrated drainage networks, and the formation of deltas and alluvial fan deposits (e.g., Gulick and Baker, 1989; Malin and Edgett, 2003; Howard et al., 2005). The development of these drainage networks and depositional fans is suggestive of runoff from precipitation or rapid melting of snow, possibly aided by groundwater sapping. It has also been suggested that Mars had extensive oceans on the basis of images and topographic data that suggest shorelines, smooth ocean floors, and glacial features (Baker et al., 1991).

The prevailing environment during the early period of fluvial erosion may have been one of a cold, thin atmosphere with very limited mechanical erosion, punctuated by short periods of thicker atmosphere and greater erosion. These thicker atmospheres may have been produced by periodic climate changes (e.g., Pollack and Toon, 1982), or generated in the impact cratering process and lasting hundreds to thousands of years (Segura et al., 2002). Fluvial erosion appears to have reached

a climax in the late Noachian period ($\sim 3\text{--}3.5$ Gyr) (Howard et al., 2005), with only limited activity since that time that is primarily associated with large catastrophic flood events, isolated channel formation, and minor incision of small gullies (Malin and Edgett, 2000).

A cold, dry Mars

Although there is strong evidence for early fluvial activity in isolated locations, the global mineral mapping shows an ancient, cratered surface whose original volcanic minerals are still largely preserved, implying very little alteration by water. Olivine and pyroxene form at very high temperatures ($>800^\circ\text{C}$), but are unstable in the presence of water at the surface as on Earth today. However, ancient pyroxene- and olivine-rich basalts are common; they are exposed more than 4.5 km below the surface in the walls of Valles Marineris and throughout the equatorial plains (Hoefen et al., 2003; Hamilton and Christensen, 2005; Mustard et al., 2005). Near the summit of Syrtis Major are a series of old, volcanic cones and flows composed of glassy lavas (Christensen et al., 2005) that are also highly susceptible to chemical erosion. The occurrence of these unstable minerals suggests that neither sub-surface hydrothermal activity nor surface aqueous weathering has significantly affected these very old rocks since they were emplaced.

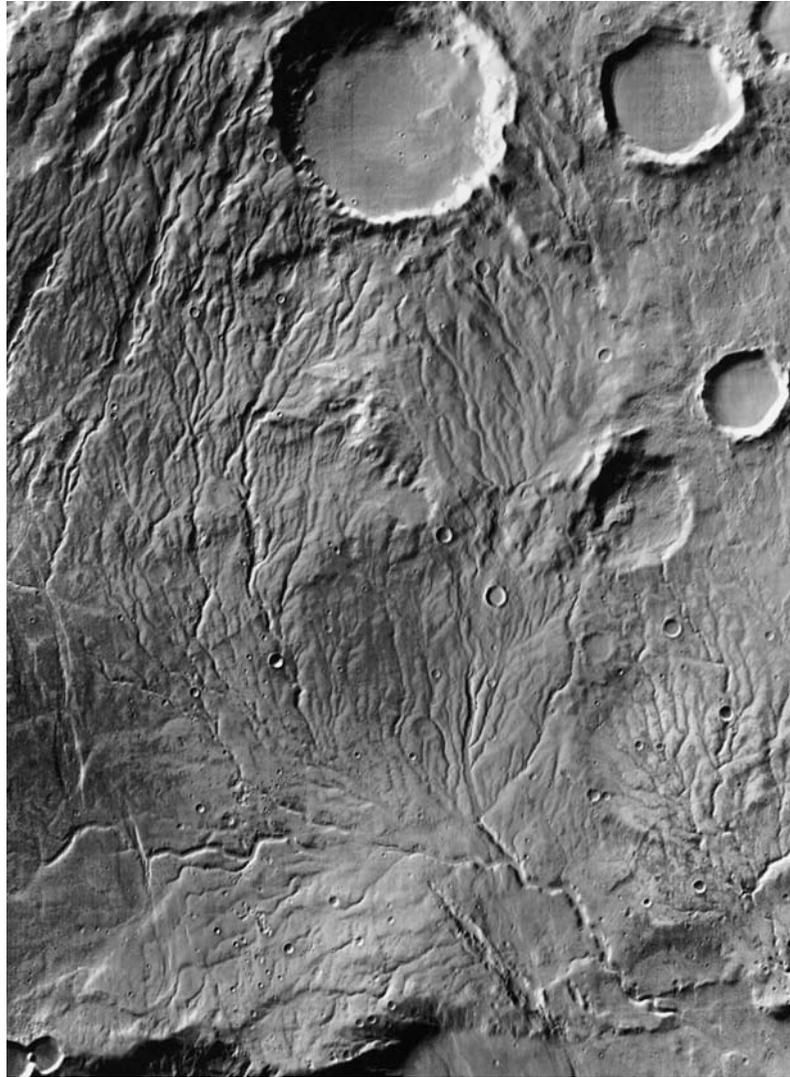

Figure M10 Evidence of fluvial processes early in Martian history is illustrated in the drainage network of Warrego Valles. This image is a mosaic of THEMIS daytime infrared images covering an area ~ 200 km wide centered near 42° S, 266° E.

The Spirit rover at Gusev Crater has provided additional mineralogical evidence for limited aqueous weathering. The rocks on the crater floor are volcanic and extremely old, perhaps as much as 3 billion years, yet the Mini-TES, Mössbauer, and Alpha Particle X-ray spectrometer (APXS) spectrometers and cameras on the rover clearly show the presence of olivine and pyroxene that have been very little altered since these lavas first cooled (McSween et al., 2004). These pristine volcanic rocks provide evidence that these plains have not been exposed to any significant amount of water since these lavas were erupted. They may have been “wetted,” as evidenced by thin coatings on some rocks, but they have not been “soaked.”

What is not found

In assessing the climate history of Mars, it is important to consider what rock types are not present. On Earth, vast deposits of carbonate rocks, composed of CO_3^{2-} with calcium, magnesium,

or iron, have precipitated from warm oceans through interactions between CO_2 gas, water, and mineral grains. If Mars ever had a warm ocean, it has been suggested that thick deposits of carbonates would have also formed through interactions with its CO_2 atmosphere. Spectra from TES and the Mini-TES on the Mars Exploration Rovers have shown that small amounts of carbonate are present in the ubiquitous Martian dust (Bandfield et al., 2003). These minerals most likely formed by direct interaction with water vapor in the atmosphere. However, no evidence of extensive carbonate rock layers has been found by the TES, THEMIS, or OMEGA instruments (Christensen et al., 2001; Bibring et al., 2005), suggesting that if Mars ever had oceans, they were either too cold, too short-lived, were covered by ice that limited interactions with the atmosphere, or had unique chemical conditions that prevented carbonates from forming. Clay minerals, which form primarily by aqueous weathering and are common on Earth, have also been shown by OMEGA and TES to be rare on Mars (Christensen et al.,

2001; Bibring et al., 2005), again suggesting that Mars has experienced little aqueous alteration.

While lakes and drainage networks clearly point to fluvial processes, the lack of extensive carbonates and clays, together with the presence of original olivine, pyroxene, and glass, argue that these processes must have been relatively short-lived. Thus, on a global scale, aqueous chemical weathering appears to have been a relatively minor process throughout much of Martian history.

Meridiani – a locally wet Mars

The Meridiani Planum site explored by the Opportunity rover was chosen based on spectral evidence from the TES for high abundances of crystalline hematite, an iron oxide that forms by several processes, most of which involve water (e.g., Christensen and Ruff, 2004) (Figure M11). Hematite can form by precipitation from fluids circulating through saturated sediments or by deposition of precursor water-bearing iron minerals that are dehydrated over time. The mineralogic evidence for water at Meridiani is corroborated by the unique appearance of the hematite-rich surface in Meridiani indicative of water deposition: the Meridiani rocks are finely layered and easily eroded, suggesting a sedimentary deposit; they sit atop an older, heavily cratered surface, implying a different process

of formation; and they embay pre-existing channels, suggesting that these rocks were deposited in water rather than covering the entire landscape as volcanic ash or windblown dust (Christensen and Ruff, 2004).

Upon landing, Opportunity's spectrometers and cameras confirmed the importance of water at Meridiani (Squyres et al., 2004). Outcrops of layered sedimentary rocks were observed by Opportunity's cameras, and the Mössbauer, APXS, and Mini-TES spectrometers found that these rocks contained high (30–40%) abundances of sulfates most likely formed by evaporation of sulfur-rich water. The hematite occurs as 1–5 mm diameter spheres that are embedded within the rock layers, and were likely formed by iron-rich fluids circulating through the lake sediments (e.g., Squyres et al., 2004). The margins of this body of water may not have extended much beyond the current deposits of hematite seen from orbit, making this a large lake (Christensen and Ruff, 2004), rather than part of a global ocean. Several nearby craters also have hematite-rich layered rocks, suggesting they may have held separate lakes (Christensen and Ruff, 2004).

The coarsely-layered rocks exposed at the base of Burns Cliff in Endurance Crater appear to have been formed by migrating dunes, whereas the layers at the top of the cliff are made of sulfate-rich sediments deposited in water (Grotzinger

Figure M11 The distribution of crystalline hematite discovered by TES in Meridiani Planum. The TES hematite abundances are shown superimposed over a mosaic of THEMIS daytime infrared images illustrating the complex morphology of the Meridiani region.

et al., 2005) (Figure M12). These layers may record variations in climate from arid eolian dunes, to wet evaporating playas where the sulfate salts were formed, to a groundwater system that formed the hematite spheres (Grotzinger et al., 2005). This system may have persisted for thousands of years.

Evidence for standing water is also seen at Aram Chaos, a 300-km diameter crater basin that is filled with layered rocks that contain both hematite and sulfate and show evidence for a lake created by the release of massive amounts of sub-surface water (Glotch and Christensen, 2005; Gendrin et al., 2005). Finely-layered erodable rocks that contain hematite and sulfate are also found in the troughs of Valles Marineris, suggesting that they also were deposited in standing water.

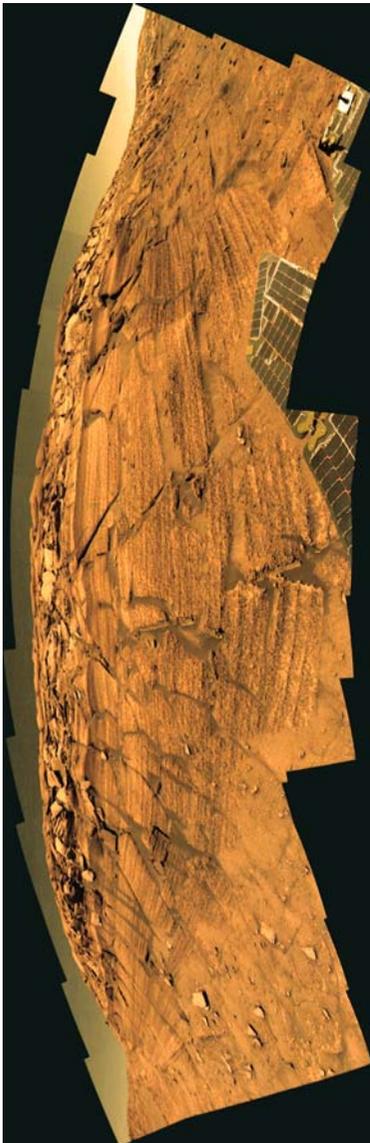

Figure M12 Burns Cliff, Endurance Crater. After descending into Endurance Crater, the Spirit rover drove to Burns Cliff, a spectacular rock outcrop ~7 m high made of finely-layered rock. These layers are composed of basaltic sands and evaporite minerals that were deposited in a varying environment of wind and water.

These discoveries provide strong evidence that water was stable in isolated regions for brief periods of time. The factors that caused water to accumulate and allowed it to remain at these sites (perhaps a combination of heat from sub-surface volcanic activity, high salt concentrations that lowered the freezing temperature, or a protective covering of ice over water released by catastrophic floods) are currently unknown.

Modern snow and ice

There is growing evidence that Mars has a large inventory of water, currently in the form of ice at mid- to high-latitudes. Both poles have deposits of ice or ice-rich sediments that are up to three km thick and cover more than 500,000 km². Temperature measurements have demonstrated that the perennial north polar cap was water ice, whereas a layer of CO₂ ice remains over much of the south polar cap even through the summer (Kieffer, 1979). Recent measurements by the MOC, THEMIS, and OMEGA instruments have shown that windows of water ice are exposed within the south polar cap, indicating that water ice is present there beneath a thin layer of overlying CO₂ ice (Byrne and Ingersoll, 2003; Titus et al., 2003; Langevin et al., 2004).

A substantial inventory of water ice was discovered using data from the Gamma Ray Spectrometer (GRS) and the High Energy Neutron Detector (HEND) instruments on Mars Odyssey (Feldman et al., 2002). The regions poleward of ~60° in both hemispheres are made up of more than 80% water ice (Figure M13). Such high ice abundances could not have formed by diffusion of water vapor from the atmosphere into the pores of the soil. Ice must have been deposited as a layer of snow or frost.

These ice deposits are reservoirs of water that can migrate as the climate changes. The Martian climate is predicted to change dramatically as the tilt of the Martian spin axis oscillates by as much as 20° on timescales of 10⁵–10⁶ years (Ward, 1974). These changes likely produce a significant mobilization of polar water, redistributing it to lower latitudes as snow and ice (e.g., Jakosky and Carr, 1985). When the axis is oriented more perpendicular to the Sun (low obliquity), the poles are the coldest places on the planet and water migrates to them. As the axis tilts toward the Sun (high obliquity) the poles warm, the mid-latitudes cool, and water, in the form of snow and ice, migrates to the mid-latitudes. Remnants of these ice deposits can be found in unusual landforms throughout the mid-latitudes. One type is a “basketball” textured terrain that only occurs between 30° and 50° latitude in both hemispheres and was suggested to have formed as soils cemented by ice deposited during the last “ice age” lost their ice and eroded as the climate warmed (Mustard et al., 2001).

A second type of deposit occurs preferentially on cold, pole-facing slopes (Carr, 2001). These “pasted on” slope mantles are up to 10 m thick, often occur in hollows, and can have features suggestive of flow (Figure M14). These characteristics suggest an ice-rich layer that was once more extensive but has been removed from all but the coldest, pole-facing slopes.

One of the more remarkable discoveries made by the MGS MOC camera is the small young gullies that also occur between ~30° and ~50° latitude in both hemispheres (Malin and Edgett, 2000) (Figure M14). These gullies have been proposed to form from discharge of liquid water from sub-surface aquifers, the rapid release of liquid CO₂, dry landslides, the melting of ground ice that percolates to an impermeable layer, the melting of pore ice that diffused inward from the atmosphere during periods of colder temperatures, or through

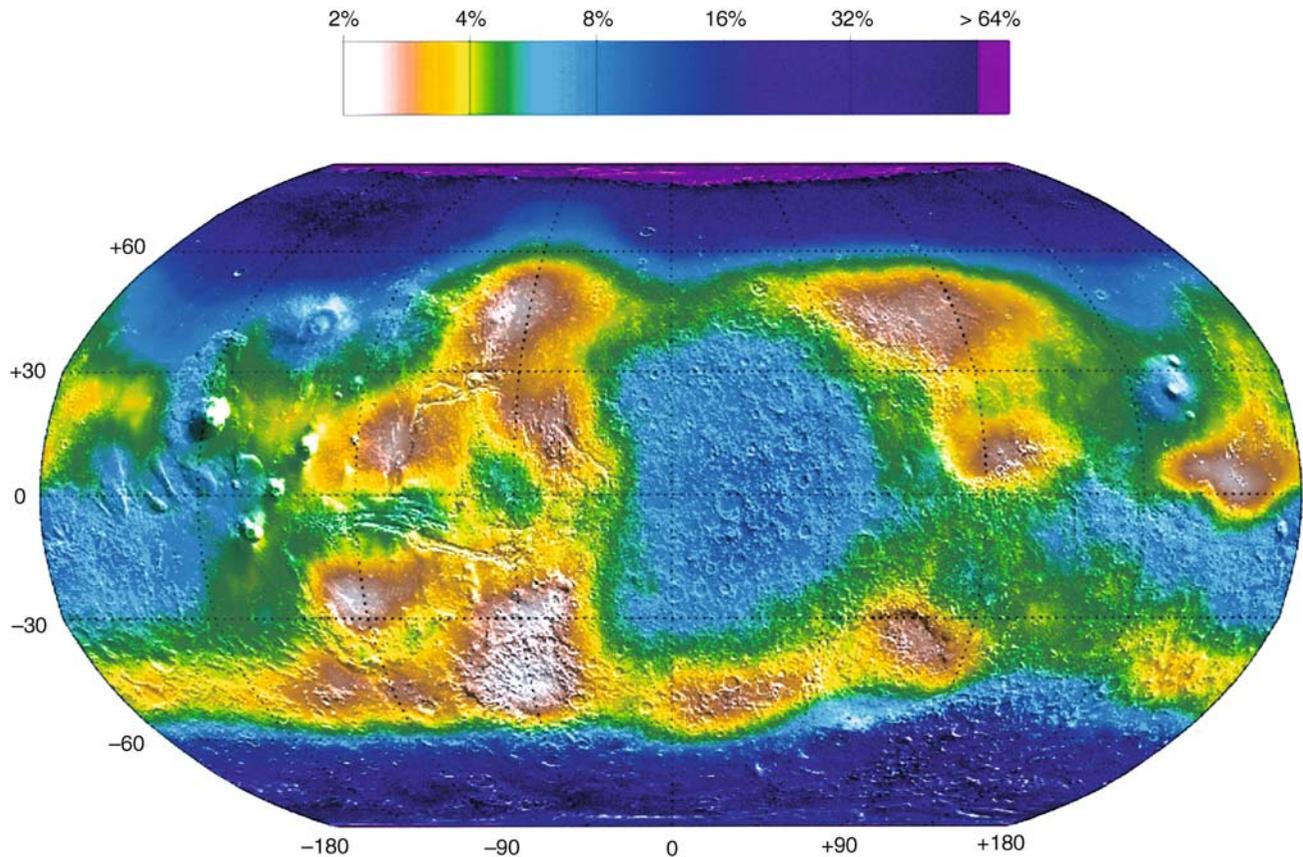

Figure M13 The distribution of sub-surface water ice. This global map was made using data from the Neutron Spectrometer that is part of the Odyssey Gamma Ray Spectrometer suite. Hydrogen in the form of water ice occurs in abundances $>80\%$ poleward of $\sim 60^\circ$ in both hemispheres (data are adapted from Feldman et al., 2002).

melting of a snow layer deposited during periods of higher obliquity when surface ice was stable at these latitudes (see recent review by Heldmann and Mellon, 2004).

The proposed melting of pore ice does not account for the fact that as the surface and sub-surface temperatures warm, the upper soil layer will become desiccated before significant liquid water can be produced (Mellon and Phillips, 2001). Water release from sub-aquifers can explain gully morphology, latitudinal distribution, and slope position (Heldmann and Mellon, 2004). The primary arguments against this model are the presence of gullies on isolated knobs and dunes with no obvious aquifer source. An aquifer source is a survival and recharge mechanism that would allow these aquifers to persist to the present, their formation only at latitudes poleward of 30° , and the ability of water to remain liquid long enough to carve gullies up to 2 km long under current atmospheric conditions.

In the snowmelt model (Lee et al., 2001; Christensen, 2003), the snow acts as a greenhouse, absorbing sunlight beneath the surface, but preventing the heat from being re-radiated (Clow, 1987). This layer of snow also acts as an insulating layer that limits evaporation of the melted water. As a result, snow can melt 10–20 cm beneath the surface and remain liquid, even when the surface temperatures are far below freezing (Clow, 1987). In this model (Christensen, 2003), a layer of snow is deposited at mid-latitudes during periods of high obliquity. As the obliquity decreases and the mid-latitude climate warms, the snow melts

and erodes gullies in the snow and underlying surface. Eventually most of the snow completely melts, revealing gullies carved in the hillsides. Patches of snow remain today as “pasted on” deposits where they are protected against sublimation by a layer of desiccated dust/sediment. Melting could be occurring at the present time in favorable locations in these snowpacks, and these patches may provide fascinating locales in which to search for life, if it exists (Christensen, 2003).

Summary – and where to look next

The new tools that have permitted a more detailed view of Mars from orbit and the surface have shown that Mars is remarkably diverse. The role of water has varied tremendously at different times and in different places on Mars. There is no doubt that Mars experienced periods of channel formation early in its history, yet those ancient rocks contain minerals that quickly break down in a wet environment, and also lack extensive clays and carbonates. The current climate is very dry and cold, yet the Opportunity rover landed on the floor of an ancient body of water. Finally, liquid water is not stable at the surface today, yet recent gullies emerge from modern aquifers or beneath modern snowpacks.

How can these apparently conflicting views be reconciled? One possibility is that the erosional periods were too brief for extensive chemical weathering to have occurred – mechanical erosion of channels can proceed much more rapidly than

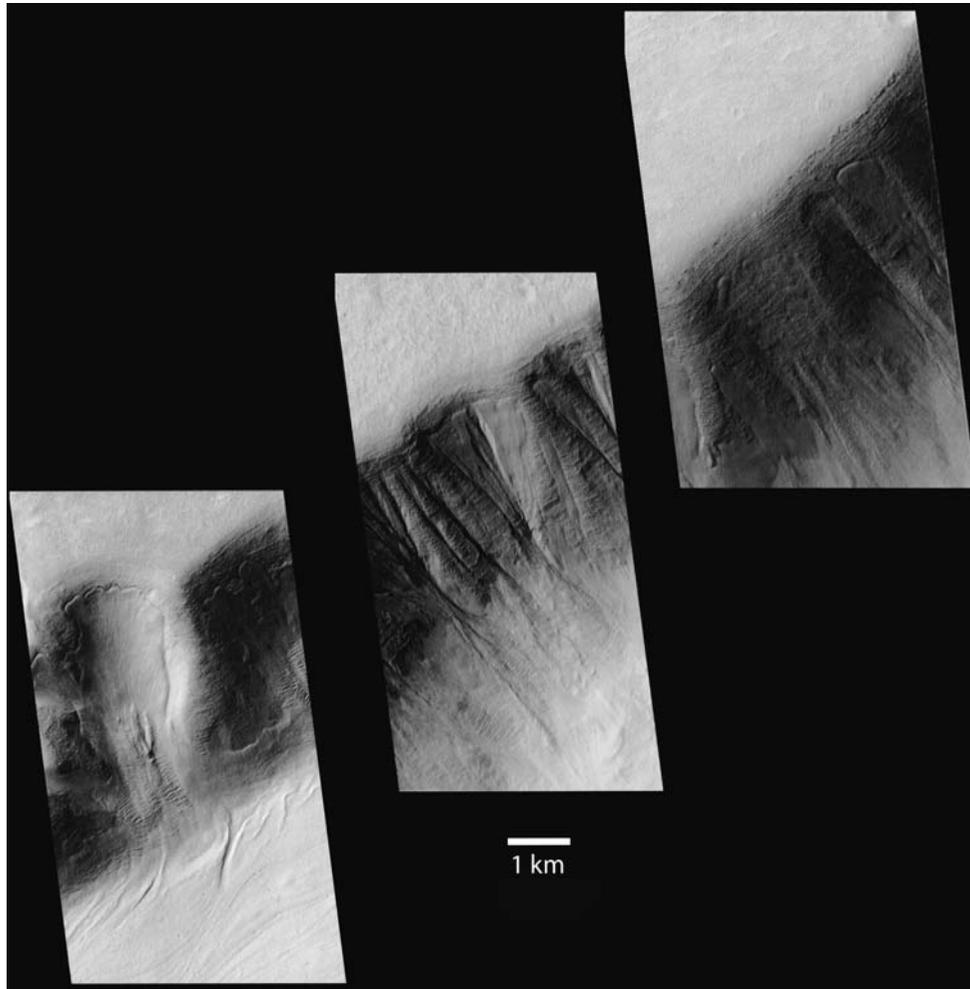

Figure M14 Ice-rich mantles and associated gullies on poleward facing slopes in the Southern Hemisphere. This collage shows MOC images from the northwest wall of Dao Valles, between 33° and 35° S. These images show well developed flow features with compressive ridges that are strongly suggestive of ice (*left panel*), mantles of ice-rich material with gullies that are only present where the mantles are lacking (*center panel*), and depressions with associated gullies, some of which still have mantles, whereas others are free of mantling material (*right panel*). These landforms could be explained by the melting of a snow mantle to form gullies, which are only visible in those locations where the snow has completely disappeared. MOC images left to right: M03-04950, M09-02885, and M0-3-6266.

chemical weathering. The erosional periods may have been caused by large impacts that produced very short-lived, thick atmospheres that allowed liquid water to persist (Segura et al., 2002). Thus, while Mars possesses a large inventory of water, it is likely that this water has remained frozen throughout much of its history, resulting in very little chemical weathering. Sporadically this water is released to form channels and lakes.

While neither typical nor common, the locations where liquid water may have been present for long periods of time – ancient lakes and modern snows – nonetheless hold the greatest promise for future exploration. In the modern gully systems, liquid water likely occurs very near the surface, is stable for extended periods of time, and is regenerated on the relatively short time-scales associated with climate oscillations. Repeated access to near-surface liquid water could provide a means for life to have survived over extended periods of Martian history, and could provide favorable sites for past or present life. Finally, the great diversity of surface environments from place to place and through

time on Mars is a sign of a complex climate history. It is also one of the most hopeful indicators for the possibility of Martian life, providing a rich suite of environments where life may have taken hold.

MASS EXTINCTION: ROLE OF CLIMATE

Introduction

Mass extinction is a defining feature of life's history. Over short periods of geologic time, geographically widespread and ecologically diverse groups of organisms disappear from the fossil record. The five largest extinctions of the Phanerozoic occurred during the Late Ordovician, Late Devonian, and at the Permian-Triassic, Triassic-Jurassic, and Cretaceous-Tertiary boundaries, when over 40% of genera and 60% of species became extinct. Some mass extinctions completely restructured many components of the world's marine ecosystems, while others caused major loss of species but little ecological restructuring.

Major changes in the Earth's climate system have been proposed to explain mass extinctions and their associated geochemical anomalies. Current debate focuses on the nature of climatic change during mass extinction and whether it results from extra-terrestrial perturbations of the Earth system or from internal processes. Additional debate centers on whether changes in the physical climate system or chemistry of the atmosphere and oceans are most important. The search for the environmental cause(s) of mass extinction is a dynamic field with a voluminous literature. Outlined below are climatic mechanisms proposed for the five largest Phanerozoic extinctions and a few important references.

Gradual climatic cooling

Gradual climatic deterioration has long been cited as an agent of mass extinction (Stanley, 1984). Extinction is caused through the gradual contraction of ranges for tropical and subtropical species, which causes loss of diversity through loss of habitat. Gradual climatic cooling is commonly associated with major regression of the world's oceans, which shrinks habitat area for organisms of the continental shelf. Temperature decline and regression are causally linked through an inverse relationship between global sea level and the volume of glacial ice, and through a direct relationship between global sea level, plate spreading rates, and atmospheric $p\text{CO}_2$.

Gradual climatic cooling was initially proposed as the dominant agent of extinction for the end-Cretaceous, based on oxygen isotopic evidence for a gradual decline in temperature during the Late Cretaceous and evidence for long-term cooling at the Cretaceous-Tertiary boundary (Clemens, 1982). However, gradual cooling is contradicted by evidence for significant temperature fluctuations during the last few million years of the Cretaceous, warming at the Cretaceous-Tertiary boundary, rapid extinction of organisms coincident with a bolide impact, and mass mortality of the terrestrial biota (see below).

Stronger evidence exists for mass extinction by gradual climatic cooling during the Late Ordovician (Hirnantian). The Late Ordovician extinction occurred in two major pulses. The first pulse occurred at the onset of global cooling and lowering of sea level associated with the growth of continental glaciers on Gondwana, while the second occurred during the rise of global sea level associated with melting of glacial ice (Sheehan, 2001). Glaciation occurred under significantly increased levels of atmospheric $p\text{CO}_2$, perhaps 10-fold pre-industrial levels or greater. Glacial ice was able to develop during a short-term (<1 Myr) fluctuation in atmospheric $p\text{CO}_2$ because of reduced solar luminosity, low seasonality on Gondwana, and the absence of trees and shrubs (Crowley, 2000; Gibbs et al., 2000).

Catastrophic climatic cooling

Catastrophic cooling consists of a sharp drop in temperature that is caused by the rapid production of an optically dense and globally widespread aerosol cloud. The lowest temperatures occur in continental interiors, which are removed from the thermal buffering of the ocean, and at high latitudes in the summer hemisphere. The severity and duration of the low-temperature excursion depends on the type and quantity of materials present in the cloud, the optical properties of these materials, and the rapidity with which dust, soot, and aerosols are removed from the atmosphere by settling and precipitation (Covey et al., 1994; Toon et al., 1997).

"Volcanic winter" results from the production of a global aerosol cloud by massive volcanic eruption, in particular stratospheric sulfate aerosols, which cause cooling that can last for up to a decade (Rampino et al., 1988; Wignall, 2001). Volcanic ash enhances the radiative effects of sulfate aerosols. However, it is removed from the atmosphere within a few months. Historic volcanic eruptions have had minor effects on global temperature (<1 °C) but greater effects on regional temperature at high latitudes. Large explosive volcanic eruptions of the geologic past produced aerosol loading of the stratosphere at least one order of magnitude greater than that of recent eruptions. The potential short-term cooling effects of fissure eruptions, which produce flood basalts and large igneous provinces, are not well understood (Wignall, 2001).

"Impact winter" results from the vaporization and fragmentation of the bolide and its target rock (Alvarez et al., 1980). Dust is produced in large quantities but remains in the atmosphere for only a few months because coagulation of dust particles promotes rapid sedimentation from the atmosphere. Ignition of vegetation and formation of a smoke cloud is caused by the impact fireball and a broiler effect resulting from the reentry of rock fragments into the atmosphere. If the bolide strikes gypsum and anhydrite rocks, then the resulting impact vaporization will create stratospheric sulfate aerosols that persist for a decade or more and cause a period of "global twilight" following the attenuation of the dust cloud (Toon et al., 1997). (see *Bolide impacts and climate; Cretaceous/Tertiary (K-T) boundary impact, climate effects*; this volume).

Blockage of sunlight can produce freezing temperatures, which kill cold-sensitive organisms. Photosynthesis ceases in the absence of light, which causes starvation of animals and animal-like protists. Survivorship would be highest for organisms with well-developed dormancy mechanisms (e.g., seeds, resting spores) and lowest for organisms with no dormancy mechanisms. Tropical ecosystems would be highly vulnerable to the effects of cold temperatures and the cessation of photosynthesis, while temperate and boreal ecosystems would be less vulnerable. Surface waters of the open ocean would be highly vulnerable to the cessation of photosynthesis because photosynthesis is the major source of energy for consumer organisms. Nearshore marine and deep ocean ecosystems would be less vulnerable because of their dependence on detritus as a major source of energy. Freshwater ecosystems would be least vulnerable because of the high influx of detritus and widespread dormancy mechanisms in freshwater algae and invertebrates (Sheehan and Hansen, 1986; Upchurch, 1989).

Catastrophic climatic cooling caused by a bolide impact is best supported for the Cretaceous-Tertiary boundary, where extinction of many organisms occurred at the base of a boundary clay that contains elevated levels of iridium, shock-metamorphosed minerals, glassy spherules, and other evidence of impact. Terrestrial plants indicate mass mortality at the Cretaceous-Tertiary boundary through an anomalous abundance of fern spores. The Chicxulub impact structure dates to the Cretaceous-Tertiary boundary, and remnants of the impacting body have been found at the Cretaceous-Tertiary boundary in the Pacific, North America, and Europe. Some authors propose that three impacts occurred across the Cretaceous-Tertiary boundary based on the stratigraphic distribution of spherule-containing beds (Keller et al., 2003).

Catastrophic climatic cooling from multiple bolide impacts probably occurred during the Late Devonian mass extinction, but the relationship between impact and extinction is not fully resolved. Evidence for Late Devonian impacts includes iridium anomalies, impact spherules, and at least two impact craters (McGhee, 1996).

Catastrophic cooling probably occurred at or near the Triassic-Jurassic boundary, based on evidence for a bolide impact (Olsen et al., 2002). Evidence includes a small iridium anomaly associated with an anomalous abundance of fern spores. Disagreement exists over whether the impact was linked to major turnover in vertebrates and plants. Massive flood volcanism started near the Triassic-Jurassic boundary (Wignall, 2001) and might have produced significant sulfate aerosols and short-term cooling events.

Catastrophic cooling also may have taken place at the Permo-Triassic boundary. Evidence for impact includes high

concentrations of microspherules and noble gas ratios in fullerenes suggestive of an extra-terrestrial source, but the case for a bolide impact is not as strong as at the Cretaceous-Tertiary boundary. Terrestrial plants provide evidence for mass mortality at the Permo-Triassic boundary, in particular anomalous abundances of fungal spores indicative of increased rates of decomposition.

Storms

Catastrophic climatic cooling by a global aerosol cloud would create a strong temperature inversion and generally stable atmosphere. However, oceanic impact of a large bolide could create a hypercane, an intense cyclonic storm that forms over the impact site when water temperature exceeds 50 °C. Pressures in a hypercane can be as low as 500–600 mbar, wind speed can exceed Mach 1, and the storm top can extend into the middle stratosphere. A hypercane injects large quantities of water into the stratosphere. This would destroy significant amounts of ozone, increase the flux of UV radiation, and cause the death of terrestrial and shallow-water organisms (Emanuel, 2003).

Acid rain

Acid rain changes the pH of water and soils. The most widely proposed mechanism for the formation of acid rain is a bolide impact. Nitric acid forms after the passage of a bolide at high speed through the atmosphere, which creates nitrogen oxides through intense heat and pressure. Sulfuric acid forms after the impact vaporization of gypsum and anhydrite. The amount of acid created by impact depends on the size and velocity of the bolide, the mass of vaporized sulfate, and the extent to which basic minerals such as larnite form during impact (Maruoka and Koerber, 2003; Toon et al., 1997).

Volcanism is a second proposed mechanism for the formation of acid rain. Rapid extrusion of large masses of lava, such as those found in many flood basalts, would inject large quantities of sulfur dioxide into the atmosphere, which forms sulfuric acid (Wignall, 2001). This could lead to the formation of acid rain with a sufficiently high rate of influx.

Empirical evidence for the formation of acid rain at mass extinction boundaries is limited. Disproportionate extinction of calcareous organisms at the Cretaceous-Tertiary boundary is consistent with ocean acidification, but high survival of freshwater aquatic organisms is inconsistent with acid rain (Hallam and Wignall, 1997).

Long-term global warming

Long-term global warming results from changes in the levels of greenhouse gases, most notably carbon dioxide (CO₂) and methane (CH₄). Carbon dioxide enters the atmosphere by mantle outgassing at spreading ridges and volcanoes. It is removed from the atmosphere by silicate weathering and incorporation into organic matter and carbonate rock. Methane is produced by bacterial reduction of CO₂ under anaerobic aquatic conditions. It is oxidized in the atmosphere to form CO₂. Organic carbon is strongly depleted in ¹³C relative to atmospheric and carbonate because of enzymatic fractionation: carbon fixed by C₃ photosynthesis has ^δ¹³C ranging from –22 to –32 per mil, while biogenic methane has ^δ¹³C ranging from –55 to –85 per mil. Changes in the rate of transfer of carbon between different reservoirs can be detected by changes in the ^δ¹³C of the atmosphere, which is recorded in the ^δ¹³C of organic matter and carbonate.

Major perturbations to the global carbon cycle are indicated by excursions in the stable isotopic record. Simultaneous negative excursions in ^δ¹³C for organic matter and carbonate

indicate an increased rate of oxidation of organic carbon and/or a decrease in its rate of burial (Kump and Arthur, 1999), which indicates possible global warming through an increase in atmospheric *p*CO₂ and/or methane. Simultaneous positive excursions in ^δ¹³C for organic matter and carbonate indicate increases in the rate of burial for organic carbon and possible global cooling through a decrease in atmospheric *p*CO₂. Flood basalts from large igneous provinces can inject significant quantities of CO₂ into the atmosphere if they are extruded at a rapid rate (Wignall, 2001), but changes in the ^δ¹³C of the atmosphere are probably small. Proxies such as stomatal index in plants corroborate trends based on isotopes and provide independent estimates of *p*CO₂ (Royer et al., 2001).

Negative excursions in carbon isotopes and large igneous provinces occur at the Cretaceous-Tertiary, Triassic-Jurassic, and Permo-Triassic boundaries. Isotopic evidence for long-term warming at the Cretaceous-Tertiary boundary is corroborated by direct temperature proxies such as leaf physiognomy and oxygen isotopes, direct estimators of atmospheric *p*CO₂ such as stomatal index, and carbon cycle models (Beerling et al., 2002; Kaiho et al., 1999; Wolfe, 1990). Post-impact levels of *p*CO₂ may have exceeded 2,300 ppm. Simulation studies indicate that rapid extrusion of Deccan Intertrappan flood basalts is insufficient to explain the increase in *p*CO₂ and that impact vaporization of carbonate is needed (Beerling et al., 2002). The carbon isotopic excursion starts at the Cretaceous-Tertiary boundary and continues well into vegetation recovery, indicating that it is controlled by marine processes rather than biomass burning (Beerling et al., 2001).

A negative carbon isotope excursion occurs at the Triassic-Jurassic boundary and lasts for approximately 600,000 years (Hesselbo et al., 2002). Increases in *p*CO₂ are indicated by changes in stomatal index, and warming is indicated by major increases in *Classopollis*, a thermophilic plant. The first extrusions of the Central Atlantic Magmatic Province began ~20 kyr after the Triassic-Jurassic boundary and continued for 2 Myr.

The Permo-Triassic extinction is known as the “mother of mass extinctions” because of its extremely high mortality (Erwin, 1993). Not surprisingly, the carbon isotopic anomaly at the Permo-Triassic boundary is the largest negative excursion associated with a mass extinction event. Hypotheses to account for this excursion include massive release of CO₂ from an anoxic ocean, sudden release of CH₄ from ocean sediments, mass mortality of the biota, volcanic release of CO₂ from the Siberian traps, and reduced oxygen levels. Evaluation of these hypotheses with a global carbon cycle model (Berner, 2002) shows that methane release was probably the most important contributor to the isotopic excursion. This is interesting in light of Ryskin’s suggestion that mass mortality at the Permo-Triassic boundary was caused by the combustion of a methane-rich atmosphere (Ryskin, 2003). Carbon cycle modeling indicates a rise in *p*CO₂ > 1,000 ppm, while combined C-S cycle modeling and sulfur isotope analysis indicate a sudden drop in atmospheric O₂ from 30 to 15% at the Permo-Triassic boundary. These results corroborate suggestions that anoxia was an important contributor to the Permo-Triassic extinction (Berner, 2002; Berner et al., 2003).

Summary and conclusions

The cause(s) of mass extinction is still open to debate. Environmental change during mass extinctions appears to be more pronounced than environmental change at other times, but whether

all mass extinctions have a single underlying cause is unclear. Temperature change appears to be one common theme to the five major mass extinctions of the Phanerozoic, but the driving mechanism(s) can differ between extinctions. The Late Ordovician extinction, for example, is clearly related to a gradual decline in global temperatures, while the Cretaceous-Tertiary boundary extinctions are related (at least in part) to catastrophic temperature decline resulting from bolide impact. Each mass extinction event probably has its own unique set of environmental changes.

Further understanding of mass extinction will require an interdisciplinary effort involving geologists, paleontologists, geochemists, and geophysicists.

MAUNDER MINIMUM

The Maunder Minimum refers to the period from about 1645 to 1715 during which very few sunspots were observed. Following Galileo’s refinement of the telescope around 1610, observations of sunspots showed that they appeared to be a fairly regular phenomenon. One of the main features was that their abundances waxed and waned approximately every 11 years, which became known as the solar cycle or sunspot cycle. During the Maunder Minimum, however, relatively very few sunspots were seen for roughly seventy years, and the 11-year cycle was dramatically reduced (Eddy, J.A., 1976). After 1715, the cycle built up again, and such a dramatic decrease in sunspots has not been seen since. When the sun is more active there are a greater number of sunspots. Though these are dark patches that emit less radiation than normal, their abundance is correlated with overall greater solar output since bright spots (faculae) are more abundant at the same times. The Maunder Minimum, with an extremely quiescent sun, is therefore thought to have been a low point for solar output. This may have contributed to colder climate conditions over many regions of the Earth during this

period (see *Little Ice Age*). The name for the minimum honors the work of E. W. Maunder.

Other evidence agrees with that of the early astronomers. Records of two independent cosmogenic isotopes (^{10}Be , ^{14}C), chemical variants formed only from cosmic rays, have been obtained from ice cores and tree rings. Since the intensity of cosmic rays reaching the Earth is modulated by the Sun, these isotopes serve as a proxy for solar output. The abundance of these isotopes varies in concert with the sunspot record over the past several centuries during which they overlap. The isotopic records corroborate the astronomical evidence for reduced solar output during the Maunder Minimum. Based on both the sunspot and isotope records, several other periods of reduced solar activity have also been identified. The exact size of the change in solar output that took place during the Maunder Minimum (or during other historical times) is still uncertain. Most estimates place it in the range of 0.2–0.5 watts per meter squared less irradiance reaching the Earth’s surface.

MEDIEVAL WARM PERIOD

Histories in western Europe have long recognized a “post-Carolingian” climatic amelioration, approximately since the death of Charlemagne (AD 814), the first of the “Holy Roman Emperors” of the early Middle Ages. The Medieval Warm Period (MWP) was also called the “Early Medieval Warm Epoch” (Lamb, 1977, 1982) and the “Neo-Atlantic” by some palynologists. The expression “Little Climatic Optimum” (LCO) has sometimes been employed to contrast it with the dramatic warming of the “Atlantic” phase of the late Mesolithic to Neolithic ages (about 6700–4200 BC, (sidereal year)). The Atlantic phase was long known in Scandinavia as the mid-Holocene “Climatic Optimum” (also termed the “Hypsithermal”), when local temperatures were 2–3 °C above present (Roberts, 1998).

Lamb (op cit. p. 35) identified a broad long-term “summer wetness index” (rising) and compared it with a “winter severity index” (falling), based on 50-year means. Both display a systematic lengthening of the wavelength of upper westerlies across northern Europe, reaching its peak around AD 1100. A comparable warming swing also marked the twentieth century. However, analysis of this period is complicated by anthropogenic greenhouse warming. The two most recent warm periods were separated by the “Little Ice Age” (LIA) from approximately AD 1300 to 1750. The warmest interval of the MWP in Europe was AD 1150–1300. A study of Canadian borehole temperatures (mentioned by Lamb, op .cit., p. 104–105) suggested that the mean MWP was up to 1.6 °C warmer than the average for the last millennium. In the Sargasso Sea area of the North Atlantic

(see [Figure M15](#)), studies of planktonicbenthic foraminifera suggest that the SST was about 1 °C warmer than today 1,000 years ago and above average for the last 3 millennia, about 2 °C higher than during the LIA (Keigwin, 1996).

Human responses to the MWP have been outlined by many writers (see LeRoy Ladurie, 1971; Bryson and Murray, 1977; Bryson and Swain, 1981). The dramatic start of the LIA has been eloquently described by Lamb (op. cit.), but less attention has been paid to the MWP as a whole. Biological proxies are very interesting. In central Europe history reports, incidents of locust (*Locusta migratoria*) plagues in the drought summers occurred as follows: nineteenth century, 8 seasons; tenth, eleventh, twelfth century, none or next to none; fourteenth century, 15 seasons; fifteenth century, none; sixteenth century, 6; seventeenth century, one only; eighteenth century, 6; nineteenth century, 4 summers. From recent data in North Africa, Landscheidt (1987) suggested there was a correlation between locust plagues and solar radiation.

Sea-surface temperatures in the North Atlantic were higher during the MWP, (by 5 °C or more), and sea-ice coverage was appreciably reduced (Mayewski et al., 1994). Wind and wave action were likewise reduced. In the Greenland ice cores, a marked lowering of sodium (from sea-salt) has been observed. These climatic factors played an important role in the occupation of Iceland by Viking (Norse) colonists in the nineteenth century (AD 860). In the North Atlantic, there were

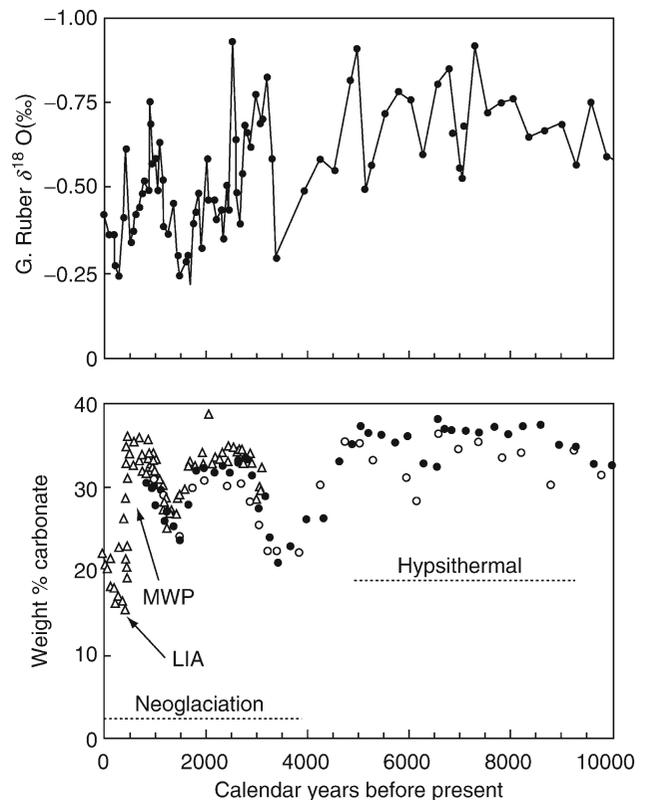

Figure M15 Variability in two proxies of sea-surface temperatures in the Sargasso Sea over the last three millennia, showing a marked contrast between the MWP and LIA (modified from Keigwin, 1996). (a) (top) $\delta^{18}\text{O}$ (‰) in the surface-dwelling foraminifera *Globigerinoides ruber* (white variety), Bermuda Rise, northern Sargasso Sea; (b) (bottom) weight % CaCO_3 .

frequent summers with calm seas and easterly winds that greatly favored their particular type of ships (shallow draft and square sails). Eventually, explorations were carried out by Eric the Red and Leif Ericsson, southern Greenland was colonized by the Norsemen (Dansgaard et al., 1975), and they settled briefly (AD 986) at Anse aux Meadows in Newfoundland ("Vinland"), the first European foothold in North America.

During the same MWP Arctic warming came a widespread development of Eskimo cultures, reaching as far north as Ellesmere Land (AD 900). From the Bering Sea, they spread out to northern Alaska, and in Siberia, they reached as far north as the New Siberian Islands. In the eleventh century a new wave of migrants brought the "Thule Culture" that spread from Alaska to northern Greenland.

In North America, native peoples spread northwards up the valleys of the Mississippi and Missouri, bringing an agricultural economy into Wisconsin and Minnesota, where pollen studies have shown there were reliable summer rains (Griffin, 1961). Eventually they reached the northern Rockies and even Utah. The Hohokam people were meanwhile developing agriculturally oriented communities in New Mexico and Arizona.

In Asia, the behavior of the Caspian Sea provides hydrographic evidence of the MWP climate. From the ninth to fourteenth Centuries, the rise of the Caspian Sea by 18 m flooded vast areas, notably in the Volga Delta. This reflected a general increase in precipitation over much of northern Russia. Clearly, this also reflects increased evaporation over the warming Gulf Stream and North Atlantic in general. The populations of central Asia showed a general expansion, but this only reached a crescendo in the early thirteenth century, which launched the celebrated conquests of Genghis Khan and his "Mongol Hordes" (AD 1205–1225).

It was the exploration of central Asia in the first decades of the twentieth century that provided the data base for Ellsworth Huntington's concept of climatic determinism (Huntington, 1924), which caused a great deal of controversy at a time when climate was assumed (by the conservative "Establishment") to be a changeless aspect of the environment. A long sediment core obtained from Lake Saki (Crimea) illustrates the higher precipitation levels of the MWP that also occurred in southern Russia. The thickness of clay varves suggests a heavier rainfall at this time (Lamb, 1977, p. 408; Xanthakis et al., 1995).

The MWP warm cycle was also seen in Scandinavia and the Alps, by glacier retreats (Röthlisberger, 1986; Karlén et al., 1995). Particularly in Sweden such glacier melts have been dated precisely by sedimentation measurements in the corresponding glacial lakes. Worldwide response was also marked by eustatic sea-level indicators including higher-than-normal beach ridges in many different regions, ranging from the Arctic coast of Alaska to the coasts of the Gulf of California and southwestern Florida (Fairbridge, 1992). The first radiocarbon dates of this higher sea-level stage were obtained in Western Australia, on Rottneest Island, and this therefore became known as the "ROTTNEEST STAGE" (Fairbridge, 1961). In Scandinavia, it is often referred to as the "Viking Stage" due to the abundant relics produced from the isostatic emergence around Stockholm and Uppsala. In northern Germany, the Netherlands and Belgium (Bennema, 1954), evidence for the higher sea level is partly drowned by tectonic subsidence but, after correction, its level was about 0.5 m above present MSL.

Inundation of low-lying coastal areas completely changed the geography in some areas. As sea level rose, there was frantic dike building in northern Germany, the Netherlands,

Belgium, northern France and in parts of eastern England. The critical moment when man-made dikes were overtopped in particular storms is recorded by historic disasters when tens of thousands of people and livestock were drowned and farms and whole villages were totally destroyed (Bakker, 1957). In the lower Rhine Valley, river floods amplified the oceanic factors (Berendsen, 1995). Outstanding events included the flooding of the lower IJssel valley in the Netherlands, with the creation of the Zuider Zee (1250–1251, 1287), and in Britain, with the creation of the Norfolk Broads (Lamb, 1977, p. 433). Other areas were affected including western France, the Rhone and Po Deltas.

The MWP ("Rottneest") rise of sea level had an important demographic effect inasmuch as it drove coastal dwellers inland, creating endless conflict with the people (mostly farmers and pastoralists) already occupying those areas. In the southern Baltic (modern Poland and northeast Germany), southern Denmark and the Frisian Belt in northwest Germany, post-glacial tectonic subsidence amplified the eustatic rise of the MWP.

An economic side effect of the MWP sea-level rise occurred in the salt industry (see a recent book, "Salt" by Mark Kurlansky). During periods of low sea level, as during much of the Roman Era, there were coastal salt pans with sea-water ponds that were organized in series to permit progressive evaporation. This was a major industry because common salt (NaCl) is an essential dietary condiment, as well as being in widespread demand for food preservation, leather tanning, etc. With the MWP rise, the salt pans were repeatedly inundated and in many cases could not be expanded inland because of low bluffs, dunes or cliffs. Industrial disaster was alleviated by a wholesale shift inland to "fossil" salt deposits, mostly of Triassic or Permian age, which had been long exploited since the Bronze Age or earlier. These deposits are known to occur in Britain, Spain, France, Germany, Austria, Poland and Russia (Moores and Fairbridge, 1997) (Many geographic names in central Europe incorporate the roots *Salz*, *Sal*, *Sel*, etc., e.g., Salzburg, Salzkammergut, Salzach).

Metallic ores were extensively mined (mainly by Saxon miners) in mountainous areas of Europe, where the Bronze Age had developed after the glaciers had receded and exposed dry outcrop areas. These expanded during the glacial recessions of the MWP. With the ensuing Little Ice Age (after 1300), there were neo-glacial advances and flooding of mines, leading to closures of the high passes in the Alps (Lamb, 1977, p. 273–274).

Lamb (1967, 1977, p. 276 ff) was fascinated by the history of grape vines and viticulture in Medieval Britain, a country not particularly celebrated today for its home-grown wines. South of lat. 53° N, this study disclosed widespread vineyards there in Medieval times, some 500 km north of present-day limits in France and Germany. To quote from William of Malmesbury writing in 1150 (tr. from *Latin*) of the vale of Gloucester "here you may behold highways and public roads full of fruit-trees, not planted, but growing naturally. . . No county in England has so many or so good vineyards as this, either for fertility or for sweetness of the grape. . ." The export of British wines to France and Germany was a major factor in international trade, and even led to diplomatic friction (when the British undersold the French). It should be recalled that in 1066 William of Normandy had led an invasion of Saxon Britain, at that time considered a remarkable prize. However, the Little Ice Age began and soon after 1300, the entire wine industry collapsed within 10 years, the vines surviving only in rare cases under the protection of walled gardens.

The abruptness of the LIA onset was a major aspect of the termination of the MWP, because it gave little leeway for organic adaptation. In human terms, this cultural shock is well dramatized by Tuchman (1978). Less well known is the effect on coral reefs that had grown vigorously to a low-tide limit about 60 cm higher than present. The fall by about 1 m created a small cliff on reef shores, with no gradual transition.

The eastern parts of North America and Greenland seem to have shared the European experience of the MWP equally (though detailed histories are lacking), as did New Zealand and some other parts of the Southern Hemisphere. However, in the North Pacific region, China, Japan and the western part of North America experienced the exact climatic opposite. In Japan, the mean blooming date of the cherry trees of the imperial gardens in Kyoto has long been monitored as the harbinger of spring and the occasion of joyful festivals. For the MWP, however, the mean blossoming date was a full 10 days later than the millennial average, or 11 days when comparing the mean for the twelfth century with that for the fifteenth century. To Lamb (1977, p. 400) "this suggests an eccentric position of the circumpolar vortex over the Northern Hemisphere in Europe's High Middle Ages, with the climatic zones persistently displaced north over the Atlantic sector and south over the whole Pacific sector and the Far East."

Archaeomagnetic studies employing the paleomagnetic orientation of baked bricks or fireplace clays indicate that the North Magnetic Pole at the time of the MWP lay in the eastern hemisphere, i.e., north of Siberia. A similar antiphase relationship is observed during Europe's cold phases (Bucha, 1984, 1988), but is not always consistent.

As noted earlier, at Mediterranean latitudes, there were commonly heavy summer rains during the MWP. In central America, these had an important role in bringing about the downfall of the Mayan civilization in Yucatan and elsewhere, as the maize (sweet corn) economy requires less humid seasons for ripening (Brooks, 1949); the maize culture required rainy and dry seasons. Repeated multiyear droughts between ca. AD 800 and AD 900 may have contributed to the collapse of the Classic Mayan civilization (Hodell et al., 2001; Haug et al., 2003).

The same delicate adjustment of agriculture to seasonal cycles may also help to explain the wonderful surge in culture and religious buildings at Angkor in Cambodia, which reached a maximum around AD 1000. During the Little Ice Age, these structures were seasonally inundated by the rise of the Mekong and back-filling of Tonle-Sap that eventually buried the entire complex in 10 m or more of sediment.

Northern Hemisphere synthesis

Basing his estimates mainly on botanical proxies (palynology), Lamb (1977, p. 404) presented a comparison between the major climatic intervals for Britain of the last 10,000 years. The MWP discloses the warmest annual mean temperatures since the Atlantic stage 6,000 years ago, 0.8 °C warmer than the warmest decades of the twentieth century. The MWP was also wetter, except for the two summer months July and August, which were characteristically dry.

A series of Northern Hemisphere oriented maps is presented by Lamb (1977, p. 444–5) for selected centuries, depicting troughs of the upper westerlies across Europe and the typical frontal depressions. For summer months during the MWP (AD 1000–1099), the mean polar jet swung from southern Greenland across northern Scandinavia to the Arctic shore of Siberia.

Meanwhile the major frontal depressions radiated from northern Greenland to east coast North America, from near Spitsbergen to Sicily, from near Lake Baikal to western China, and from Alaska to around Wake Island. For the same areas and season during the LIA (1550–1599), the polar jet ran across Scotland and southern Sweden, while the principal European frontal depressions ran from western Spain across the British Isles and the west of Norway.

For the winter seasons, the MWP polar jet crossed Quebec and swung north of Iceland to the Barents Sea while its southern branch crossed Spain and the Mediterranean to Syria. The latter brought plentiful winter rains and prosperity to the kingdom of Palmyra (Syria) and the peoples of Palestine and Mesopotamia. Five centuries later in the LIA, the winter jet unified and crossed Iceland to head for southern Russia, and to bring desertification to parts of Syria, Mesopotamia, and the Indian Peninsula (Bryson and Murray, 1977).

These mean jet trajectories help explain the antiphase relationships between climate proxies in Western Europe and the Far East. The inferred positions of the polar vortex swing to and fro, to eastern or western hemisphere; this appears to be analogous, on a greatly amplified (century) scale, with the "North Atlantic Oscillation" (NAO), which operates on a roughly decadal basis.

[Editor's note: More recent paleoclimate reconstructions over the last millennium provide additional support for the existence of a warmer period roughly 1,000 years ago, at least over the Northern Hemisphere. Less can be said about the Southern Hemisphere, inasmuch as reliable data are still fairly scarce. Based on long tree-ring records from 14 sites in North America and Eurasia, the warming of the MWP peaked between 950 and 1045, with temperatures comparable to those of the twentieth century prior to 1990 (Esper et al., 2002). A composite curve derived from multi-proxy data, including tree rings, boreholes, marine and lake sediments, and speleothems, also shows a period of higher temperatures around AD 1000 to AD 1100, followed by below average temperatures, with a minimum around AD 1600 (Moberg et al., 2005).]

Summary

1. The MWP (or Little Climatic Optimum) is a roughly 450-year climatic interval, at around AD 850–1300. Based on historical documentation, this was a warming cycle in Europe and eastern North America, but cooling in the north Pacific.
2. Based on (a) CO₂ and temperature indicators in the Greenland ice cores, and (b) C-14 flux (inverse) levels in the dendrochronology, this interval is confirmed as a warming cycle in the Atlantic realm, with temperatures at least 1 °C above millennial means, on average.
3. Based on astrochronology (using the 45.4-year resonance interval of the three major planets, Jupiter, Saturn and Uranus) there were three warm peaks: "Post-Carolingian" (AD 852), "Dunkerque-3" (944), and "Viking/Rottmest" (1125). Two cool peaks (marked by extended interruptions caused by low sunspots and reduced solar emissions) occurred at the "Normanian" (peak: AD 1034) and the "Ottoman" (AD 1307).
4. In general, precipitation rose in step with the mean temperature oscillations, but most glaciers tended to retreat. In exceptional areas, glaciers showed temporary advances.
5. Mean sea level rose and fell eustatically and caused coastal retreat matching eustatic rise in more or less stable crustal

- areas, and vice versa. However, in areas of crustal subsidence or rapid compaction, coasted retreat increased.
6. During much of the MWP, the general atmospheric circulation (prevailing westerlies, trade winds, etc.) slackened, but in the subarctic latitudes, the 45-year summer storminess cycle persisted. With weakening trade winds, El Niño cycles became more important (but detailed monitoring is not available). However, the associated warm coastal currents are known to have reached farther south in Peru, and farther north in California.
 7. The influence of the Gulf Stream and Kuroshio Currents were shifted northwards, together with their characteristic ameliorating effects in maritime areas (increased oceanicity), contrasted by reduced continentality.
 8. Sea ice coverage in the North Atlantic and Barents Sea decreased. Due to the longer ice-free seasons in areas of abundant sediment supply, the beach ridge buildup was anomalously high in places.
 9. In subarctic lakes and swamp deposits, the level of pine (or conifer) pollen rose in contrast to that of tundra species. Farther south, the mixed forest boundaries moved northwards.
 10. Equatorial lakes displayed localized change in level, as did rainfall, while savanna (monsoon) boundaries tended to shift poleward by some hundreds of km. The Southern Hemisphere was broadly in phase with the Northern Hemisphere, but out-of-phase for short cycles.

MESOZOIC CLIMATES

Introduction

The Mesozoic Era (250–65.5 million years ago) consists of the Triassic, Jurassic and Cretaceous Periods. Each of these periods is divided into many epochs and stages. The name Mesozoic comes from the Greek words “meso” meaning middle and “zoe” meaning life. The first to use the term Mesozoic was John Phillips in 1840. It has been considered to represent a time of greenhouse climates (e.g., Hallam, 1985), with elevated atmospheric CO₂ levels and higher mean global surface temperatures and is therefore considered as a possible analog for future climates.

Only sparse and often equivocal evidence for Mesozoic glacial sediments is seen, whereas abundant evidence for Precambrian, Paleozoic and late Cenozoic glaciations are recognized (Figure M16). Changes in continental configuration throughout the Mesozoic Era had important consequences for global climate.

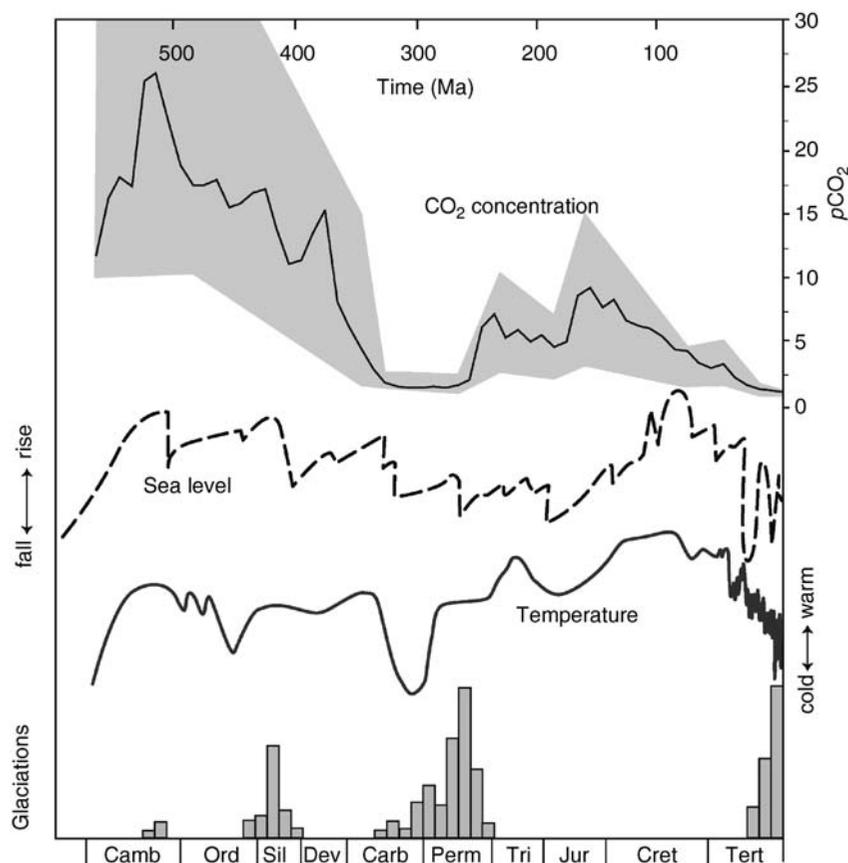

Figure M16 Phanerozoic climatic indicators and reconstructed $p\text{CO}_2$ levels. The upper set of curves describes the reconstructed histories of the past $p\text{CO}_2$ variations (GEOCARB III) by Berner and Kothavala (2001). The shaded region depicts the uncertainties quoted within the GEOCARB III reconstructions. Sea level data is from Vail et al. (1977) and temperature data from Merritts et al. (1998). The Phanerozoic distribution of glaciations is modified from Hambrey (1994). A semi-quantitative measure of the extent of the Earth's surface affected is indicated by the heights of the peaks.

At the end of the Paleozoic, as a result of the final Variscan suturing of all of the continent components, the supercontinent Pangea (meaning "all-earth") was formed. Very few continental fragments escaped incorporation into Pangea and because of its sheer size it was relatively unstable from its beginning. Hence, parts of the supercontinent began to break away, whilst collision was occurring in other areas. The break-up of the continent continued throughout the Mesozoic and into the Cenozoic.

The proportion of greenhouse gases, and in particular CO_2 , in the atmosphere of the Mesozoic has had a major control on global climate. CO_2 transmits incoming short-wave solar radiation, but greenhouse gases absorb outgoing long-wave radiation and the trapped radiation warms the lower part of the Earth's atmosphere. The atmospheric CO_2 curve shows low values during the Carboniferous, which then rise in the Permian, throughout the Triassic and Jurassic, followed by a gradual decline through both the late Mesozoic and Cenozoic (Berner and Kothavala, 2001). The long-term carbon cycle reflects atmospheric CO_2 exchange between the atmosphere and carbon stored in rocks. Loss of CO_2 from the atmosphere is accomplished by photosynthesis and burial of organic matter in sediments and by the reaction of atmospheric CO_2 with Ca and Mg silicates during continental weathering. The release of CO_2 to the atmosphere takes place by means of oxidative weathering of old organic matter and by the thermal

breakdown of buried carbonates and organic matter (via diagenesis, metamorphism and volcanism) resulting in degassing to the Earth's surface (Berner and Kothavala, 2001). The long-term global (eustatic) sea-level trend shows a gradual fall, from the end of the Paleozoic to the early Mesozoic, changing in the latest Triassic to a rising trend that continued into the middle Cretaceous. Sea levels only begin to fall again in the latest Cretaceous and into the Cenozoic (Figure M16). Although atmospheric levels of CO_2 are commonly assumed to be a main driver of global climate, clearly longer-term changes in sea level are also strongly influenced by other (tectonic) processes, the most important of which is sea-floor spreading, which changes the volume and elevation of ocean ridges. A first order correlation is seen between atmospheric CO_2 and global temperature estimates.

Early Mesozoic Pangean climates

The dawn of the Triassic saw the geography of the world looking quite similar to how it did during the Permian. Data suggest that sea level rose a little from its Permian low. The combination of a huge land mass and lower global sea level (related to the reduced rates of tectonic activity) should have resulted in extremely arid continental climatic conditions. Sedimentary deposits in Brazil and South Africa give us a window into the Triassic world. Many of the sedimentary rocks deposited in

Triassic terrestrial environments are dune-deposited sandstones or oxidized fluvial sandstones and mudstones (red beds). Additionally, evaporite deposits are more extensive in the Triassic than at any other time during the Phanerozoic. These deposits attest to the hot and dry conditions within the interior of Pangea. Modeling results suggest that the global average temperatures were up to 7°C warmer than today. Extreme temperature ranges >45°C are predicted for the lowland interior of Pangea. Precipitation in large areas of the interior was less than 0–2 mm d⁻¹, comparable with modern arid and semi arid deserts.

Temperatures of the equatorial oceans may have been 5–10°C warmer than those seen today, but data are scarce and are not derived from the most reliable sources. Nevertheless, warm conditions are thought to have extended to the poles. For example, a combination of roots, logs, and leaves of woody plants has been taken to be indicative of temperate climatic conditions in Antarctica during the middle Triassic. The wood samples of Antarctica exhibit distinct growth rings, which have also been analyzed for climate signals. Such analyses reveal that the climate was strongly seasonal and that light may have been a limiting factor in the growth of these forest trees. The distributions of fossil reefs and carbonate build-ups has also been interpreted as reflecting the presence of ancient warm water seaways analogous in terms of their distributions to those of the present day. However, the communities of organisms that constructed many ancient build-ups were often dissimilar to the coral-rich ecosystems represented by modern reefs. During the Late Triassic, carbonate build-ups became both large and widespread throughout the Tethyan margins, particularly along the western and northern borders. These were formed by corals, calcisponges, hydrozoans and algae.

The assumption that the climatic history of the Triassic was characterized by uninterrupted hot and arid conditions has, however, been questioned. Humid zones occurred close to the coast and at high latitudes, as shown by coals and bauxite deposits in these areas. A number of General Circulation Model simulations of the Triassic (e.g., Kutzbach, 1994; Wilson et al., 1994) predict that the geography of the supercontinent Pangea was conducive to the establishment of a “megamonsoonal” circulation (Parrish, 1993). Particularly in the late Triassic, the climate of the Colorado Plateau region became relatively wet, though still seasonal. Furthermore, Parrish (1993) suggests that evidence for monsoonal conditions is apparent at higher latitude locations such as Australia (beyond the normal influence of a monsoonal circulation), during the Late Triassic. The strength of the monsoon must therefore have been at its greatest at this time.

A few studies have also provided possible evidence of glacial conditions during the late Triassic. Breccia-like conglomerates of Triassic age containing large angular rock fragments from Japan and alleged tills from southern South America have also been recorded (see Price, 1999 for a summary). A glacial origin for these deposits has, however, been strongly questioned. The possible existence of sizeable ice cover during the middle and late Triassic, based upon evidence for high frequency Milankovitch-influenced sea level oscillations, has been recorded in platform carbonates from Europe. In as much as tectonic movements cannot operate on a sufficiently rapid timescale to account for the observed high frequency sea level changes, only glacio-eustatic mechanisms likely controlled such sea level change. If these sea level changes were glacio-eustatically controlled, this implies the occurrence of a significant number of sufficiently large glaciations affected global sea level during the Triassic. However, if ice caps were either absent or negligible during the Mesozoic,

alternative mechanisms to account for the observed changes in sea level are required, such as possibly regional tectonic events. However, tectonic movements have generally been considered to operate neither at a sufficiently rapid timescale, nor on a global scale. An alternative mechanism is that changes in plate density associated with tectonic-induced stresses could account for many of the transgressions and regressions traceable over areas larger than individual sedimentary basins. Other possibilities to account for short-term global changes in sea level include the thermal expansion and contraction of ocean water and desiccation of isolated ocean basins. The General Circulation Model simulations for the Triassic (e.g., Kutzbach, 1994; Wilson et al., 1994) using elevated CO₂ concentrations (ranging from 1,000 to 1,650 ppm) and relief reaching a maximum of 2 km also provide results consistent with extreme temperature variability at polar latitudes. For example, the model of Kutzbach (1994) simulated a mean annual temperature of -5°C, with winter temperatures of -30°C and summer temperatures of 25°C over parts of Antarctica. The simulation of Wilson et al. (1994) produced summer temperatures of 20°C and winter temperatures dropping to a minimum of -50°C over Antarctica and solid permafrost zone. Although a tract of sea-ice was simulated all year round, Wilson et al. (1994) considered the results to be inconsistent with polar ice sheet development.

The climate of disintegrating Pangea

Latest Triassic to Jurassic times saw the progressive break-up of Pangea. Ocean floor was present in the central Atlantic region by middle Jurassic times, heralding the separation of Gondwana and Laurasia. This rifting removed the major forcing factor of the monsoon, the distinctive Pangean geography (Parrish, 1993). The postulated warmth that characterized the Triassic appears to have continued into the Jurassic (Figure M16). Global sea level began to rise, possibly associated with the increased sea-floor spreading as Pangea began to break up. Based on the global distributions of lithological climate indicators such as coals, as well as evaporites and eolian sands, a general symmetry of climate zones about the paleoequator appeared throughout the Jurassic. Using lithological and floral data, Rees et al. (2000) suggested that the Jurassic world was one in which low latitudes were seasonally dry, succeeded polewards in both hemispheres by desert, seasonally dry, warm temperate and cool temperate biomes. Modeling studies (e.g., Moore et al., 1992) have implied that the tropical regions reached temperatures as high as 40°C during parts of the summer months. Precipitation in these regions during the summer months locally exceeded 16 mm per day. Siberian floras were assigned to a cool temperate biome, characterized by cold winters and warm summers, implying polar conditions considerably warmer than today. Rees et al. (2000) did not, however, identify any geological evidence for tropical year-round wet or, at the other extreme, tundra or glacial biomes. The occurrence of a theropod dinosaur of Jurassic age from Antarctica has likewise been used as evidence for a warm climate in polar regions.

One of the most common methods of establishing quantitative values for past ocean temperatures has been the use of oxygen isotopes derived from well-preserved biogenic carbonate material. Studies assessing Jurassic ocean temperature variation at high southern latitudes, using isotopic ratios from belemnites, certainly support the notion that high latitudes were significantly warmer than today and ice-free. Paleotemperature estimates for the European area range from 12 to 30°C, again considerably warmer than today. The Lower and Upper parts

of the Jurassic appear to have been the hottest periods. Such a trend possibly mirrors the CO₂ curve (Figure M16). A cooler middle Jurassic is not inconsistent with the findings of Frakes et al. (1992). A great deal of information regarding the temperature of Earth during the Jurassic has been gained from faunal data and in particular the analysis of the patterns and degree of provinciality. It has been widely considered that, in particular, the early Jurassic period was characterized by low faunal provinciality, possibly due to equable climates and the lack of polar ice caps. Faunal provinciality became more marked from Middle Jurassic times onwards and two major faunal provinces existed in the Northern Hemisphere, the northern Boreal realm and the lower latitude Tethyan realm. A Southern Hemisphere Austral realm corresponding to the northern Boreal realm has also been recognized. The possible existence of Boreal and Austral realms, delineated by temperature, during parts of the Mesozoic certainly does lend support to the existence of cold conditions at the poles for certain times.

In a similar fashion to the Triassic, General Circulation Model simulations of the Jurassic climate (e.g., Moore et al., 1992) reveal also that high latitude regions may have developed cold temperatures providing adequate leeway to argue for the presence or absence of high latitude ice. Siberian Jurassic tillites stretching from the Yenisey River eastwards to the Oloy Ridge have also been described (see Price, 1999, for a review). The principal characteristics of these deposits are non-bedded, silty and pebbly claystones that have been considered to be glacio-marine in origin or formed by seasonal ice of mountain rivers. A recent study by Chumakov and Frakes (1997) re-investigating some of these Jurassic deposits suggested, however, that sediments previously attributed to ice rafting display instead characteristics of mass movement, including contorted bedding and evidence of turbidity currents.

The late Jurassic–early Cretaceous was characterized in many areas of the world by a sea-level lowstand (Figure M16) possibly initiated by low spreading rates, resulting in large semi-restricted epicontinental seas and widespread deposition of non-marine sediments. The progressive weakening of the monsoonal circulation is also evident resulting from the increasing dispersion of continental components and increasing asymmetrical continental configuration. The latest Jurassic Purbeck group of the UK, which contains evidence of evaporite deposition, may be the local expression of the spread of an equatorial arid zone across Europe during these times. Clay mineral assemblages also reflect the expansion of the arid zone northwards during the middle to late Jurassic within the East European Platform.

The Cretaceous Period was a time of considerable tectonic activity. The supercontinent Gondwanaland began to break up in the early Cretaceous: India began to move northwards and the North Atlantic began to open. Early Cretaceous freshwater sediments and plants of Europe point to a change to warm and humid conditions. A warm and wet climate may be a result of the continents becoming significantly more dispersed and rising sea levels. By mid-Cretaceous times, the Tethys Ocean began closing. Evidence points towards an unusually high rate of volcanic activity, especially at mid-oceanic ridges. Magma erupted at oceanic ridges and created new oceanic crust, thereby forcing the continental landmasses apart. Rates of continental drift (i.e., sea-floor spreading rate) were then about three times as great as they are now. During the mid-Cretaceous (~90 million years ago), sea levels rose dramatically, possibly up to 200 m higher than present levels, flooding up to 40% of the continents and resulting in the widespread deposition

of chalk-dominated facies. The Western Interior Seaway of the USA was at this time at its maximum. Much of central and western Europe was under water. Hence, mid-Cretaceous indicators of aridity, such as evaporites, are generally restricted to low latitudes and occur within northern Africa, South America, the Gulf of Mexico and also in the middle East. By late Cretaceous times, the evaporate-producing arid zones had contracted to a Mesozoic minimum (Hallam, 1985). These areas generally correlate with areas of climate model-predicted warmth, coupled with low soil moisture. Year-round moist-wet conditions prevailed at higher latitudes. Extensive coal deposits of mid-Cretaceous age are found in Northern Eurasia and Eastern Europe. Abundant coals occur also in the USA, particularly adjacent to the Western Interior Seaway.

In addition, during the mid-Cretaceous, vast outpourings of lava created a succession of immense undersea plateaus beneath the Pacific Ocean between 135 and 115 million years ago. One of these – the Ontong Java Plateau in the southwest Pacific – may be the largest flood basalt province in the world (roughly the size of Alaska) and certainly led to an huge increase in hydrothermal activity and an increase in CO₂ outgassing, which was ultimately released to the atmosphere. Extensive outgassing of CO₂ would have led to climatic warming, due to the greenhouse effect. In addition to this increase in outgassing of CO₂, the reduced continental area (due to the sea level maximum) would presumably also have resulted in a decrease in continental weathering and a reduction in the drawdown of CO₂. Therefore, the global climate at this time should have been one of the warmest in Earth's history. Abundant isotopically-derived foraminiferal paleotemperature data, gathered particularly from equatorial latitudes, suggest that globally averaged ocean surface temperatures in the Cretaceous were as much as 6–12 °C higher than at present. Although changes in equatorial regions may not have been so marked, these data support the hypothesized “Cretaceous greenhouse” and a thermal maximum occurring at ~90 Ma. However, Figure M16 shows a mismatch between peak Cretaceous warmth (and sea level) and peak CO₂ production. A pulse of volcanic activity and crustal production and hence CO₂ outgassing appears absent or has yet to be identified at this time (Wilson et al., 2002).

The prospect of generally warmer tropics poses important implications for hurricane genesis. Frequency of hurricanes greatly increases during times when an extensive ocean area has surface temperatures in excess of 27 °C. As broad areas of the Cretaceous oceans were probably above this threshold temperature, in all likelihood hurricanes should have been substantially more frequent in the mid-Cretaceous than at present. Particularly compelling evidence for polar warmth is also provided by the analysis of fossil wood and by the physiognomic analysis of middle and late Cretaceous floras from Alaska and northeastern Asia (e.g., Herman and Spicer, 1997). Data from this latter study suggests that an Arctic Ocean with a winter surface temperature of ~6 °C maintained Northern Alaska coastal temperatures above freezing. Rich fern, gymnosperm and angiosperm floras are also known from the Cretaceous of Greenland, Siberia and Antarctica. Such warmer polar conditions would have been maintained by increased atmospheric and oceanic poleward heat transport. Significantly warmer tropical oceans also provided appropriate environmental conditions for enhanced evaporation and hence the production of warm saline bottom waters. Today, oceanic deep waters form in higher latitudes, where sea-ice formation increases the salinity and therefore the density of surface water.

It is possible that the extensive outgassing of CO₂ would have had other effects upon the oceans. Oxidation of reduced material in hydrothermal effluents and the stimulation of primary productivity owing to the injection of hydrothermal Fe into surface waters are both potential O₂ reducing mechanisms. Major episodes of organic carbon rich black shale deposition within the Cretaceous corresponded to Oceanic Anoxic Events. These have been interpreted in terms of increased burial of organic carbon, attributed to enhanced preservation under reduced O₂ conditions, or driven by changes in surface water productivity (that delivered more organic carbon to the sea floor). A loss of CO₂ from the atmosphere may well have resulted from enhanced organic-matter production and burial in the oceans, sequestering CO₂ and eventually leading to a reduction in paleotemperatures. Such trends may not necessarily be resolvable on the atmospheric CO₂ curves of Berner and Kothavala (2001).

Paleoclimate data for the early Cretaceous are derived largely from mid-low latitudes and may not necessarily reflect ambient climatic conditions at the poles. At least seasonally cold ocean temperatures and more controversially limited polar ice caps have been postulated to have existed during the early Cretaceous. Studies have revealed distinct faunal belts throughout parts of the early Cretaceous resulting from considerable temperature gradients from north to south. These paleobiogeographic patterns support the idea of a cooler phase for parts of the early Cretaceous and hence disagree with the suggestion of a globally warm equable climate throughout the Cretaceous. Many studies have recorded large and globally synchronous Milankovitch-influenced oscillations of Cretaceous sea level and fluctuating polar ice volumes have sometimes been invoked as a primary mechanism to account for such changes. Furthermore, Frakes et al. (1992) described tillites and dropstones, providing at least equivocal evidence for the presence of ice sheets. However, such data are poorly distributed in the Cretaceous. Short-term climatic cycles, related to variations in the geometry and mechanics of the Earth-Sun system (i.e., Milankovitch cycles), have been recognized throughout the Mesozoic. (The Milankovitch cyclic variations include eccentricity of the Earth's orbit with a periodicity of ~100 kyr, precession with a periodicity of ~21 kyr, and obliquity of the axis of rotation with a periodicity of ~41 kyr). Small-scale rhythms, often marl-limestone couplets within some Mesozoic sedimentary successions, have also been attributed to orbitally-modulated (Milankovitch) climatic change. Changes in productivity and temperature, for example, provide mechanisms for the translation of orbital variations into cyclic sedimentation during non-glacial times.

Towards the end of the late Cretaceous there was a decrease of temperature and a fall in global sea level (Figure M16), reducing the area of shallow marine environments. The close of the Cretaceous witnessed a major extinction event that saw the disappearance of at least 75% of the species on Earth, both in the oceans and on the continents. The most famous of these were the dinosaurs, although they represent only a small fraction of the plants and animals that disappeared. Although most agree that the Cretaceous-Tertiary extinction event was caused by a catastrophic bolide impact, climate change, continental reconfigurations and sea level change have also been considered as complementary mechanisms to account for the extinction events.

Summary

The Mesozoic Era has been considered to represent a time of greenhouse climates, with elevated atmospheric CO₂ levels and higher mean global surface temperatures. However,

empirical observations and modeling studies do not conclusively suggest high latitude ice-free environments during the whole of the Mesozoic. The combination of the massive size of the Pangean landmass and lower global sea level resulted in extremely arid continental climates, especially during the Triassic period. More humid zones did occur close to the coast and at high latitudes, as shown by coals and bauxite deposits in these areas. Associated with the progressive break-up of Pangea, global sea level began to rise. Aridity was slowly replaced by climates that were more humid during the late Mesozoic, although they were still punctuated by periods of extreme aridity. This increase in continental humidity certainly appears to have been related to an increasing maritime influence. Global temperatures and sea levels rose, reaching a maximum at ~90 Ma. The atmospheric CO₂ curve shows increasing values throughout the Triassic, with a maximum in the early Cretaceous, whereas temperatures and sea levels were at their highest somewhat later. Thus, mismatch between peak Cretaceous warmth (and sea level) and peak CO₂ production is observed.

MESSINIAN SALINITY CRISIS

During the Messinian (uppermost Miocene), the Mediterranean area was involved in a rapid and dramatic salinity crisis, as indicated by the discovery of 1–2 km thick evaporite deposits beneath its sea floor (Hsü et al., 1973). The problems in envisioning viable depositional models for these evaporites generated a number of contrasting hypotheses regarding the timing (synchronous versus diachronous), the origin (glacioeustatic versus tectonic), the environmental conditions (deep versus shallow water) and the impact (global versus regional) of the salinity crisis. An international controversy arose mostly because different sub-basins could have experienced different evaporite deposition at the same time and direct data on the evaporite rocks in the deep Mediterranean depressions are limited to only a few meters of boreholes. Other significant problems were the absence of an accurate and reliable time frame for the Messinian, the difficult application of biostratigraphy in unfavorable hypersaline sediments, and lithologies that are not well suited to magnetostratigraphy (diatomites and evaporites).

Originally, three main models were proposed to explain the origin of the Mediterranean evaporite giant: (a) a shallow, rapidly subsiding basin able to create accommodation space for shallow-water to supratidal evaporite accumulation (Nesteroff, 1973); (b) a preexisting deep basin that became partially cut off from world sea level, resulting in drawdown and deposition of shallow-water to desiccated hypersaline facies (Hsü et al., 1973); and (c) a preexisting deep basin in which deposition occurred in deep hypersaline water (Busson, 1980). Other hypotheses integrate different environments of deposition to explain the complex array of evaporite facies throughout the Mediterranean Basin.

On a broad scale, the evaporite deposits beneath the deep Mediterranean depressions indicate progressive restriction of the Mediterranean-Atlantic connection. As suggested by seismic data, the evaporites can be divided into two main sulfate-bearing units, the Lower Evaporites (or First Cycle), containing thick halite deposits, and the Upper Evaporites (Second Cycle), separated by an interregional unconformity. The Second Cycle does not have a marine signature like that of First Cycle and is not evaporitic across all of the Mediterranean. In most land sections it consists of detrital sediments with a brackish fauna, the so-called “Lago Mare” (Lake Sea) facies, which represents a dominantly freshwater body of Paratethyan origin, marking the complete isolation of the Mediterranean from the ocean. Normal marine conditions were suddenly re-established at the beginning of the Pliocene as a consequence of flooding from the Atlantic.

Recently, astrochronology and integrated stratigraphy have demonstrated that the onset of evaporite formation was a

synchronous event over the entire Mediterranean basin, dated at 5.96 Ma (Krijgsman et al., 1999). Cyclic evaporite deposition is related to circum-Mediterranean climate changes driven by changes in the Earth’s precession with an average periodicity of 21.7 kyr. Isolation from the Atlantic Ocean was established between 5.59 and 5.33 Ma, causing a large fall in Mediterranean water level followed by erosion (5.59–5.50 Ma) and deposition of the non-marine “Lago Mare” sediments (5.50–5.33 Ma). According to these data, the total duration of the Messinian salinity crisis is approximately 640 kyr. This view is not shared by all authors (Butler et al., 1995; Clauzon et al., 1996; Riding et al., 1998), but the general consensus is toward a marked drawdown of the Mediterranean water level. Estimations of the water level drop range from a few hundred meters up to 3,000 m (Tay et al., 2002), but some parts of the Mediterranean appear to have remained under relatively deep-water conditions throughout the entire salinity crisis (Roveri et al., 2001).

Another common view is that the deeply incised subaerial erosional surface that produced the incised canyons of the Rhone, Ebro, Po and Nile Rivers represents the time interval during which evaporites accumulated in the deep basins. More controversial is the stratigraphic position of the marginal evaporites, which are placed by different authors either above or below the main unconformity (Riding et al., 1998; Clauzon et al., 1996), thus postdating or predating the desiccation phase in the deep basins.

The compilation of a detailed chronology challenged the original view that the Mediterranean isolation could have been triggered by glacioeustatic sea level lowering (Kastens, 1992). The latest Miocene glaciation occurred from 6.26 to 5.5 Ma. It was marked by 18 glacial-to-interglacial oscillations controlled by the 41-kyr cycle of obliquity (Hodell et al., 2001). Although the glaciation may have contributed to the isolation of the Mediterranean, it preceded the base of the Lower Evaporites by 300 kyr, supporting tectonic or local climatic forcing for the crisis inception (Krijgsman et al., 1999; Hodell et al., 2001). This hypothesis is supported by the discovery of large and rapid climate variations during the salinity crisis, as documented by biomarkers, stable hydrogen, and carbon isotope compositions (Andersen et al., 2001). Moreover, the end of the salinity crisis preceded the most prominent interglacial conditions by 170 kyr, suggesting that sea level outside the Mediterranean began to rise prior to the base of the Pliocene. This implies that tectonics were responsible for the end of the crisis or there was a significant lag between sea level rise and the resumption of normal marine conditions in the Mediterranean (Hodell et al., 2001).

METHANE HYDRATES, CARBON CYCLING, AND ENVIRONMENTAL CHANGE

Overview

Enormous amounts of methane reside as solid gas hydrate and free gas bubbles in the pore space of marine sediment along continental margins. Most of this methane has formed through the microbial breakdown of organic matter originally deposited on the seafloor. At present, a small fraction escapes to ocean waters through seafloor venting. Reaction with dissolved sulfate consumes additional methane in pore waters of shallow sediment. These potentially important carbon fluxes, which remain absent from most global carbon cycle models, could change dramatically through time because the stability and distribution of gas hydrate and free gas depend on external conditions, particularly ocean temperature. Chemical anomalies in sediment or sedimentary rocks may document such variations in methane release and hint at an under-appreciated mechanism for past climate change.

Chemistry and theoretical occurrence

At relatively low temperatures, high pressures and high gas concentration, certain low-molecular-weight gases such as methane, ethane, propane, carbon dioxide and xenon can combine with water to precipitate crystalline substances

200--1244C-10H-2 (83.70-84.30 mbsf)

Figure M17 Example of natural gas hydrate recovered from Hydrate Ridge off the coast of Oregon (Shipboard Scientific Party, 2002).

resembling ice (Figure M17). These solid compounds are called clathrate hydrates of gas, or more conveniently “gas hydrates,” because the gas molecules exist within cages of water molecules. Three types of clathrate structures have been identified: Structure I, Structure II and Structure H. Each of these structures contains small and large cavities that can host guest gas molecules; their general formulae are $8C \cdot 46H_2O$ (S1), $24C \cdot 136H_2O$ (S2), and $4C \cdot 34H_2O$ (SH), where C is the total number of available cavities. The type of clathrate structure formed depends on the size and composition of the guest gases. Moreover, the chemical composition may differ from the ideal formulae because gas molecules need not occupy all cavities (Sloan, 1998). Indeed, natural clathrate hydrates of methane seem to be S1 with a composition of approximately $CH_4 \cdot 6H_2O$. For all three structures, the solid gas hydrate can dissociate to constituent water and gas phases with a decrease in pressure or increase in temperature, although gas chemistry and crystal structure determine the precise conditions (Sloan, 1998).

Gas hydrates naturally precipitate in the pore space of water-bearing sediments when gas concentrations exceed saturation conditions at appropriately high pressure, low temperature and low salinity (e.g., Dickens and Quinby-Hunt, 1997). These criteria are met in two general environments: Arctic regions beneath several hundreds of meters of permafrost, and along continental margins beneath several hundreds of meters of seawater (Kvenvolden, 1999). This article focuses on the latter because the marine realm hosts the vast majority of natural gas hydrate (>99%) (Kvenvolden and Lorenson, 2001).

Within deep-sea sediments, gas hydrates can potentially exist between the seafloor and a relatively shallow, sub-bottom depth where temperatures become excessively warm because of the geothermal gradient (Figure M18). This depth interval is commonly called the gas hydrate stability zone (GHSZ) and its lower bound generally increases with water depth because of greater pressure and invariant salinity. Thus, across a continental margin, the GHSZ forms a lens within sediment that starts at some shallow water depth and thickens beneath deeper water (Figure M18). This lens begins nominally at 250–500 m water depth at present, depending on local bottom water temperature and gas composition (Dickens, 2001). Below the GHSZ, where temperatures are too warm, free gas bubbles will exsolve from solution when gas concentrations exceed saturation (Holbrook et al., 1996;

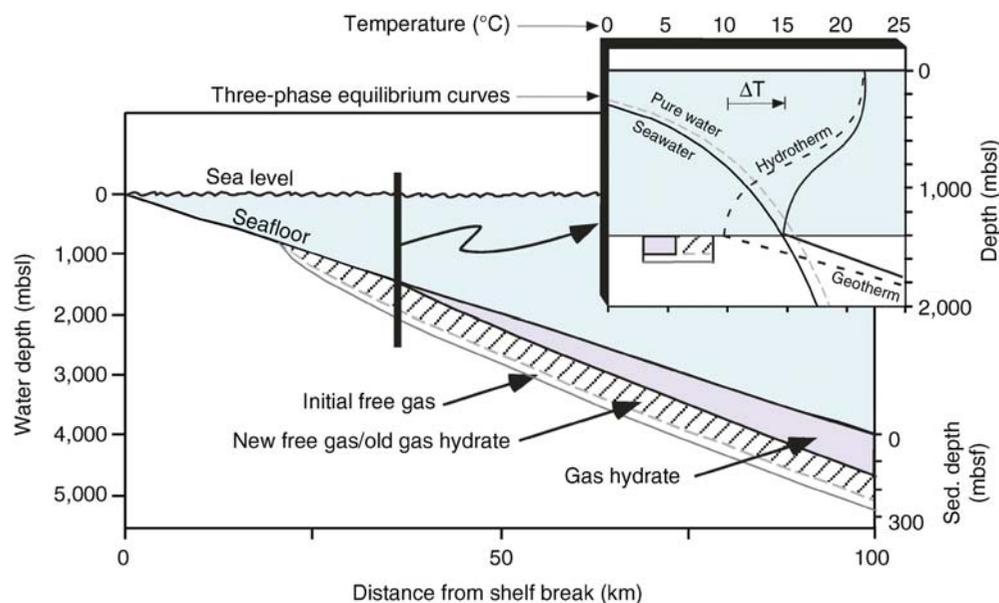

Figure M18 Theoretical location of crystalline gas hydrate and free gas bubbles below the seafloor before and after a 5 °C rise in bottom water temperature (after Dickens, 2001). The phase boundaries pertain to the pure methane system in pure water and seawater. Note that the diagram pertains to an initial bottom water temperature of 10 °C, as inferred for the Paleocene prior to the PETM.

Dickens et al., 1997). Significant amounts of gas hydrate cannot accumulate above the seafloor because, like ice, it has a density less than liquid water and floats.

Natural distribution and composition

Although appropriate pressure and temperature conditions exist throughout the deep ocean, insufficient concentrations of requisite gases preclude gas hydrate formation in many deep-sea sediment sequences. Along continental margins, however, the decomposition of organic matter through microbial activity or thermal cracking generates enough low molecular weight hydrocarbon gases to saturate pore waters within portions of the GHSZ.

Gas hydrates can be recovered from at or near the seafloor in a few places where hydrocarbon gases escape from sediment along fluid conduits such as faults. Locations documented to date include numerous sites in the Gulf of Mexico and on Hydrate Ridge off the coast of Oregon (Figure M17 and M19). Interestingly, these hydrates lie in contact with water containing very low concentrations of hydrocarbon gases. Evidently, a rapid supply of hydrocarbon gases can prevent the dissolution of gas hydrates on the seafloor.

Good evidence for gas hydrates has been documented in marine sediment well beneath the seafloor at over 60 locations in all oceans (Kvenvolden, 1999). Most of this evidence is indirect, coming from geophysical methods and an understanding of how sound waves propagate through sediment (Kvenvolden, 1999; Kvenvolden and Lorenson, 2001). Relative to sediment with pore space filled by water, the presence of solid gas hydrate and free gas bubbles increases and decreases the velocity of sound, respectively. A drop in sound velocity therefore occurs where gas hydrate directly overlies free gas bubbles at the base of the GHSZ. Seismic profiles generated on ships can image this acoustic interface (Figure M19), commonly named a bottom-simulating reflector (BSR) because it represents a solid/gas phase boundary,

parallels the seafloor and cross-cuts sedimentary strata (Holbrook et al., 1996; Kvenvolden, 1999). However, significant amounts of gas hydrate can exist at locations without a BSR, when insufficient gas concentrations to saturate pore waters occur at the bottom of the GHSZ (Dickens, 2001). Remote sensing of gas hydrate using current methods offers only a partial view of their distribution.

Considered unsafe for scientific drilling until the last decade, only a few areas of the seafloor with gas hydrate have been drilled so far in order to evaluate its vertical distribution and characteristics. These places include the Blake Ridge offshore of South Carolina, the Peruvian Margin, and Hydrate Ridge. In drill holes at each of these locations, some gas hydrate samples were recovered within the GHSZ. However, most gas hydrate eluded recovery and dissociated to constituent methane and water as pressure decreased and temperature increased during sediment core retrieval (Paull and Matsumoto, 2000; Shipboard Scientific Party, 2002). This inference comes from the results of various proxy techniques for measuring gas hydrate abundance. For example, a special tool was used at each drilled location to collect sediment cores at *in situ* pressure. The amounts of hydrocarbon gases released from these pressure cores (Figure M19) exceed gas hydrate saturation at many depths (Dickens et al., 1997; Milkov et al., 2003). In addition, the dissociation of gas hydrate is an endothermic reaction that decreases the temperature of sediment and releases fresh water to surrounding, relatively saline pore water. Anomalous low temperatures and fresh pore waters measured after core recovery can thus record the presence of gas hydrate in sediment at *in situ* conditions (Paull and Matsumoto, 2000; Shipboard Scientific Party, 2002). A major find resulting from this recent drilling is that gas hydrate in these locations is widely dispersed in sediment at low concentrations (<5% of pore space) except along local fluid conduits where, in some cases, the amount of gas hydrate exceeds the mass of sediment over m-scale intervals.

In most regions with gas hydrate, microbial production of gas dominates, and the gas within recovered samples of

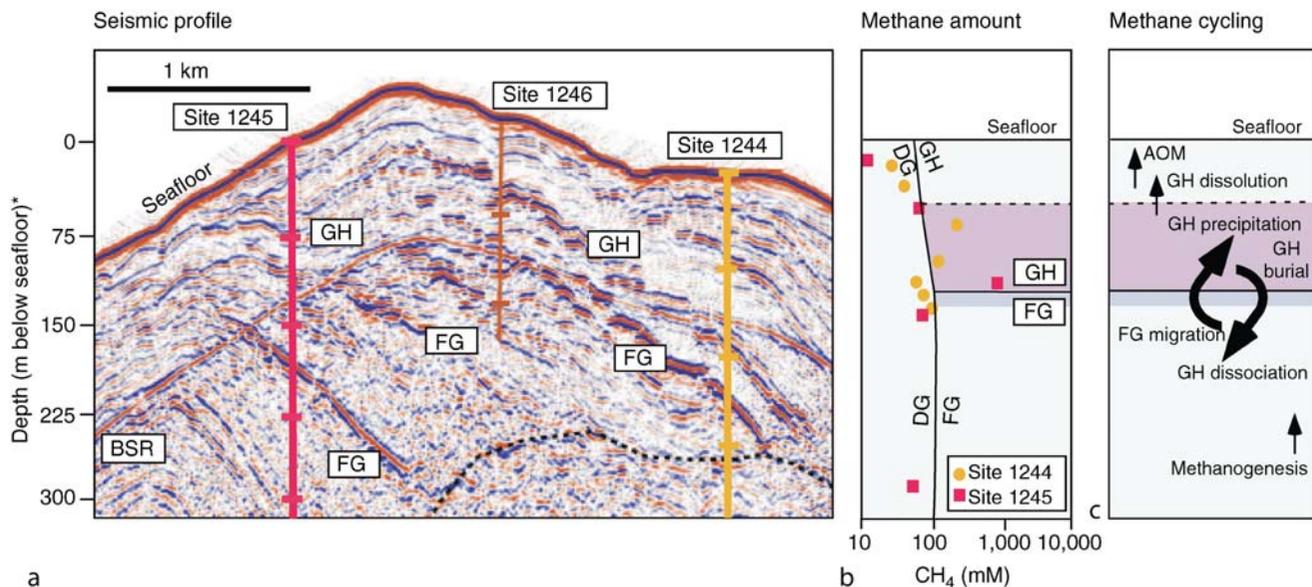

Figure M19 Seismic reflection profile across southern Hydrate Ridge on the Oregon Margin showing the bottom simulating reflector (BSR) and the location of three sites drilled during Leg 204 (Shipboard Scientific Party, 2002). Also shown are methane concentrations determined using pressure cores (Milkov et al., 2003), and the inferred dynamic cycling of methane in this region (modified from Dickens, 2003). The BSR is an acoustic interface separating gas hydrate from underlying free gas bubbles.

hydrate comprises mostly methane, often in excess of 99% (Kvenvolden and Lorenson, 2001). The microbial origin also leads to an exceptional depletion in the isotope ^{13}C (Kvenvolden and Lorenson, 2001). These microbial gas hydrates are Structure I clathrates. In some regions such as the Gulf of Mexico, however, thermogenic gas dominates, and gas hydrate samples may contain significant amounts of ethane and propane (Kvenvolden and Lorenson, 2001). These mixed hydrocarbon gas hydrates are often Structure II clathrates.

Global amount and significance

Estimates of the worldwide amount of gas hydrate in marine sediment remain poorly constrained and vary greatly. This reflects the intrinsic difficulty in quantifying the abundance of a phase that defies straightforward detection by remote methods and simple recovery by conventional drilling methods.

In theory, the global amount of gas hydrate in the oceanic realm can be calculated from two parameters: the volume of pore space within the GHSZ along all continental margins (Figure M18), and the average amount of pore space occupied by gas hydrate within this volume (Dickens, 2001). Estimates for the first parameter range from 1 to $6 \times 10^6 \text{ km}^3$ at present. On average, pore space within this volume probably contains between 1% and 10% gas hydrate. This implies that present-day oceanic gas hydrates hold somewhere between 1,000 and 22,000 Gt of carbon ($\text{Gt} = 10^{15} \text{ g}$) as methane (Dickens, 2001), with most but not all current literature typically suggesting about 10,000 Gt of carbon (cf. Kvenvolden, 1999; Milkov et al., 2003). Not included in these estimates are amounts of carbon stored in dissolved gas or in free gas bubbles beneath gas hydrate, which have not been assessed rigorously. Whatever the total, these amounts are enormous considering that the atmosphere contains about 700 Gt C, and the entire standing-stock of the terrestrial biosphere only accounts for about 500–1,000 Gt C.

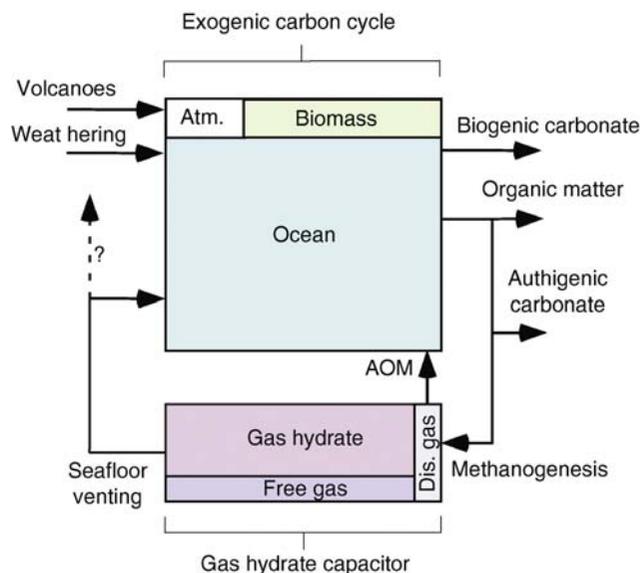

Figure M20 A basic, steady-state view of the exogenic global carbon cycle (ocean, atmosphere and biomass) with postulated connections to gas hydrates and free gas (after Dickens, 2003).

A dynamic view and a large capacitor

Oceanic gas hydrates and associated free gas constitute a major pool of ^{13}C -depleted methane intimately connected to the global carbon cycle (Figure M20). This view can be understood by considering individual deposits of gas hydrate and free gas in marine sediment as dynamic systems where carbon cycles between the ocean, sediments, dissolved gas, gas hydrate and free gas over time (Figure M19).

Photosynthetic organisms in surface waters produce complex organic molecules, which eventually sink through the water column to the seafloor. Within the sediment, bacteria utilize dissolved oxygen, nitrate, and sulfate to convert this organic matter to a series of products including carbon dioxide and acetate. Other microbes, probably archaea, use these simple carbon-based compounds to generate methane (e.g., Marchesi et al., 2001). This dissolved gas migrates both laterally and vertically via diffusion and fluid flow. Eventually, at sufficiently high gas concentrations and appropriate pressure and temperature conditions, gas hydrate can precipitate in pore space. Sediment burial over time slowly brings these solid methane-bearing molecules to higher temperatures. At some relatively shallow depth in the sediment column, gas hydrate is no longer stable and dissociates to gas-saturated water and free CH_4 gas bubbles.

Although much of the methane released from gas hydrate at depth migrates upward to recycle through the above processes, some quantity escapes these systems through one of two pathways. In many places, upward moving methane encounters sulfate diffusing down from the seafloor. This leads to anaerobic oxidation of methane (AOM), a biochemical reaction whereby consortia of archaea and bacteria convert methane to bicarbonate ion across a sulfate/methane transition (SMT) (e.g., Boetius et al., 2000). The SMT often occurs in the first 40 m below the seafloor (D'Hondt et al., 2002). However, in a few places with gas hydrate, notably where faults extend from the seafloor to depths below the GHSZ, high rates of fluid flow along conduits discharge methane into deep waters of the ocean. Aerobic oxidation of methane by bacteria probably consumes most of this methane in the water column (Valentine et al., 2001).

Pressure and temperature affect the location and fluxes of methane cycling within these dynamic carbon pools. As such, gas hydrate systems may serve as a large “capacitor” in the global carbon cycle, with relatively steady carbon inputs but highly variable carbon outputs (Dickens, 2003). The burial and degradation of organic carbon slowly contributes methane carbon to gas hydrate systems over time. At steady-state conditions, AOM and seafloor methane venting also slowly return methane carbon to the ocean. However, the rates of venting could change, perhaps dramatically, when deep ocean temperatures or sea level vary. Consider, for example, a modest rise in seafloor temperatures along continental margins from 0°C to 5°C (Figure M18). Once propagated into sediment, this perturbation would significantly shrink the global GHSZ, dissociating large amounts of gas hydrate to free gas bubbles. The build-up of free gas within sediment would lead to local pressures that exceed those from overlying water and, in some cases, overlying sediment. Such overpressure might cause sediment failure and rapid release of methane from the seafloor to the ocean or atmosphere through slumping or venting (Figure M21).

The capacitor concept is crucial for understanding gas hydrates throughout time in three regards (Dickens, 2003). First, widely accepted models for the global carbon cycle do not contain gas hydrates and methane fluxes to and from the seafloor. Nonetheless, these models may reasonably portray the fundamental operation of the carbon cycle when methane carbon inputs and outputs are small and roughly balanced, which is probably the case at present. Second, a capacitor allows for the production, storage and release of methane. Since sedimentary rocks show that organic carbon has accumulated in relatively cold deep waters ($<15^\circ\text{C}$) over significant intervals

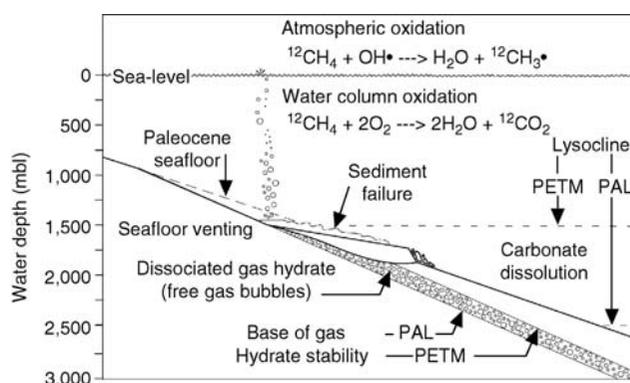

Figure M21 Schematic diagram highlighting the gas hydrate dissociation hypothesis for the Paleocene/Eocene boundary (modified from Katz et al., 1999). Large quantities of gas hydrate convert to free gas bubbles, which escape through sediment slumping (shown here) or venting to produce ^{13}C -depleted carbon dioxide in either the ocean or atmosphere.

of the geological record, presumably gas hydrates and free gas bubbles have always been a common phenomenon. Third, a capacitor allows for major injections of ^{13}C -depleted carbon to the ocean or atmosphere when external conditions change.

Potential climatic effects of seafloor methane release

Massive release of methane from marine gas hydrate systems to the atmosphere could significantly impact climate and the environment (Paull et al., 1991; Kvenvolden, 1999). Methane is a greenhouse gas with a much higher warming potential than carbon dioxide. Although methane molecules have a fairly short lifetime in the present-day atmosphere (about 10 years on average), this residence time depends strongly on atmospheric concentrations of methane and other species. Additionally, methane removal in the atmosphere eventually produces carbon dioxide. Consequently, a large transfer of methane from gas hydrate systems to the atmosphere could have a profound and lasting effect on earth surface temperatures (Schmidt and Shindell, 2003).

Microbes in the water column rapidly oxidize most methane venting above modern gas hydrate systems (Valentine et al., 2001). Therefore, direct injection of methane from gas hydrates to the atmosphere presents a conceptual problem (Kvenvolden, 1999). Conceivably, methane could escape oxidation if it was released sufficiently fast or if bubbles were coated with hydrate (Heeschen et al., 2003). Dislodged gas hydrate could also float toward the surface (Paull et al., 2002).

Substantial release of methane to the ocean could also affect the marine environment, primarily by changing the chemistry of deep ocean water (Dickens, 2000). Microbial oxidation of methane removes dissolved oxygen and produces carbon dioxide (Valentine et al., 2001), which decreases pH upon reaction with water, to form carbonic acid. In turn, increased acidity dissolves calcium carbonate, a common constituent of marine shells and seafloor sediment.

Irrespective of whether methane oxidation occurred in the atmosphere or ocean, its ultimate fate would be production of carbon dioxide, which could propagate throughout the ocean, atmosphere and terrestrial biomass. Consequently, a massive release of ^{13}C -depleted methane would decrease the $^{13}\text{C}/^{12}\text{C}$ ratio of all carbon upon the Earth's surface (Dickens, 2000).

Ancient methane release

Events of extreme environmental change punctuate Earth's history. Across some of these aberrations, the $^{13}\text{C}/^{12}\text{C}$ ratio of calcium carbonate and organic matter decreased at multiple locations, suggesting a major and rapid input of ^{13}C -depleted carbon to the atmosphere or ocean. Over the last 500 million years, such intervals include the Permian/Triassic boundary ca. 252 million years ago (Ma), several episodes in the Jurassic through middle Cretaceous ca. 183–120 Ma, and the Paleocene/Eocene boundary ca. 55 Ma. Increasingly, Earth scientists have argued that these abrupt geochemical anomalies signify massive release of methane from marine gas hydrate systems (e.g., Katz et al., 1999; Hesselbo et al., 2000; Beerling et al., 2002; Berner, 2002).

Of these events, the Paleocene/Eocene boundary (see *Paleocene-Eocene thermal maximum*, this volume) warrants special attention because evidence for massive methane release is compelling. First, unlike older intervals, stratigraphic relationships unequivocally demonstrate that the carbon isotope perturbation was global and rapid. At least 40 different stable isotope records, constructed using deep and shallow marine carbonate, and terrestrial carbonate and organic matter, now show a prominent drop in the $^{13}\text{C}/^{12}\text{C}$ ratio across the Paleocene/Eocene boundary (e.g., Katz et al., 1999; Bowen et al., 2002; Zachos et al., 2001). In records from open-ocean locations (Figure M22), the initial decrease occurs over 10–40 cm while the return to near initial values occurs over 100–400 cm, depending on sedimentation rate. The exact shape and timing of the carbon isotope excursion remain open issues, even at the same location. Nevertheless, on the basis of different dating methods (see Dickens, 2003), its decrease and return spanned <20 kyr and <220 kyr, respectively. Given the abruptness of this change, only methane release from the seafloor provides a satisfactory explanation for the very large drop in carbon isotope ratios (Dickens, 2003). Arguments for a comet impact (Kent et al.,

2003), while interesting, have little merit (Dickens and Francis, 2004; Schmitz et al., 2004).

Ancillary information from sediment cores across the Paleocene/Eocene boundary further supports a massive release of methane from gas hydrate systems. The $^{18}\text{O}/^{16}\text{O}$ ratio of carbonate shells precipitated by benthic foraminifera living on the seafloor also decreased significantly at this time (e.g., Katz et al., 1999; Zachos et al., 2001). This change suggests a major rise in deep ocean temperatures, perhaps upwards of 6°C , which would affect the distribution of gas hydrate dramatically (Figure M18 and M21). Deep marine sediment sequences furthermore display clear evidence for a substantial drop in dissolved oxygen and pronounced dissolution of calcium carbonate (e.g., Katz et al., 1999). In addition, these observations appear to coincide with unusual slumping along continental margins (Katz et al., 1999).

The cause and effects of presumed methane release during the Paleocene/Eocene boundary remain open issues, in large part because of intrinsic difficulties distinguishing the relative timing of rapid environmental changes in 55 million year old strata. However, all of the above observations closely correlate with a prominent benthic foraminifera extinction (e.g., Katz et al., 1999), extreme global warming (e.g., Zachos et al., 2001), and an extraordinary diversification of terrestrial mammals (e.g., Bowen et al., 2002).

Methane venting in the Quaternary

Major fluctuations in polar ice volume caused sea level to fall by greater than 100 m several times during the last few hundred thousand years. Several papers have speculated that these sea level drops may have released substantial quantities of methane from oceanic gas hydrate systems because of a decrease in the pressure within seafloor sediment (e.g., Kayen and Lee, 1991; Paull et al., 1991). If this idea is correct, methane must have come from sediment in shallow water depths or through other geological processes (e.g., sediment slumping) because the GHSZ would remain relatively unchanged at deeper water depths (Figure M18 and M21). A general correlation seems to exist between known locations of gas hydrate and sediment slumps formed during sea level low stands (e.g., Kennett et al., 2002). However, there is little if any ancillary data (e.g., carbon isotope deviations) to suggest that changes in sea level induce significant variations in global methane outgassing from deep marine sediment.

Climate records for the late Quaternary also indicate numerous brief atmospheric warming events that occurred during glacial times and that probably reflect some combination of changing ocean circulation patterns and elevated greenhouse gas concentrations. Notably, these “interstadial” events corresponded to prominent highs in atmospheric methane. Most literature has attributed the methane peaks to increased emissions from terrestrial wetlands (e.g., Severinghaus and Brook, 1999), although there is limited evidence in the geological record for their contemporaneous and requisite existence (Kennett et al., 2002). On the other hand, several lines of evidence suggest that water at intermediate depths in the ocean rose by several degrees centigrade prior to the atmospheric warming events. Recent papers have thus argued that these increases in bottom water temperature would propagate heat into sediment, dissociate gas hydrate to free gas, and release methane to the ocean and atmosphere through sediment failure (e.g., Kennett et al., 2002). Sediment records from the California margin provide some support for this interpretation. Immediately after episodes

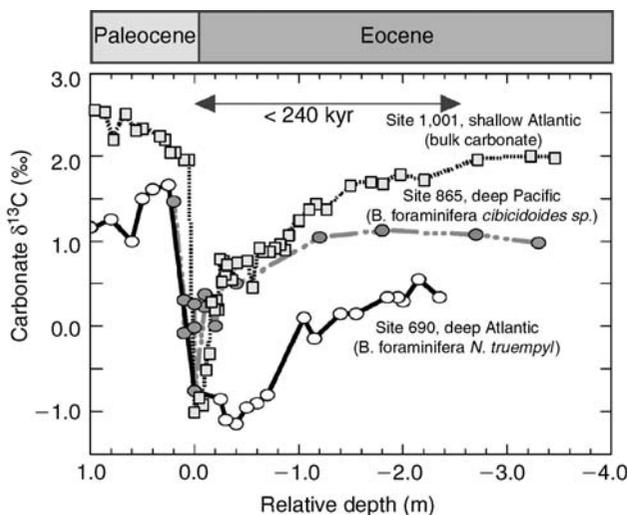

Figure M22 Carbon isotope records across the Paleocene/Eocene boundary in different phases at three deep-sea locations (see Dickens, 2003). Original records have been placed on a common depth scale with the carbon isotope minimum at 0.0 m. Note that the sedimentation rates vary between sites, giving different shapes to the excursion. Carbon isotopes are expressed in conventional delta notation ($\delta^{13}\text{C}$) so that negative values signify a drop in the $^{13}\text{C}/^{12}\text{C}$ ratio.

of intermediate water warming in the Santa Barbara Basin, the $^{13}\text{C}/^{12}\text{C}$ ratio of benthic foraminifera decreased (Kennett et al., 2000), and the abundance of organic compounds produced by methane-consuming bacteria increased (Hinrichs et al., 2003). To date, however, no compelling evidence has been provided to suggest that methane released from the seafloor during interstadial events escaped microbial consumption in the water column, or that atmospheric methane in fact initiated climate change.

Conclusions

A large although unconstrained mass of ^{13}C -depleted hydrocarbons, mostly methane, exists as crystalline gas hydrates and free gas bubbles along modern continental margins. Although specimens of massive gas hydrate can be recovered from the seafloor, the bulk of methane in these phases lies dispersed within the upper few hundreds of meter of sediment. Most methane in gas hydrates and free gas escapes collection during conventional sediment recovery, but can be detected through various proxy techniques. All information indicates that the overall distribution of methane depends on carbon fluxes to and from the ocean, and external conditions such as pressure and temperature. In all likelihood, gas hydrates have occurred throughout most of geological time. An open issue is whether gas hydrate systems can suddenly discharge large amounts of methane. If this is the case, rapid methane release could impact the environment by contributing to atmospheric warming or by changing ocean chemistry. A burgeoning body of literature suggests that methane released from gas hydrate systems explains unusual observations during certain intervals of extreme environmental change in the ancient geological record, such as the Paleocene/Eocene boundary. The idea that methane contributes significantly to changes in Quaternary climate is more controversial but has some support.

MID-PLIOCENE WARMING

The middle Pliocene is the most recent period in Earth history with temperatures as warm as those we expect the Earth to experience by the latter part of the 21st Century. Estimates of middle Pliocene warming are from 2.0 °C to 3.2 °C (Figure M23), placing them in the range of the Intergovernmental Panel on Climate Change (IPCC) projections of global temperature rise by the year 2100. Yet, in many respects, the mid-Pliocene is very much like the

modern world. Terrestrial geography and ocean basin configuration are largely unchanged, many floral and faunal species are still extant, and altered internal and external forcings (e.g., mid-ocean ridge spreading rates, solar luminosity) are not factors as they would have been for much more ancient periods. While most scientists are confident that we have identified the primary forcings triggering the present warming trend, no one is certain of the ultimate climate impact of those forcings, or their associated feedback processes. The middle Pliocene presents us with somewhat the reverse situation: extensive global data reveal the mature state of a warmer world, essentially the resulting climate impact of a prior global warming. The forcings that led to Pliocene warming may be only partially identified, but in both the mid-Pliocene and the present day, the myriad of feedbacks that exist between the forcing triggers and their eventual impacts remain the topic of extensive research.

Data collection, process studies, and numerical simulations, all of which provide both validation and predictive capacity, are targeted at narrowing estimates of climate change. The middle Pliocene world provides an excellent paleo-laboratory for testing the sensitivity of the physical models that we rely upon for estimating future warming impacts. It challenges our understanding of the sensitivity of key components of the climate system and how we simulate that system: polar vs. tropical sensitivity, the role of ocean circulation in a warming climate, the hydrological impact of altered storm tracks, and the regional

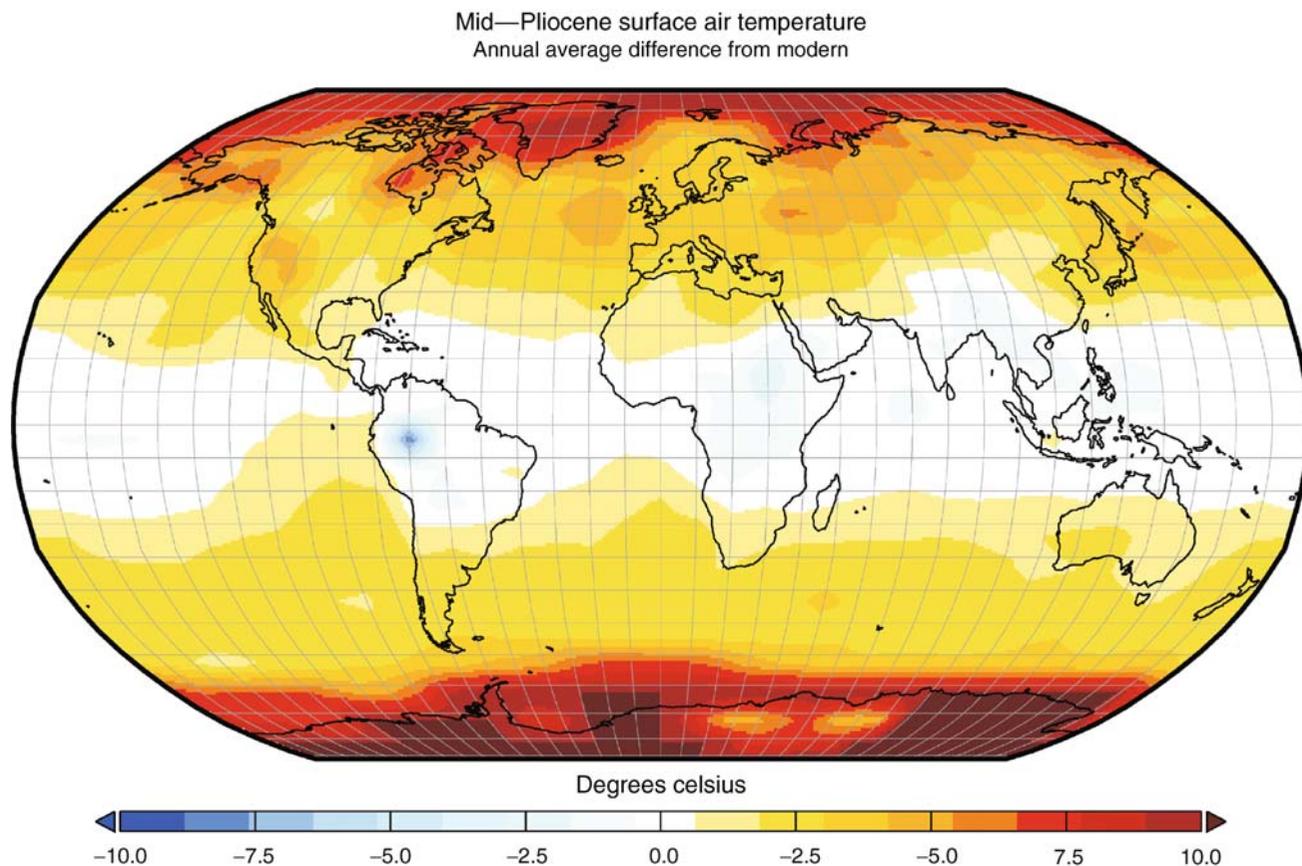

Figure M23 Simulations of mid-Pliocene surface air temperatures show that the Earth was more than 2 °C warmer than during the mid 20th century. Warming was greatest in high latitudes, particularly in regions where land and sea ice extent were lower. Slight cooling in some regions results from increased elevation, or increased standing water in the case of the Amazon River basin.

climate impacts of modified atmospheric and oceanic energy transport systems.

Issues in middle Pliocene warming

The interpretation of a mid-Pliocene global warming, where temperatures were significantly higher than modern, is supported by both terrestrial and marine paleoclimate proxies (e.g., Dowsett et al., 1996; Dowsett et al., 1999; Haywood et al., 2005; Thompson, 1991; Thompson, 1992; Thompson and Fleming, 1996; Wara et al., 2005). Marine microfaunal evidence suggests that warming was greatest at high latitudes (Dowsett et al., 1996), resulting in a reduced equator-to-pole temperature gradient and tropical oceans that were, in the end, far less sensitive to change. Estimates of paleo-CO₂ levels including analyses of the stomatal density of fossil leaves (Kürschner et al., 1996; vanderBurgh et al., 1993), analyses of $\delta^{13}\text{C}$ ratios of marine organic carbon (Raymo and Rau, 1992), and measurements of differences between the carbon isotope composition of surface and deep waters (Shackleton et al., 1992) all suggest an elevation of atmospheric CO₂ of roughly 60–100 ppmv above pre-industrial concentrations. Present-day atmospheric CO₂ levels are close to 384 ppmv (in 2008) and are, therefore, within the envelope predicted to have existed during the middle Pliocene (360–400 ppmv). Increases in additional greenhouse gases, such as methane, may have accompanied the CO₂ increase during the Pliocene. However, an open question is whether the middle Pliocene climate represents the lag effect of modest greenhouse warming, revealing how the oceans and ice-sheets integrate, redistribute, and even amplify climate impacts through longer-term feedback mechanisms (i.e., ocean circulation, sea level rise, permafrost melting, etc.).

Paleoclimate modeling studies have suggested that the middle Pliocene pattern of warmer sea surface temperatures and surface air temperatures is more consistent with enhanced ocean heat transports than with a simple increase in the atmospheric CO₂ level (Figure M24) because low latitude regions

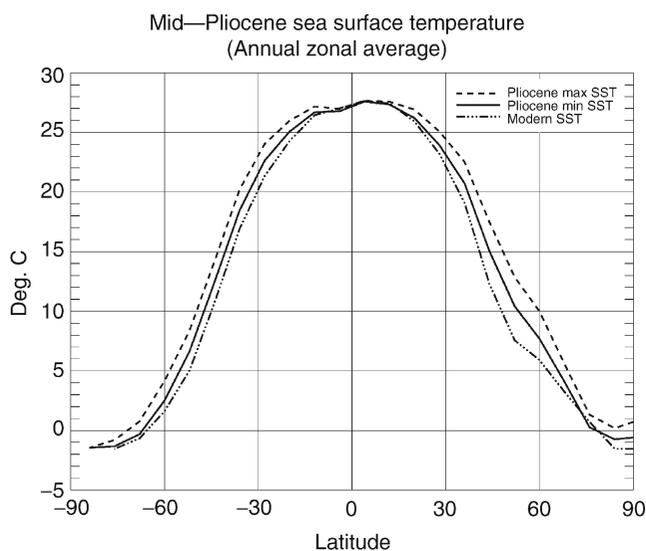

Figure M24 Modern and middle Pliocene sea surface temperatures show no significant difference in the tropics, in contrast to mid and high latitude regions, suggesting a role for altered ocean heat transports in surface warming.

show such limited warming compared to high latitudes. However, there is some disagreement between proxy records of tropical temperatures, particularly in the Pacific Ocean. Several recent studies using Mg/Ca ratios and alkenones find that the eastern equatorial Pacific may have been warmer than previously thought. These findings are somewhat more consistent with moderately increased greenhouse gas levels, and have been used to suggest that the middle Pliocene warming may have been characterized by a tropical sea-surface temperature pattern that is akin to a permanent El Niño. Although no study has yet determined a specific set of forcings and feedbacks that were responsible for triggering changes in ocean circulation during the Pliocene, data suggest that a combination of increased greenhouse gases and altered ocean heat transports, and perhaps additional factors, acted concurrently (linked by feedback relationships) to generate the middle Pliocene warming (e.g., Dowsett et al., 1996; Raymo et al., 1996).

Enhanced ocean heat transports may have been the result of strengthened thermohaline circulation (THC) and/or increased flow of surface ocean currents. The latter process has not been widely accepted, since generating enhanced wind stress under a regime of reduced latitudinal temperature gradients and a decreased dynamic circulation of the atmosphere is difficult (Crowley, 1996). Recently, however, Haywood et al. (2000) showed that regionally enhanced wind stress fields over the North Atlantic, North Pacific and Southern Ocean occur in middle Pliocene experiments using the Hadley Centre's General Circulation Model (GCM). Such regional increases may be sufficient to strengthen the gyre circulations in these ocean basins and cause an increase in meridional heat transport. Moreover, greater wind stress curl and consequent gyre strengthening in the North Pacific is supported by paleoceanographic evidence along the California margin (Ravelo et al., 1997).

Other factors must also be considered. Surface conditions in the middle Pliocene were somewhat different from present-day: vegetation distributions were altered (Thompson and Fleming, 1996) and sea level was probably around 15–25 meters higher than modern (e.g., Dowsett and Cronin, 1990). In addition, both the Greenland and Antarctic Ice Sheets were probably smaller (though the size of the Antarctic Ice Sheet remains a key Pliocene controversy), and topographic relief may not have reached modern proportions in the Western Cordillera, the East African Rift region and on the Tibetan Plateau (Raymo et al., 1988; Ruddiman and Kutzbach, 1989; Raymo and Ruddiman, 1992).

Middle Pliocene warming and estimates of future climate change

Despite these differences, the middle Pliocene displays more similarities with our anticipated future climate than almost any other period in Earth history. Foremost among these is the magnitude of warming in the middle Pliocene, which is similar to future global climate change simulations at high latitudes and over mid-latitude continental interiors. If forcings and associated feedbacks are proportional to the ultimate climate impacts, then the middle Pliocene is probably closer to what we can expect from future global warming than are the warm climates of the Holocene or Pleistocene interglacials. The potential to use the middle Pliocene as an analogue for future climate change is also reinforced by the fact that many key boundary conditions, such as the position of the continents, vegetation types and the intact state of the isthmus of Panama, were the same as or similar to those of the present day (Crowley, 1991; Crowley, 1996; Maier-Reimer et al.,

1990). The opportunity to conduct detailed data-model comparisons is also excellent as there is:

1. Abundant paleoclimatic information from both the marine and terrestrial realm (relative to older time periods);
2. A large number of extant species, making micropaleontologically-based climate interpretations feasible;
3. A reduced chance that diagenesis will hamper geochemical analyses and more precise dating of proxy data, and thus more precise validation of equilibrium GCM simulations (Chandler et al., 1994).

The ability to use numerical climate model simulations to study this past global warming is also greatly enhanced by the development of the PRISM (Pliocene Research, Interpretation and Synoptic Mapping) series of quantitative digital data sets produced by the United States Geological Survey since 1992. The ocean surface maps were updated using data from more than 170 sites worldwide, and are available as the PRISM2 data set of middle Pliocene conditions (Dowsett et al., 1999). Efforts are now underway to extend the PRISM data to include 3-dimensional temperature data for the mid-Pliocene oceans. These data are designed specifically for use in paleoclimate modeling studies utilizing GCMs. As such, the PRISM2 reconstruction represents the most detailed global paleoclimate reconstruction for any time other than the Last Glacial Maximum (21 ky BP), and the *only* major reconstruction of a globally warmer time period.

MILLENNIAL CLIMATE VARIABILITY

Introduction

One of the most puzzling features of Earth's past climate is a series of strikingly abrupt and robust variations that occur roughly every 1,000–7,000 years. First recognized in temperature records from Greenland ice cores and North Atlantic deep-sea sediments, these millennial climate cycles are now known to have a global or nearly global footprint, and they have been found in records spanning at least the last half million years. Paleoclimate records reveal at least four modes of millennial climate change: Heinrich events, Bond cycles, and Dansgaard/Oeschger cycles that occur exclusively within glacials, and unnamed persistent cycles that punctuate both glacials and interglacials. (*Note that the term cycle, as used here, refers to a repeating process that is not necessarily periodic.*)

Records of millennial climate variations have drawn widespread attention because they produced the first convincing evidence that Earth's climate system is much less stable than once thought and can shift suddenly on human time scales. The millennial cycles typically exhibit threshold behavior; i.e., abrupt transitions from one mode of operation to another during which temperature changes of several degrees Celsius occur within decades if not years. Although these striking temperature jumps appear to have taken place predominantly during glaciations, results of some modeling experiments imply that they might be induced in the near future by continued global warming. Even though the likelihood of that happening might be low, the impact on society is potentially so severe that understanding why the climate system is prone

to such behavior has become a high priority. Yet after more than two decades of research, the underlying mechanisms remain elusive.

Millennial climate cycles: history and description

Heinrich events

Heinrich (1988) was the first to recognize that glacial sediments in a deep-sea core from the Dreizack Seamount (Figure M25) were punctuated by six distinct layers demarking brief ($\leq 1,000$ years) episodes of extreme ocean surface cooling, dramatic reductions in abundances of planktic foraminifera, depletions in planktic $\delta^{18}\text{O}$, and exceptionally large increases in IRD (ice-rafted debris) produced by melting of armadas of debris-laden icebergs discharged into the subpolar North Atlantic. Later, these six episodes were named Heinrich events by Broecker et al., (1992).

Building on Heinrich's discoveries, Bond et al. (1992, 1993) demonstrated that IRD maxima and the strong depletions in $\delta^{18}\text{O}$ in the six Heinrich events (H1–H6) occurred suddenly at the end of cooling ramps containing bundles of progressively colder Dansgaard/Oeschger (D/O) cycles (Figure M26a–e). The cooling ramps were followed abruptly by an unusually large warming that raised sea surface temperatures by several degrees Celsius to nearly Holocene values. Cores containing these features extend from the Labrador Sea eastward across the entire North Atlantic between latitudes of about 40°N and 55°N , the so called IRD belt (Figure M25). Petrologic and geochemical tracers in the IRD point to sources of the massive Heinrich iceberg discharges in eastern Canada, probably in the Hudson Strait region.

Heinrich events are sometimes defined as corresponding to the full range of the increases in IRD. Detailed analyses of the anatomy of Heinrich layers, however, demonstrate that the initial increase in IRD does not contain tracers linked to Hudson Strait sources. To avoid confusion over the age of Heinrich events the term should apply only to layers rich in IRD derived mainly from eastern Canada. For an excellent summary of Heinrich events see Hemming (2004) and this volume (*Heinrich events*).

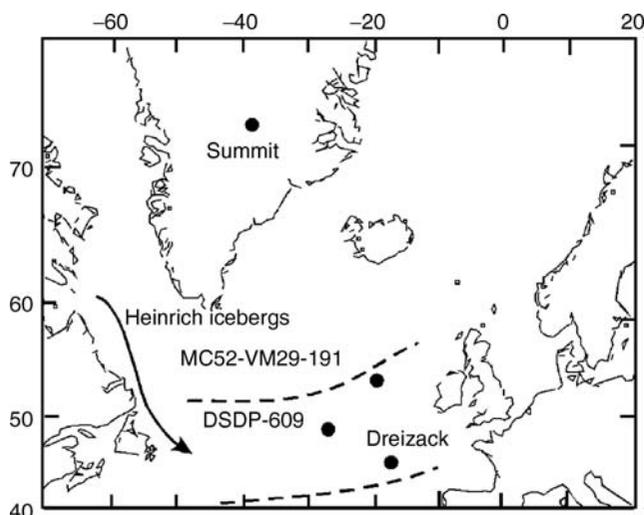

Figure M25 Locations of cores mentioned in text and location of the Ruddimann IRD belt (dashed lines).

Bond cycles

Named by Broecker (1994), a Bond cycle, first identified in Greenland ice cores and North Atlantic temperature records, begins with the post-Heinrich event warming, followed by a gradual cooling ramp that contains a bundling of progressively colder D/O cycles, and then ends abruptly at the peak cooling of the next Heinrich event (Figure M26a,b). The atmosphere and ocean surface temperature drop over the course of a Bond cycle is a few to several degrees Celsius. IRD concentrations in North Atlantic sediments follow this pattern, with short cycles of progressively larger amplitude, probably correlative with D/O cycles, developing as temperatures decrease (Figure M26c).

The shapes of Bond cycles were the basis for correlating temperature records from Greenland ice cores and North Atlantic deep-sea sediments over the entire last glacial cycle (Figure M26a,b). The correlation documented for the first time the relation between D/O cycles in the ice cores and Heinrich events in the ocean.

D/O cycles

The typical evolution of these abrupt events, also named by Broecker (1994), begins with a rapid ocean surface and atmospheric warming, completed usually within a few decades, followed by gradual cooling over a few hundred years, and a distinct cold phase afterwards for a few centuries to a millennium (Figure M26a). Approximately 23 D/O oscillations occurred during the last glacial cycle. The well-known Younger Dryas (YD) event is the last of these and was followed abruptly by the onset of the present interglacial or Holocene (Figure M26a). A recent revision of ice core temperature calibration suggests that the YD ended with a remarkable atmospheric warming of 10°C in decades or less (Grachev and Severinghaus, 2005).

Within the D/O stadials that terminate Bond cycles, the large IRD peaks of Heinrich events are confined to the last few hundred years, suggesting that the massive discharges of Heinrich icebergs came after several hundred years of cold temperatures (Bond et al., 1993). Cold phases of the other D/O cycles also contain peaks in the concentrations of IRD, although they are not as large as those during Heinrich events (Figure M26c). The sources of IRD in D/O cycles are diverse, including Europe, east Greenland, and Iceland (Hemming, 2004). Percentages of detrital carbonate remain low during the cold phases of D/O cycles (Figure M26d), suggesting that, in contrast to Heinrich events, sources in eastern Canada were not important.

Persistent multi-century to millennial cycles

High-resolution measurements of two IRD grain types, hematite-stained grains derived from red bed deposits and fresh volcanic glass derived from Iceland and or Juan Mayen have revealed robust oscillations that do not follow the D/O cycle pattern, but instead punctuate both cold and warm phases of those cycles (Figure M26f). Surprisingly, these persist across the glacial-interglacial transition and continue through the entire Holocene (Bond et al., 2001). The pacing of the cycles is highly irregular, varying from about 900 years to about 2,000 years. The petrologic changes are thought to reflect repeated southward advections of cooler waters carrying ice with debris rich in the two grain types from the polar seas north of Iceland. These shorter cycles are sometimes incorrectly called Bond cycles.

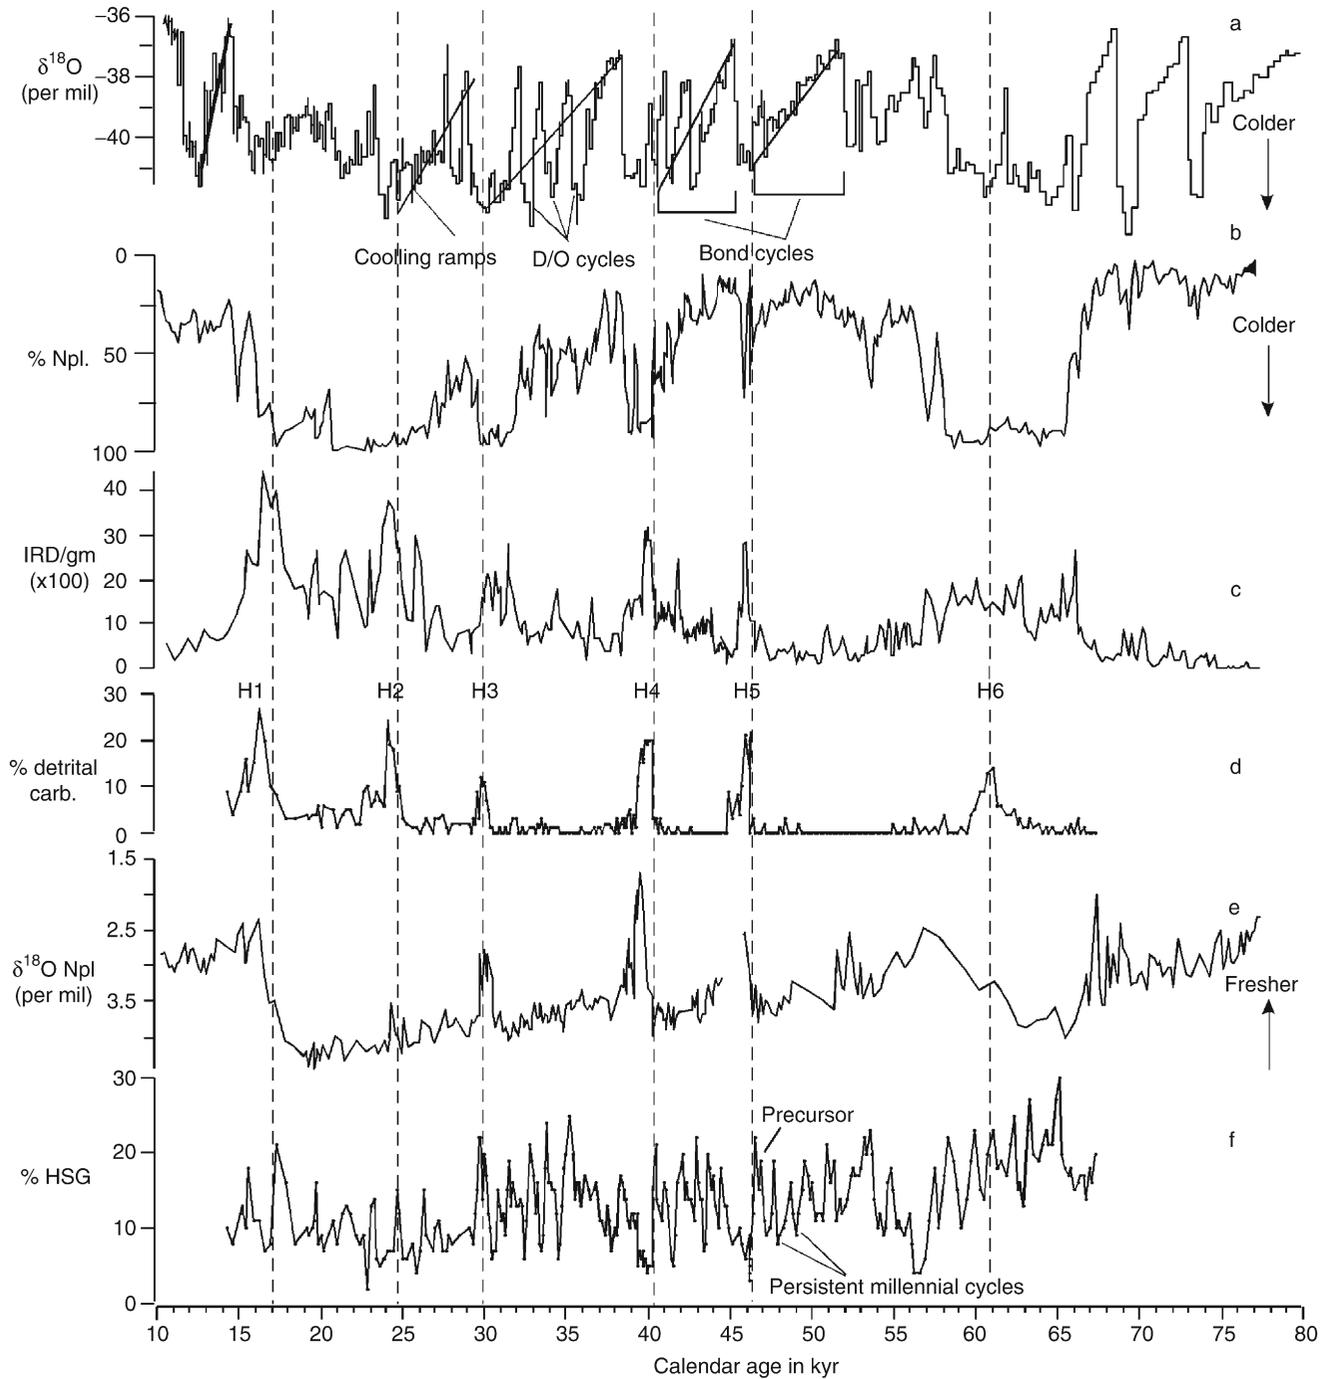

Figure M26 (a) Records from GISP2 ice core, and (b–f) DSDP 609. *Npl.*, *N. pachyderma* (s.); *HSG*, hematite-stained grains; *H*, Heinrich event. Dashed lines mark boundaries between increases in detrital carbonate (Heinrich events) and precursory events as defined by *HSG* record. See text for discussion (modified from Bond et al., 1999).

At least some of these persistent oscillations also occur in the Greenland ice core records where subtle variations in $\delta^{18}\text{O}$ and in estimates of temperature punctuate many of the stadial and interstadial intervals of D/O cycles (North Greenland Ice Core Project members, 2004; Landais et al., 2004). Prominent depletions in $\delta^{18}\text{O}$ also are present in early Holocene ice at about 11,300, 10,900, 10,300, 9,300, 8,200 years.

Global distribution of millennial variations

Heinrich events, Bond cycles and D/O cycles have now been found in climate records far from the North Atlantic where they were first identified. Voelker (2002) compiled evidence that revealed their presence in both hemispheres extending from high polar latitudes to the tropics. The best records, however,

are from stalagmite deposits, which can be dated accurately with uranium-thorium methods, and from ice cores whose chronology is constrained in part by layer counting. A map of the stalagmite and ice core sites (Figure M27) documents the global footprint of these three types of millennial variations. Outside of the North Atlantic the imprint of the persistent millennial cycles has been found in late Holocene sediments from the Cariaco Basin off Venezuela, in Holocene lake records from Ecuador, in glacial-Holocene loess deposits from the Mississippi Valley, China and Tibet, in tree ring records from Finland, and in a stalagmite record from Yemen.

Mechanisms

Oscillatory ice sheet dynamics

Although no consensus has been reached on the cause of millennial climate variability, one widely held view maintains that the fundamental mechanism arises from oscillatory internal dynamics of glaciers flowing into the northern North Atlantic. Recurring surges or collapses of those glaciers are thought to have caused

repeated and rapid increases in the flux of icebergs (i.e., freshwater) into the ocean. Upon reaching the convecting regions north and south of Iceland, the freshwater injections are presumed to have lowered ocean surface salinities enough to force ocean circulation across a threshold, induce a hysteresis behavior, and abruptly reduce or shut down North Atlantic Deep Water (NADW) formation (Ganopolski and Rahmstorf, 2001). Models of this process have shown that a shutdown of NADW production triggers a precipitous drop in ocean surface temperature that is broadly consistent with paleotemperature data.

To explain the oscillatory dynamics, MacAyeal (1993) proposed a free oscillation mechanism that has come to be known as the binge-purge model. A large glacier or ice sheet frozen to bedrock will slowly build up during the binge phase. The purge phase (i.e., the Heinrich event) occurs when geothermal heat melts the basal sediment and produces a lubricated discharge pathway. The model produced massive collapses of the ice every 7,000 years, agreeing reasonably well with the observed timing of Heinrich events. In a more elaborate development of the model, Greve and MacAyeal (1996) found that free oscillations from 1,000 to 10,000 years could occur within a large ice sheet, thereby potentially providing an explanation for both Heinrich events and the faster-paced D/O cycles.

Climate-centered mechanisms

The elegant glacier-centered hypothesis was called into question, however, by the results of efforts to test two of its corollaries. If the hypothesis were correct, the IRD increases in both Heinrich events and D/O cycles should occur at the same time as, or slightly lead, the ocean-climate response, and synchronicity of discharges from different glaciers would be unlikely owing to the vagaries of internal glacier dynamics. Instead, it was found in high-resolution North Atlantic records that the onset of ocean surface coolings actually preceded, by at least several hundred years, the IRD increases, and that the IRD in D/O cycles discharged from different glaciers at the same time (Bond et al., 1999; Hemming, 2004). Moreover, each Heinrich event appeared to have been immediately preceded by an increase in IRD (precursory events) whose composition recorded the same simultaneous discharges of icebergs from different sources that were found in D/O cycles (e.g., Figure M26c,f).

Those findings raised the specter of the chicken or egg problem. The lead of ocean surface coolings and the synchronous IRD discharges from different glaciers during D/O events seemed best explained by the effects of a climate-ocean mechanism that operated upon glaciers flowing into the North Atlantic. The observation of D/O-like IRD discharges immediately preceding each Heinrich event implied that even Heinrich events were triggered by the same climate mechanism. Attempts to identify the climate triggering mechanism have invoked changes in salinities in the Gulf Stream (Broecker et al., 1990), stochastic resonance (Alley et al., 2001), collapse of an ice shelf in the Labrador Sea (Hulbe et al., 2004), and super El Niños driven by ocean surface salinity changes in the tropical Pacific (Stott et al., 2002). None of these mechanisms, however, has been generally accepted.

The enigmatic 1,470-year cycle

Mayewski et al. (1997) were the first to recognize the presence of a spectral peak in $\delta^{18}\text{O}$ records from Greenland ice cores centered on about 1,470 years. The peak is narrow and statistically significant, suggesting to them that the cycle is truly periodic. Bond

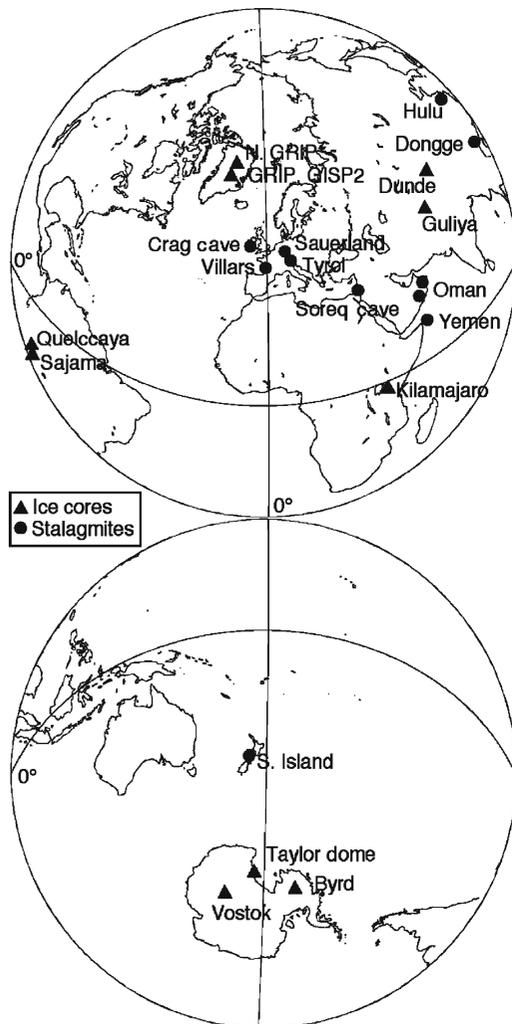

Figure M27 Locations of ice cores and stalagmite records with evidence of Heinrich events, Bond cycles, and D/O cycles.

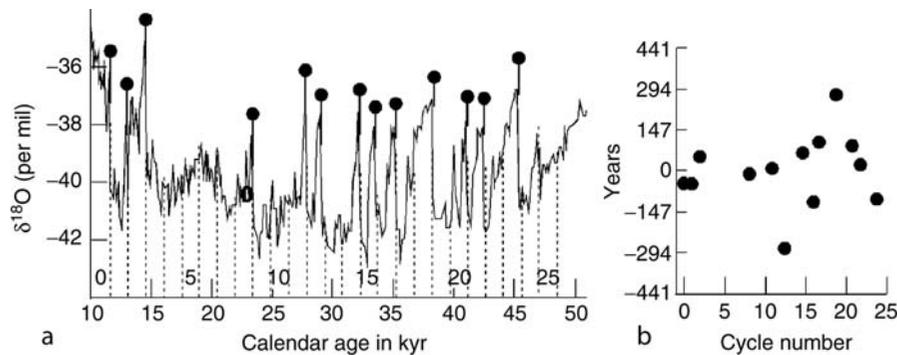

Figure M28 (a) The 1,470-year timing of D/O events from Rahmsdorf (2003). Dashed lines mark out exact 1,470-year intervals. Markers with solid dots denote onset of D/O cycles as defined by warming above a threshold defined by amplitude and range. (b) Deviation in years of onset of D/O cycles from an exact 1,470-year pacing (modified from Rahmsdorf, 2003).

et al., (1997, 1999) found that the pacing of the two petrologic tracers, hematite-stained grains and Icelandic glass, through the last glacial cycle had a mean value of $1,470 \pm 500$ years (1 sigma). Whether the cycle is truly periodic is unclear due to error in the radiocarbon-dated time series. Recently, Rahmstorf (2003), using non-spectral methods, demonstrated that the spacing of D/O cycles in the GISP2 ice core was exactly 1,470 years or even multiples of 1,470 years, thereby clearly tying the D/O oscillations to the 1,470-year cycle (Figure M28). From that finding, Rahmstorf argued that D/O events are discrete events paced by the 1,470-year cycle rather than being discrete cycles themselves.

The cause of the 1,470-year cycle remains a mystery. Rahmstorf (2003) argued that no internal processes in a complex non-linear system such as the Earth's climate system could produce such a regular oscillation, a conclusion supported by results of modeling experiments. He suggested that the cycle might have been produced by orbital variations within the Milankovitch band or by solar forcing.

The Holocene dilemma

Once regarded as a long period of climate stability, it is now clear from ice core, marine, and terrestrial records that the entire 12,000 years of the Holocene is punctuated by a series of robust cycles of millennial duration. The Holocene dilemma arises from evidence that, in many records, these cycles have about the same $\sim 1,500$ -year pacing found in records from the last glacial. In particular, after extending their analyses of the two petrologic tracers, hematite-stained grains and Icelandic glass, to the present, Bond et al. (1999, 2001) found that the Holocene cycle pacing fell within the same range as documented for the glacial record, $1,470 \pm 500$ -years. In addition, the amplitude of the cycles is about the same in both the glacial and Holocene intervals. One interpretation of those findings is that the Holocene and glacial $\sim 1,470$ -year cyclicity was produced by the same mechanism. Given the absence of large glaciers and ice sheets during most of the Holocene, the mechanism could not have been linked to oscillatory ice sheet dynamics. Moreover, the mechanism underlying the cyclicity must have operated independently of the glacial-interglacial climate state. Those arguments have been criticized, however, because the Holocene cycles do not have the precise 1,470-year periodicity of the D/O oscillations (e.g., Schulz and Paul, 2002).

Braun et al. (2005) have proposed an intriguing solution to this problem. Building on evidence in Bond et al. (2001) that the

Holocene cycles may have been forced by variations in solar irradiance, Braun and his colleagues made the remarkable discovery that their climate system model, CLIMBER-2, when forced by the DeVries solar cycle (210 years) and the Gleissberg solar cycle (88 years), can produce robust D/O events with a precise period of 1,470 years under glacial boundary conditions, but not under Holocene boundary conditions. Their surprising results have far-reaching implications for the fundamental mechanisms that underlie abrupt climate change, and they clearly deserve much further investigation and rigorous testing.

Summary

Views on what causes millennial climate variability fall into two camps. One is glacier-centered and assumes that free oscillations in glaciers and ice sheets cause repeated discharges of icebergs into the ocean. The iceberg freshwater injections force recurring changes in the North Atlantic's deep-water circulation that in turn produce a series of robust abrupt climate changes with a global or nearly global footprint. The other is climate-centered and assumes that a climate mechanism of unknown origin forces increases in iceberg discharge either through direct effects on glacier mass balance or through changes in the North Atlantic deep circulation. In this case the glacier activity and its effects on NADW production operates as a non-linear positive feed back that amplifies the climate signal and transmits a series of abrupt climate shifts well beyond the North Atlantic region. Both views have been criticized and neither can fully account for the 1,470-year pacing of the D/O cycles and the presence of similar cycles in the Holocene when the large glaciers and ice sheets were absent.

MINERAL INDICATORS OF PAST CLIMATES

Introduction

A mineral is a naturally occurring crystalline solid created by geological or biogenic processes (e.g., calcite/aragonite in mollusk shells or coral). Minerals that form at or near the Earth's surface are products of chemical weathering, evaporation, authigenic crystallization, and bio-mineralization. They reflect ambient conditions at the Earth-atmosphere interface. Therefore they can furnish important clues about former climates. Minerals are utilized as paleoclimate indicators or proxies in several different ways:

1. To infer past climates and changes over time.
2. To deduce changes in atmospheric composition.
3. As mineralogical “markers” in provenance studies.
4. As “hosts” for climate-sensitive stable isotopes and trace elements.

The most direct mineral indicators or proxies are those that are generated under relatively narrow climatic ranges or within restricted environmental settings. Examples include chemical precipitates such as evaporites, low temperature minerals such as ikaite and hydrohalite, residual soils (iron and aluminum oxyhydroxides, kaolinite), and authigenic minerals (forming *in situ*, e.g., glauconite, berthierine, phillipsite, barite). Evaporite minerals (e.g., gypsum, anhydrite, halite, sylvite) are generally indicative of arid to hyperarid climates. They form in restricted marine basins, narrow rift valleys, coastal lagoons, sabkhas (salt flats), and internally-drained continental interiors, where rates of evaporation exceed rates of water supplied by rivers or rainfall (McLane, 1995; Parrish, 1998; *Evaporites*). The distribution of modern evaporites closely corresponds to the distribution of deserts. In addition, diagnostic of aridity are chemically-resistant minerals like quartz that are concentrated into eolian sand deposits (and ultimately sandstones) by wind transport and deposition. Sedimentary rocks of biogenic origin (e.g., chalks, cherts, phosphorites) provide information on paleotemperatures, productivity, and ocean circulation. Clay minerals derived from chemical weathering of rocks are relevant climate indicators, since they denote prevailing conditions at the time of formation. Kaolinite, for example, although widespread in many soils, is characteristic of tropical weathering, whereas chlorite is usually more abundant in colder regimes, where physical weathering predominates. Changes in composition of marine or lacustrine clays often parallel climate fluctuations (e.g., Mallinson et al., 2003; Robert and Kennett, 1997; Yuretich et al., 1999, see below).

Minerals that are sensitive to oxidation may provide information about past atmospheres. Pyrite and uraninite oxidize and alter rapidly under current atmospheric conditions. Their preservation in detrital grains from 3 billion year old sediments implies much lower atmospheric oxygen than at present (Fleet,

1998; Kirk et al., 2003). The abundance of *banded iron formations* (BIFs) older than 2 billion years also suggests reduced oxygen levels at that time. The accumulation of large BIF deposits required transport of dissolved ferrous iron over long distances, followed by precipitation in locally, more oxygenated environments (see *Banded iron formations and the early atmosphere; Atmospheric evolution, Earth*; McLane, 1995).

Minerals act as markers of provenance in paleoclimate studies. For example, changing pyroxene to amphibole ratios in late Quaternary Nile delta sediments point not only to variations in the relative contributions from the Blue and White Nile tributaries, but also to oscillations in rainfall in the two source areas that are linked to larger-scale climatic changes (Foucault and Stanley, 1989). An important clay mineral tracer is the latitudinally-sensitive kaolinite/chlorite ratio, one of several parameters used to establish an eastern Asian desert source for ice-age dust in the GISP2 (Greenland) ice cores (e.g., Biscaye et al., 1997).

Stable isotopes and trace elements housed in minerals furnish quantitative paleoclimate data. Oxygen isotope ratios in foraminiferal calcite are related to seawater temperatures and global ice volume (see *Stable isotope analysis*). Oxygen and carbon isotope ratio fluctuations in speleothem calcite reflect variability in atmospheric circulation, precipitation patterns, and vegetation cover (Genty et al., 2003; *Speleothems*). Oxygen isotope ratios in marine barite have been attributed to altered redox conditions, changes in continental shelf area, and sea level during the Plio-Pleistocene (Turchyn and Schrag, 2004). Magnesium/calcium and strontium/calcium ratios in foraminiferal calcite are also important paleo-ocean temperature indicators.

Mineral paleoclimate indicators are briefly described below and summarized in Table M1.

Ice

Ice (H₂O), the solid form of water at or below 0 °C and under normal atmospheric pressure, occurs in massive accumulations in polar ice sheets, and also in mountain glaciers, ice shelves, and sea ice (see *Cryosphere*). The lower density of ice (0.92 g cm⁻³) relative to water results from a relatively open crystal lattice, due to H-bonding of H₂O molecules. Ice, although solid, deforms readily under the force of gravity, which sets glaciers into motion.

Because the temperature of the water-ice phase transition lies within the diurnal or seasonal range of many regions, ice is sensitive to climate change on many time scales. The extent of the cryosphere has varied markedly during Quaternary glacial-interglacial cycles. The growth and decay of polar ice sheets can be reconstructed from the distribution of geomorphological features and marine oxygen isotope ratios that record paleosea-level variations (see *Glacial geomorphology, Stable isotope analysis*). Ice cores from Greenland, Antarctica, and mountain glaciers contain important archives of past temperatures and atmospheric trace gases (see *Ice cores, Antarctica and Greenland; Ice cores, mountain glaciers*).

Iron oxides and oxyhydroxides

Hematite

Hematite (α -Fe₂O₃) is a common constituent of sedimentary rocks formed under oxidizing conditions. Hematite occurs in Phanerozoic *ironstones*, iron-rich rocks that also contain goethite, berthierine, and siderite. Ironstones may be deposited in lakes, bogs or coal swamps, or on shallow marine shelves or under semi-arid

Table M1 Mineral indicators

Mineral	Paleoclimatic and/or paleo-environmental significance
<i>Oxides, hydroxyoxides</i>	
Ice	Cryosphere volume, glacial-interglacial cycles
Hematite	Oxic conditions; tropical/semi-tropical/temperate weathering
Goethite	Oxic conditions; tropical/semi-tropical/temperate weathering
Lepidocrocite	Oxic conditions; tropical/semi-tropical/temperate weathering
Maghemite	Magnetostratigraphic dating
Magnetite	Magnetostratigraphic dating
Gibbsite	Component of bauxite; humid, tropical chemical weathering
Boehmite	Component of bauxite; humid, tropical chemical weathering
Birnessite	Component of desert varnish; aridity
<i>Sulfides</i>	
Pyrite	Reducing (anoxic) conditions; low atmospheric O ₂ (as detrital grains)
<i>Halides</i>	
Halite	Evaporite; aridity
Sylvite	Evaporite; aridity
Hydrohalite	Evaporite; low temperature, hypersalinity
Antarcticite (rare)	Evaporite; low temperature, hypersalinity
<i>Carbonates</i>	
Calcite	Paleotemperatures (oxygen isotope, trace element ratios), "calcite seas – greenhouse climates"
Aragonite	Like calcite; "Aragonite seas – Icehouse climates"
Dolomite	Arid, hot-saline lakes, sabkhas
Siderite	Reducing (suboxic-anoxic) conditions
Ikaite (glendonite)	Low temperature, near-freezing
<i>Sulfates, phosphates</i>	
Gypsum	Evaporite; aridity
Anhydrite	Evaporite; aridity
Mirabilite	Evaporite; aridity, hypersalinity, low temperature
Barite	Ocean paleoproductivity
Franconite	Ocean paleoproductivity
<i>Silica minerals</i>	
Quartz	Eolian sand, sandstones – aridity; eolian dust (marine sediments, ice cores) – wind strengths, direction.
Opal, chert	Ocean paleoproductivity
<i>Clay minerals</i>	
Kaolinite	Tropical/semi-tropical chemical weathering
Chlorite	High latitude physical weathering
Sepiolite	Warm, semi-arid to arid climates
Palygorskite	Warm, semi-arid to arid climates
Glauconite	Weakly reducing (suboxic) conditions, low sedimentation rates
Berthierine	Reducing environments
<i>Zeolites</i>	
Analcime	Desert soils, alkaline lakes–aridity
Chabazite	Alkaline lakes; aridity
Phillipsite	Alkaline lakes; aridity
Clinoptilolite	Alkaline lakes; aridity

or seasonally-alternating wet/dry climates (Parrish, 1998). Hematite coats quartz and clay grains, and cements detrital particles in continental *red beds* (iron-stained sandstones, siltstones, and shales). These rocks occur in a variety of geologic settings, including desert sandstones, evaporitic tidal flats, lagoons, and savanna soils. Ferric iron, initially deposited as goethite, gradually transforms into hematite, intensifying the reddish color. The chemical reaction is enhanced by increasing temperature, alkalinity, and dehydration. Although once believed to be an indicator of arid climates, red beds are now thought to develop also in warm

climates with seasonal precipitation (Parrish, 1998; see also *Red beds*, this volume).

Hematite also concentrates within nodular horizons in *ferricrete* – an iron-rich lateritic duricrust (also termed “cuirasse”) that is a product of intense chemical weathering in semi-tropical to tropical climates, with seasonally varying rainfall ($T = 25\text{--}30^\circ\text{C}$, $P = 1,500\text{ mm yr}^{-1}$, $\text{RH} = 65\%$ (Tardy, 1992). Most silicates and even resistant minerals such as quartz are leached out, enriching the soil in residual iron oxides (hematite, goethite), and minor kaolinite.

Hematite-stained quartz and feldspar grains derived from sedimentary red beds have been used as lithologic tracers for late Quaternary to Holocene North Atlantic *ice-rafted debris* (IRD) (Bond et al., 1997). The hematite-stained grains were probably derived from eastern Greenland and Spitsbergen, in contrast to volcanic glass – another lithic tracer – from Iceland or Jan Mayen. Peaks in the record of hematite-coated grains provide a reliable and consistent proxy for estimating the pacing of IRD events.

Hematite, magnetite (Fe_3O_4) and siderite (FeCO_3) alternate with bands of chert (SiO_2) in early Proterozoic *banded iron formations* (BIFs). The accumulation of large BIF deposits implies the transport of soluble iron (as Fe^{2+}), likely derived from submarine volcanic sources, over long distances. Upwelling subsequently brought dissolved iron onto locally more oxygenated, shallow marine shelves, where oxidation of iron and precipitation occurred (McLane, 1995). Since most BIFs are older than 2 billion years, the availability of ferrous iron implies lower atmospheric oxygen levels than at present.

Maghemite

Maghemite ($\gamma\text{-Fe}_2\text{O}_3$) is a magnetic polymorph of hematite (with the same chemical composition, but a different crystal structure). It is a widespread, although minor component of paleosols and loess. Along with magnetite, it carries the magnetic signal employed in magnetostratigraphic dating.

Goethite

Goethite ($\alpha\text{-FeOOH}$) is an *oxyhydroxide*, widely distributed in sedimentary rocks, including ironstones, red beds, and also found in lateritic soils. Upon burial, it dehydrates and inverts to hematite. Lepidocrocite ($\gamma\text{-FeOOH}$), a polymorph of goethite, is also common in soils. Ferrihydrite ($\text{Fe}_2\text{O}_3 \cdot 2\text{FeOOH} \cdot 2.6\text{H}_2\text{O}$) is a poorly crystallized iron oxyhydroxide found in recent soils, sediments, and iron concretions. Since it is metastable, it slowly dehydrates and recrystallizes to goethite or hematite (Evans, 1992).

Magnetite

Magnetite (Fe_3O_4), a di- and tri-valent iron oxide, forms under somewhat more reducing conditions than hematite, in the absence of carbonate or sulfide (McLane, 1995). Magnetite, along with maghemite is the dominant source of magnetic signal in soils or sediments (Maher, 1998). Magnetic susceptibility (the ratio of induced magnetization to the inducing magnetic field) is a measure of the ability of a substance to be magnetized. It is directly proportional to the quantity of strongly magnetic minerals (i.e., magnetite and maghemite) present in loess, paleosols, and marine sediments.

Magnetite formation and soil magnetization increase in well-drained soils overlying Fe-rich source rocks that are exposed to seasonally-varying wet and dry cycles. On the other hand, excessively arid, wet, or acid soils show little magnetic enhancement.

Furthermore, magnetically-enhanced soils show some correlation between maximum soil susceptibility and annual precipitation (Maher, 1998). Thus, paleo-susceptibility values in carefully-selected soil or loess samples, as in the Loess Plateau, China, provide a useful proxy of annual rainfall, and potentially of changes in monsoonal patterns and atmospheric circulation.

The Earth’s magnetic field has reversed episodically over time, the last major reversal (Matuyama-Brunhes) occurring 780,000 yrBP. The timing of changes in direction of magnetization of rocks over time has therefore been used as a dating tool in paleoclimatology (see *Dating, magnetostratigraphy*). The time-varying magnetic properties of eolian loess deposits in a stratigraphic sequence also record a high-resolution history of climate change, including precipitation patterns. Paleoclimate studies show that paleosols formed under relatively warm, humid, interglacial conditions are characterized by relatively high magnetic susceptibilities that correlate with high illite/chlorite ratios in the southern Loess Plateau, China, signifying more intense chemical weathering (Zhao et al., 2005) and with more negative oxygen isotope ratios in deep sea sediments (Reynolds and King, 1995). The reverse is found during cold, dry glacial periods.

Aluminum oxides and oxyhydroxides

Gibbsite ($\text{Al}(\text{OH})_3$) and boehmite (AlOOH) are major constituents of *bauxite*. Bauxite (Figure M29) is a residual, lateritic soil that is formed by intense chemical weathering of rocks under wet, tropical climates with annual mean precipitation above $1,700\text{ mm yr}^{-1}$, whereas ferricretes (see above) develop under hot, but seasonally-variable precipitation ranging between $1,300\text{--}1,700\text{ mm yr}^{-1}$ (Tardy and Roquin, 1992). However, others have suggested that both bauxites and laterites were generated under similar tropical climates, with one or more dry

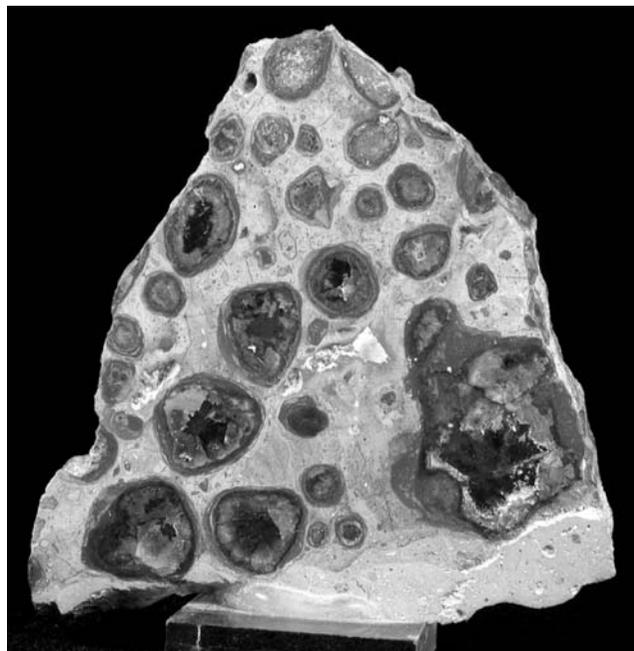

Figure M29 Bauxite with pisolitic texture, Arkansas ($6.4\text{ cm} \times 6.4\text{ cm}$). Bauxite is composed of a mixture of aluminum oxides and oxyhydroxides, resulting from intense chemical weathering under wet, tropical climates (specimen, V. Gornitz; photograph, John Betts).

months (Parrish, 1998). Under these climate regimes, most silicates and even resistant minerals such as quartz are destroyed, leaving insoluble aluminum minerals, such as gibbsite and boehmite, with lesser quantities of diaspore (AlOOH), kaolinite, hematite, and goethite.

The geographic distribution of bauxites has changed over time, reflecting not only changing climates, but also the northerly motion of the African and American plates since the opening of the Atlantic Ocean in the Jurassic period. Quaternary to Recent bauxites in Africa and South America are nearly equatorial, whereas pre-Quaternary bauxites on both continents tend to lie to the northeast (and also south) of their present positions (Tardy and Roquin, 1992).

Manganese oxides and oxyhydroxides

Manganese minerals occur in diverse environments, including terrigenous soils, rock varnish, and oceanic nodules. Among the more common phases in soils and sediments are pyrolusite (MnO_2), manganite ($\text{MnO}\cdot\text{OH}$), vernadite ($\delta\text{-MnO}_2$) or $((\text{Mn,Fe,Ca,Na})(\text{O,OH})_2\cdot n\text{H}_2\text{O})$, birnessite $((\text{Na,Ca})_{0.5}(\text{Mn}^{4+}, \text{Mn}^{3+})_2\text{O}_4\cdot 1.5\text{H}_2\text{O})$, hollandite $(\text{Ba}_2(\text{Mn}^{4+}, \text{Mn}^{2+})_8\text{O}_{16})$, and todorokite $(\text{Mn}^{2+}, \text{Ca, Mg})\text{Mn}_3^+\text{O}_7\cdot \text{H}_2\text{O}$. Manganese (and iron) oxides are concentrated in lateritic soils, ferricretes, and duricrusts (Tardy and Roquin, 1992). Iron-manganese nodules are also widespread in clay-rich soils of temperate to warm climates (Stiles et al., 2001). Initially depositing as hydrous phases, such as birnessite, these eventually dehydrate and invert to anhydrous phases such as hollandite during diagenesis. Total Fe content of Fe-Mn nodules in both modern and paleo-Vertisols has been used as a proxy for mean annual precipitation, showing a positive correlation (whereas total Mn varies inversely) with this climate parameter (Stiles et al., 2001).

Exposed rock surfaces in desert environments are frequently coated by thin laminations of manganese and iron oxides. Desert (or rock) varnish consists of around 70% clays and 30% Fe and Mn oxides, mainly hematite, birnessite, and lesser todorokite (McKeown and Post, 2001). Rock varnish is produced by oxidizing bacteria that extract iron, manganese, and other metals from airborne dust, and precipitation. The manganese content of varnish increases with mean annual precipitation, in contrast to that of soil Fe-Mn nodules. Accurate radiometric dating and chemical analyses of varnish laminations show promise as a paleoclimate proxy (Broecker and Liu, 2001; see also *Desert varnish as a climate proxy*).

Oceanic manganese nodules are rounded concretions that develop in areas of low sediment accumulation rates on the deep seafloor. The nodules are a complex intergrowth of poorly crystalline hydrous manganese and iron phases, including birnessite, todorokite, and vernadite (Li and Schoonmaker, 2003). Most nodules have accreted on nuclei of sharks' teeth, fish bone, shell or rock fragments.

Iron sulfides

Pyrite

Since iron can exist in two different oxidation states, iron minerals are potentially sensitive indicators of soil or sediment redox conditions, which are linked to biogeochemical cycles, and thus indirectly to climate. Pyrite (FeS_2), in particular, has been used an indicator of soil/sediment redox state. Decomposition of organic matter in sediments creates a locally anaerobic environment, in which bacterial reduction of sulfates

to hydrogen sulfide (H_2S) takes place. The H_2S reacts in turn with dissolved iron to precipitate pyrite or marcasite. Marcasite (FeS_2) is less stable in acidic solutions than pyrite, and is therefore less abundant in the geologic record. Deposition of pyrite is favored by euxinic lacustrine or marine environments (restricted water circulation), presence of organic-rich sediments, locally elevated CH_4 levels, and (on land), poorly-drained or water-logged soils. The degree of pyritization (DOP)¹ has frequently been taken as a marker for soil/sediment redox state. DOP values <0.46 represent aerobic conditions, with $0.46\text{--}0.75$ intermediate, and $\text{DOP} > 0.75$ euxinic conditions (Raiswell et al., 1988). However, DOP may also depend on iron availability. Furthermore, in certain shallow water environments, such as tidal salt marshes, DOP values may reflect pore water redox state and sediment chemistry rather than bottom water oxygen levels (Roychoudhury et al., 2003).

Pyrite is rapidly oxidized in today's atmosphere and thus generally does not occur as a detrital mineral. Therefore, well-rounded "detrital" grains of pyrite, also uraninite (UO_2), and siderite (FeCO_3), from the Witwatersrand basin in South Africa have been widely regarded as evidence for much lower than present atmospheric oxygen levels during the Archean eon ($>2,500$ million yBP). The significance of these grains as paleo-atmosphere indicators has been controversial, since a hydrothermal origin was proposed for "placer" gold nuggets associated with these minerals in conglomerates. However, several recent studies strengthen the case for the placer theory. Precise $^{187}\text{Re}/^{187}\text{Os}$ radiometric dating shows that the rounded gold nuggets (and associated pyrite and uraninite grains) are ~ 3 billion years old as compared to significantly younger ages of 2.76–2.89 billion years for the enclosing host conglomerates, and that therefore the heavy minerals must be detrital (Kirk et al., 2003). Textural and isotopic evidence also favors the placer theory. Rounded, As-bearing pyrite grains with truncated compositional growth bands clearly demonstrate that the grains were mechanically abraded (Fleet, 1998). The rounded pyrite exhibits a broader range in δS^{34} values, suggestive of a placer origin, in contrast to crystalline pyrite overgrowths, which probably were produced by later hydrothermal alteration or metamorphism (England et al., 2002).

Halides

Halite

Halite (NaCl) crystallizes from a supersaturated brine at the air-water interface as thin square plates, which grow faster at their edges. These expand into pyramidal crystals with hollowed centers (hoppers), and eventually coalesce into floating rafts and sink. The hopped crystals continue to grow on the basin floor, ultimately creating a distinctive layered, chevron-like pattern in sedimentary salt deposits (Figure M30). In addition to precipitating directly from brine, halite can also grow within soft mud or silt into large displacive cube crystals, often with hollow faces (Figure M31; Gornitz and Schreiber, 1981). Displacive halite is well-known from the geologic record. The presence of such crystals in sedimentary rocks suggests an origin within shallow marine sediments or from the intertidal to supratidal zone, in fairly hot, arid climates (Gornitz and Schreiber, 1981).

¹DOP = $\% \text{Fe}_{\text{pyrite}} / (\% \text{Fe}_{\text{pyrite}} + \text{reactive Fe})$, where $\text{Fe}_{\text{pyrite}}$ is the fraction of iron associated with pyrite, while reactive Fe is the fraction of iron that reacts with dissolved sulfur.

Halite crystals often trap droplets of the brine from which they precipitate. Such fluid inclusions, if primary (i.e., trapped at the time of growth), can supply useful information about the temperature and composition of the brine. For example, primary fluid inclusions in “chevron”-type halite from shallow ephemeral saline lakes or salt pans from the Permian Nippewalla Group, western Kansas yield homogenization temperatures in the range 21–50 °C. (Benison and Goldstein, 1999). Since these

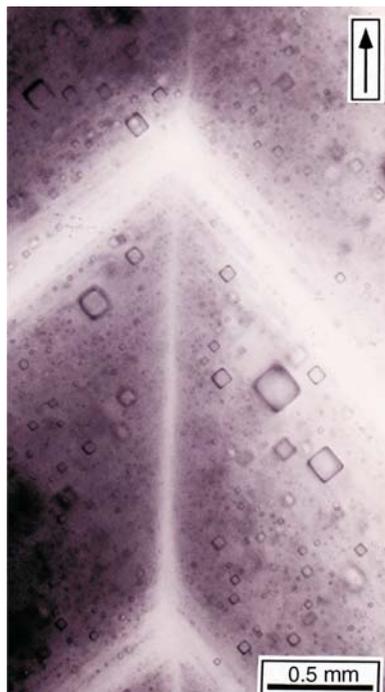

Figure M30 Chevron texture in bedded halite from the mid-Permian Nippewalla Group, western Kansas formed by precipitation of rafts of hopped halite in supersaturated brines (photograph, Kathy Benison, Central Michigan University; reproduced with permission).

shallow saline pools were exposed to the surface, these values closely reflect atmospheric temperatures and support other paleogeographic evidence pointing to a hot, arid climate of the mid-North American continent during the mid-late Permian. Primary inclusions in marine chevron halite have also been used to track major oscillations in Phanerozoic paleosea water chemistry (Lowenstein et al., 2001). Mg^{2+}/Ca^{2+} ratios of Phanerozoic seawater derived from the fluid inclusions show systematic variations over time, with peak Mg^{2+}/Ca^{2+} ratios occurring during the late Precambrian, Permian, and Neogene. These periods of high Mg^{2+}/Ca^{2+} values were associated with periods of enhanced aragonite ($CaCO_3$) and $MgSO_4$ deposition, as well as slower seafloor spreading rates.

Other halides

Sylvite (KCl) is an evaporitic salt, often associated with halite, which forms under similar conditions of high aridity. Hydrohalite ($NaCl \cdot 2H_2O$) is a form of salt that precipitates from highly saturated brines at low temperatures (Roberts et al., 1997). Because of its solubility, it is rarely preserved in the geologic record, but its former presence may be inferred from pseudomorphs of halite or other minerals. Antarcticite ($CaCl_2 \cdot 6H_2O$), is a rare soluble chloride, discovered in saline lakes from the dry valleys of Antarctica (Torii and Ossaka, 1965). It precipitates from saturated brines at below-freezing temperatures (see also *Evaporites*).

Carbonates

Calcite, aragonite, and dolomite

Calcite and aragonite are the common polymorphs of $CaCO_3$. (Vaterite is a much rarer form of $CaCO_3$). Aragonite is less stable than calcite, but is stabilized by magnesium in seawater (McLane, 1995). High Mg-calcite, a variety of calcite, may contain up to 10–18 mol-% $MgCO_3$. In dolomite ($CaMg(CO_3)_2$), the molar proportion of magnesium to calcium is 1:1. Calcite, aragonite, and dolomite occur over a broad range of geologic settings, including karst terrains, arid soils, lacustrine, coastal, and shallow to deep-water marine environments. These minerals can form as inorganic chemical precipitates and through biogenic processes.

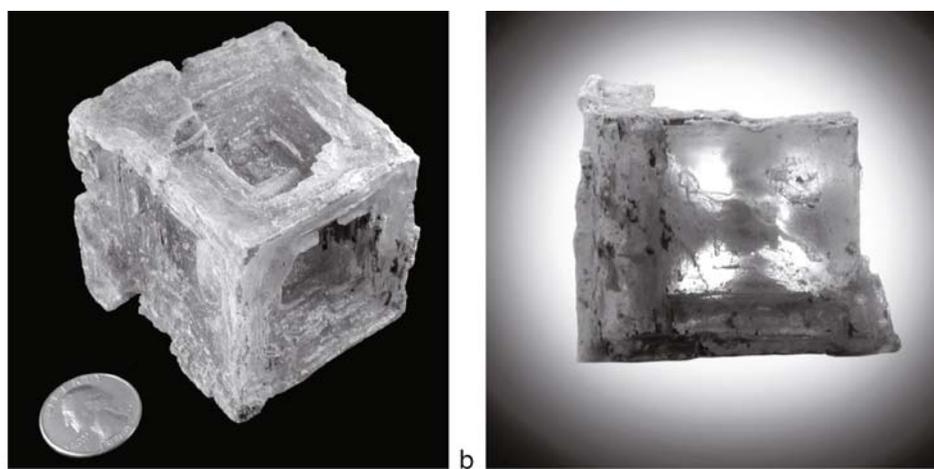

Figure M31 (a) Displacive halite, hopper (hollow) cube with mud inclusions, Dead Sea, Israel (6.3 cm × 6.3 cm). (b) Displacive halite, Dead Sea, Israel (2.5 cm × 3.2 cm). Mud inclusions have been incorporated into the halite along crystallographic directions during growth, forming a Maltese cross pattern (specimens, V. Gornitz; photographs, John Betts).

Calcite and, to a lesser extent, aragonite are the most common minerals in cave *speleothems* (i.e., stalactites and stalagmites). The concentric, layered rings in speleothems record annual climatic or environmental variations, much like tree rings. Thus, trace elements or oxygen and carbon isotope ratios in speleothems have been used as paleoclimate proxies (e.g., Genty et al., 2003; *Speleothems*). In arid to semi-arid climates, calcite and dolomite concentrate within hardpan soil layers, forming *calcrete* (or “caliche”), a type of *duricrust* (Milnes, 1992; *Duricrusts*). Calcite and aragonite constitute the bulk of carbonate-rich *eolianites*, which accumulate as wind-blown dunes adjacent to mid-latitude beaches (see *Eolianite*). Eolianites develop along dry, low relief coasts, with high wave and wind energy. Mg-calcite and aragonite are characteristic cements of *beachrock*, a clastic rock that is lithified within the intertidal zone of tropical to subtropical coasts (McLane, 1995; see *Beachrock*). Beachrock has been used as a paleo-sea-level indicator.

Calcite is the dominant bio-mineral of deep-sea calcareous oozes or chalk, which consists mainly of skeletal coccolithophores and foraminifera. Aragonite is derived from pelagic pteropods. Modern shallow-water carbonates, largely confined to subtropical and tropical climates, are dominated by aragonite and high Mg-calcite (Morse, 2003). Aragonite is produced by scleractinian coral, calcareous green algae, and some mollusks, whereas high Mg-calcite is created by benthic foraminifera and sea urchins. Oolitic carbonates (composed of aragonite or high Mg-calcite) are generally non-biogenic (Morse, 2003).

A number of trace elements, such as magnesium, strontium, or barium are incorporated into marine carbonates. Mg/Ca and Sr/Ca ratios in foraminiferal calcite serve as paleotemperature proxies, and Cd/Ca and Ba/Ca ratios as proxies of ocean paleoproductivity and circulation (Kastner, 1999; Parrish, 1998). Oxygen and carbon isotopes in foraminifer calcite yield information on ocean paleotemperatures, polar ice volume, and the carbon budget (Parrish, 1998). Coccoliths have been used for biostratigraphic dating of marine sediments.

The abundance of biogenic carbonates has varied considerably during the Phanerozoic eon. Periods of calcite dominance (“calcite seas”) from the Ordovician through Devonian periods and Jurassic-Cretaceous have alternated with periods of aragonite dominance (“aragonite seas”) during the Carboniferous-Triassic and more recently, the Neogene (Montañez, 2002). Calcitic corals and stromatoporoids dominated the reefs of calcite seas, in contrast to the aragonitic sponges, corals, algae, and Mg-calcite red algae that occupied the reefs of aragonite seas. Modern reefs are populated by aragonitic scleractinian corals and Mg-calcite coralline algae. The calcite-dominant periods are closely associated with “greenhouse” climates, whereas the aragonite-rich periods are linked to “icehouse” conditions. These temporal variations in marine bio-mineralogy have been attributed to changes in seawater Mg/Ca ratios, shifts in long-term rates of sea-floor spreading, eustatic fluctuations, and climate cycles. Periods when the seawater Mg/Ca mole ratio exceeds two favor the production of high Mg-calcite and aragonite, and vice-versa (Lowenstein et al., 2001).

Although dolomite occurs massive in sedimentary rocks, it forms at present in restricted environments such as highly saline lakes or sabkhas. These are coastal salt flats, or shallow, tidal pools in hot, arid regions (e.g., the Persian Gulf, also around the Caribbean, Southern California) that are periodically flooded by seawater and concentrated by evaporation. Gypsum (sometimes anhydrite) precipitates first, leaving the residual brine enriched in magnesium, which then reacts with

calcium carbonate sediments, resulting in the deposition of dolomite (McLane, 1995).

Ikaite (glendonite)

Ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$) is a rare mineral that is stable only at very low temperatures and several kilobars pressure. It occurs in nature at temperatures up to 7°C in alkaline, phosphatic marine and continental waters (De Lurio and Frakes, 1999). Although ikaite has generally been replaced by calcite (“glendonite”), its original crystal habit of individual bipyramids or radiating clusters has been preserved in the sediments (Figure M32; Swainson and Hammond, 2001). Because of the rather restricted conditions under which ikaite/glendonite forms, it has been used as a proxy for near-freezing water temperatures (De Lurio and Frakes, 1999).

Siderite

Siderite (FeCO_3) occurs in minor amounts in reducing, low sulfide, lacustrine, deltaic environments (McLane, 1995), and on marine continental margins, where it forms during late diagenesis in suboxic to anoxic pore fluid waters near a source of detrital Fe (Kastner, 1999). *Sphaerosiderite* is a distinctive millimeter-sized, spherulitic variety of siderite found in silty mudstones from reducing soils in continental wetlands (Ludvigson et al., 1998). The $\delta^{18}\text{O}$ ratios of sphaerosiderite and co-existing calcite have been used to estimate paleotemperature and ground-water $\delta^{18}\text{O}$ values (Ludvigson et al., 1998). Careful selection of unaltered samples is necessary to avoid errors in the paleothermometry introduced by diagenetic alteration (Ludvigson et al., 2000).

Siderite figures prominently in the debate surrounding the composition of the Earth’s early atmosphere. The existence of ancient oceans presumes that the reduced luminosity of the

Figure M32 Glendonite (calcite pseudomorph after ikaite), Olenitsa River, Kola Peninsula, Russia, (2.5 cm) (specimen, V. Gornitz; photograph, John Betts). Ikaite, or glendonite, is an indicator of near-freezing water temperatures.

Sun prior to 3 billion years was offset by higher levels of greenhouse gases such as carbon dioxide or methane (see *Faint Young Sun Paradox*). The lack of siderite in paleosols older than ~2 billion years has been interpreted to indicate an insufficient amount of atmospheric CO₂ to compensate for the faint young Sun, and that therefore the major greenhouse gas was CH₄. However, Ohmoto et al. (2004) use thermodynamic arguments to conclude that massive Archean siderite deposits were laid down under a CO₂-rich atmosphere. The formation of iron (II)-rich carbonate (Fe_{0.53}Mg_{0.44}CO₃) weathering rinds on conglomerate pebbles from the 3.2 billion year old Barberton Greenstone Belt, South Africa also hints at higher paleo-atmospheric CO₂ levels than present (Hessler et al., 2004).

Sulfates

Gypsum and anhydrite

Gypsum (CaSO₄·2H₂O) and anhydrite (CaSO₄) are among the most abundant evaporite minerals. Gypsum also crystallizes within muds in desert playas or coastal sabkhas (Figure M33a–c). Gypsum nodules grow directly by displacing the enclosing mud sediment, coalescing into nodular layers. Gypsum dehydrates to anhydrite at the higher temperatures and pressures caused by burial to depths of several hundred meters (McLane, 1995). Anhydrite precipitates directly from highly saturated brines at temperatures above 22 °C (McLane, 1995).

Mirabilite

Mirabilite (Na₂SO₄·10H₂O) is a soluble evaporite mineral that precipitates under conditions of high salinity and at low temperatures.

Barite

Barite (BaSO₄) forms in hydrothermal and in sedimentary environments. It also precipitates from seawater, accumulating on the ocean floor, often in association with plankton and organic matter (Derry and Murray, 2004; Kastner, 1999). Furthermore, its insolubility and resistance to diagenetic alteration under oxic conditions help preserve it in marine sediments. These features make barite accumulation rates a useful marker for ocean paleoproductivity (Parrish, 1998; Paytan et al., 1996) (see *Ocean paleoproductivity*). Oxygen isotope ratios in marine barite record changes in exposure to sulfur oxidation on continental shelves during glacial-interglacial cycles and thus indirectly record fluctuations in sea level (Turchyn and Schrag, 2004).

Phosphates

Francolite, or carbonate-fluorapatite (Ca₅(PO₄,CO₃)₃(F,OH)), is the chief mineral in phosphorite, a sedimentary rock rich in phosphates (see *Phosphorite*). The chemical composition of francolite is variable, with differing amounts of Na, Sr, or Mg replacing Ca, and SO₄ substituting for PO₄. Francolite occurs as pellets, nodules, crusts, or laminations. Collophane is an amorphous or cryptocrystalline form of sedimentary phosphate.

Phosphorites accumulate on continental margins, epeiric seas, and to a lesser extent on seamounts or ocean islands. They are generally formed in zones of marine upwelling and high biologic productivity (Parrish, 1998). The main source of phosphorus comes from vertebrate skeletal remains, or breakdown of organic matter. Fish scales or bones frequently act as nuclei for the buildup of francolite pellets or nodules.

Silica minerals

The most common varieties of silica found near the earth's surface include quartz, chalcedony, chert, and opal.

Quartz

Low-quartz (α -SiO₂) is the stable form of crystalline silica at the earth's surface and one of the most abundant minerals in crustal rocks. Quartz is a hard ($H = 7$ Mohs scale), chemically resistant mineral that survives the rock weathering cycle in nearly all climates, except for hot and humid tropical climates (e.g., see *Bauxite*, above). It is a major constituent of eolian desert deposits, sandstones, and many littoral beach sands. In deserts, winds concentrate quartz grains into dunes and huge sand seas (ergs). Fossil sand dunes show characteristic cross-bedding and wind-ripple forms. The orientation of cross-bedding and other sedimentological features enable the reconstruction of paleowind directions (Parrish, 1998). Examples of quartz-rich eolian sandstones include the Jurassic Navajo and Kayenta Sandstones of Utah and Colorado, the Permian Coconino Sandstone of the Grand Canyon region, New Red Sandstone (Permo-Triassic, England) and the Yellow Sands – Permian, England (Parrish, 1998). Quartz is also a significant component of eolian dust in marine sediments and in ice cores. Variations in concentrations and grain sizes of eolian dust grains provide information on changes in glacial to interglacial wind directions and intensities (*Eolian dust, marine sediments*).

Opal-A, opal-CT, chert, chalcedony

Opal-A is an amorphous, structurally disordered form of silica which contains several percent of water. Widespread in deep sea sediments (e.g., in siliceous oozes), it is largely derived from the remains of marine micro-organisms, such as diatoms, radiolarians, silicoflagellates, and siliceous sponge spicules (Parrish, 1998). (However, some marine opal may be of volcanic origin). Over time, opal-A gradually transforms to opal-CT, which shows domains of short-range order similar to the atomic arrangement in cristobalite and tridymite. Further diagenesis leads to opal-C and chert.

Chert is a sedimentary rock consisting of opal, crypto- to microcrystalline quartz, and chalcedony (a fibrous variety of quartz). Extensive bedded chert deposits are mostly products of former marine biogenic sedimentation. Bedded chert is often associated with phosphorites and black shales (see *Phosphorite*; McLane, 1995). Such cherts, or siliceous oozes, have deposited in zones of marine upwelling that are diagnostic of high organic primary productivity (Kastner, 1999; Parrish, 1998). Tracking shifts in the distribution of upwelling zones over time may also reveal information about changes in paleo-ocean circulation.

Clay minerals

Clay minerals are phyllosilicates, or sheet silicates, consisting of layers of silica tetrahedra attached to layers of aluminum or magnesium atoms, each of which is surrounded by six oxygen atoms or hydroxyl ions in octahedral layers. Other cations, such as iron, potassium, sodium, or calcium, can also be present. The clays differ in the nature of the cations within and between sheets and in their stacking arrangements. Important clay minerals and their ideal chemical formulas are listed in Table M2.

Clay minerals are produced by the chemical weathering of rocks near the earth's surface (Figure M34). The clay

Table M2 Common clay minerals

Kaolinite	Al ₂ Si ₂ O ₅ ·(OH) ₄
<i>Smectite group (expanding clays)</i>	
Montmorillonite	(Na,Ca) _{0.3} (Al,Mg) ₂ Si ₄ O ₁₀ (OH) ₂ ·nH ₂ O

Illite	KAl ₂ (Si ₃ Al)O ₁₀ (OH) ₂
Glaucanite	(K,Na,Ca)(Fe ³⁺ ,Al,Fe ²⁺ ,Mg)(Si,Al) ₄ O ₁₀ (OH) ₂
Vermiculite	(Mg _{2.7} Fe _{0.3})(Si ₃ Al)O ₁₀ (OH) ₂ ·nH ₂ O
Chlorite group	(Mg _{2.6} Fe _{0.4})Si _{2.5} (Al,Fe) _{1.5} O ₁₀ (OH) ₈
Berthierine	(Fe ₅ ,Al) ₃ (Si,Al) ₂ O ₅ (OH) ₄
Sepiolite	Mg ₄ Si ₆ O ₁₅ (OH) ₂ ·6H ₂ O
Palygorskite	(Mg,Al) ₂ Si ₄ O ₁₀ (OH) ₂ ·4H ₂ O

detritus is removed by water erosion and accumulates in lacustrine, estuarine, and marine sediments. Clays are also major constituents of terrestrial soils and of airborne dust. The relative abundance of clays is closely related to climate or to environmental setting, although source rock mineralogy also influences their development. Kaolinite (Figure M34a), for example, is created by intense chemical weathering of warm, humid climates, in which silica is leached out, leaving soils enriched in alumina (Chamley, 1989). Chlorite (Figure M34b) and illite (Figure M34c) tend to form in soils dominated by physical weathering – both in colder, often formerly glaciated regions, and hot, dry climates (Chamley, 1989). Consequently, these clays generally reflect the composition of their parent rocks. Smectite (Figure M34d), illite, chlorite, and mixed-layer clays are more prevalent in temperate-cool, moist climates (Chamley, 1989). Well-crystallized iron-rich smectites (e.g., nontronite) occur in sub-arid climates (Chamley, 1989). Montmorillonite – a smectite – also forms by weathering of volcanic ash. Sepiolite, palygorskite, and attapulgite are three rather rare clay minerals found in calcrete soils, and in warm, semi-arid to arid climates (Chamley, 1989; Parrish, 1998; Watson, 1992).

Glaucanite, (K,Na,Ca)(Fe³⁺,Fe²⁺,Mg)(Si,Al)₄O₁₀(OH)₂, is a dark-green to black mineral, related to mica and mixed-layer clays, usually found as tiny rounded grains that most likely formed as fecal pellets. It occurs in weakly reducing environments, near upwelling zones on continental shelves and margins between depths of 100–250 m (Chamley, 1989), characterized by relatively slow sedimentation rates (Kastner, 1999; Parrish, 1998; Velde, 2003), and is often associated with phosphorites (McLane, 1995; Velde, 2003). The presence of potassium in glaucanite allows dating of sea level cycles in marine sediments, via the potassium-argon or rubidium-strontium methods (Velde, 2003).

Berthierine, (Fe₅,Al)₃(Si,Al)₂O₅(OH)₄, a dark-greenish phyllosilicate closely related to kaolinite and serpentine, occurs in near-shore or deltaic sediments (Velde, 2003) from chemically reducing environments, but more rarely in terrigenous soils. Its presence in early Triassic continental paleosols may indicate low atmospheric oxygen levels, possibly resulting from catastrophic methane release, mass mortality, and rise in CO₂ at the Permian-Triassic boundary (Sheldon and Retallack, 2002).

Inasmuch as non-biogenic marine sediments are largely derived from continental sources, the distribution of clay minerals in the oceans closely corresponds to that of adjacent landmasses. Thus, marine clays display a latitudinal zonation broadly paralleling the major climate zones (Chamley, 1989; Evans, 1992; Parrish, 1998). Kaolinite is abundant in equatorial waters, whereas chlorite

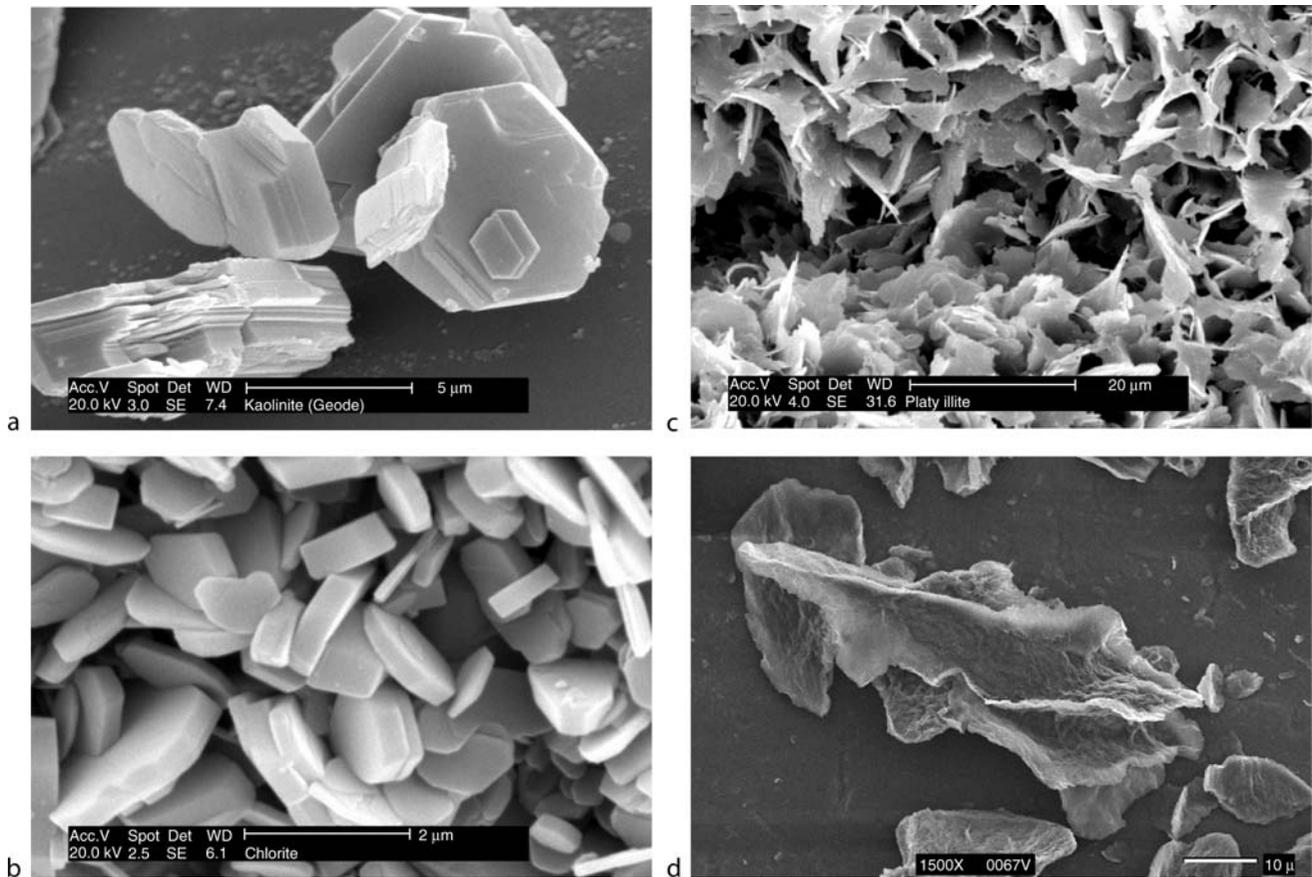

Figure M34 (a) Kaolinite, Keokuk geode, USA. (b) Iron-rich chlorite, Spiro Sandstone, Arkoma Basin, Oklahoma, USA. (c) Illite, Rotliegend Formation, Northern Germany. and illite concentrations increase toward higher latitudes. The distribution of smectites, on the other hand, is not quite as strongly zoned, indicating the influence of other, non-climate factors.

Temporal changes in clay mineralogy record important paleoclimate events. For example, Kennedy et al., (2006) associated a significant increase in clay minerals relative to quartz during the late Neoproterozoic (800–550 million years ago) with a growing degree of terrigenous chemical weathering, clay-organic matter burial, and increasing oxygen levels. Kaolinite and expandable clays (i.e., smectites) became more abundant at the expense of illite, chlorite, and mica during this period, consistent with development of soils, possibly promoted by biotic activity. Variations in relative abundances of kaolinite, smectite and mixed-layer illite/smectite have been used as a paleoclimate proxy for wet versus dry climates during the Mesozoic of northwestern Europe (Ruffell et al., 2002), with high kaolinite indicating humid periods. Elsewhere, increases in smectite and kaolinite relative to illite in marine sediments off Antarctica at around 33.5 Ma have been correlated with a marked positive δO^{18} shift and onset of significant Antarctic glaciation (Robert and Kennett, 1997). Decreasing kaolinite/illite, smectite/illite ratios after 33.4 Ma signal enhanced physical weathering under cooler, drier climates. A similar pattern of higher kaolinite/illite and smectite/illite ratios at ~33.5 and 33.4 Ma, succeeded by increased illite content is observed in cores

from the Great Australian Bight (Mallinson et al., 2003). These cores also show 22-Kyr cyclicality in kaolinite/smectite ratios, linked to precessional changes in precipitation, wind patterns and runoff that affected the mineralogy and transport of clays to the Bight.

Enhanced chemical weathering during warmer interglacials generated higher concentrations of interlayered illite-smectite in Lake Baikal sediments, Russia, whereas greater physical weathering during colder, glacial periods resulted in chlorite and illite enrichment (Yuretich et al., 1999). Changes in illite/chlorite ratios in Chinese loess sections have been used to reconstruct monsoonal activity during the late Pleistocene (Zhao et al., 2005). In the southern Loess Plateau, the illite/chlorite ratio and magnetic susceptibility are higher in interglacial paleosols and lower in glacial loess. More intense weathering of chlorite, leading to higher illite/chlorite ratios, indicates a stronger monsoonal regime operating during interglacial periods.

The distinctive mineral assemblage of high illite, low smectite, and low kaolinite/chlorite ratio in the dust from the GISP2 (Greenland) ice core pinpoints a likely source of the clays in deserts of eastern Asia. Although dust composition (and sources) remained fairly constant during the last glaciation, changes in total concentrations and grain sizes reveal

significant variations in wind speed and strength during stadials and interstadials (Biscaye et al., 1997).

Zeolites

Zeolites (Table M3) are a group of hydrated aluminosilicate minerals with an open framework structure, into which various large ions and water molecules can fit and which possess a certain degree of mobility. They are widespread in cavities in basaltic lavas, as authigenic or diagenetic minerals in marine sediments, and in low-grade metamorphic rocks. Phillipsite is an authigenic zeolite that forms on the seafloor or at shallow depths (Kastner, 1999). Clinoptilolite forms in silica-rich marine sediments, derived from opal-A. Zeolites also form from the alteration of volcanic glass, tuff, or lavas in high pH, alkali-rich, semi-arid to arid environments. Analcime is common in sodium-rich alkaline desert soils (Watson, 1992). Zeolites from saline, alkaline lakes include analcime, chabazite, clinoptilolite, erionite, mordenite, and phillipsite. These zeolites are often associated with evaporites (Parrish, 1998). Zeolites in lacustrine deposits have been used as markers for dry, alkaline environments, as for example at Lake Naivasha, Kenya, where low lake levels are represented by the presence of chabazite and phillipsite, with even greater aridity indicated by clinoptilolite and analcime (Trauth et al., 2001). The East African lake level fluctuations have been linked to precessional cycles in springtime insolation and monsoonal precipitation.

Summary

Minerals that form at or near the earth's surface in contact with the atmosphere and hydrosphere can provide important information about former climates. They have been used to reconstruct past climates and changes over time, deduce changes in atmospheric composition, trace eolian and precipitation patterns, and serve as "hosts" for climate-sensitive stable isotopes and trace elements.

The most useful mineral indicators or proxies are those that are generated under relatively narrow climatic ranges or within restricted environmental settings. Examples include evaporites, low temperature minerals (e.g., ikaite and hydrohalite), residual soils (e.g., iron and aluminum oxyhydroxides, kaolinite), and certain authigenic minerals (that form *in situ*, e.g., glauconite, berthierine, phillipsite, barite). Minerals that are sensitive to oxidation (e.g., pyrite and uraninite) reflect past atmospheric oxygen levels. Distinctive detrital minerals in eolian deposits act as markers of wind direction and intensity. Similarly, minerals in deltaic sediments point not only to variations in the relative contributions from source tributaries, but can also indicate precipitation variability in source areas. Trace elements and stable isotope ratios contained within minerals such as calcite (both biogenic and non-biogenic) have provided a wealth of paleoclimatological information.

MONSOONS: PRE-QUATERNARY

Monsoon circulation has existed throughout geological history whenever the tropics were occupied by both land and sea. Pre-Quaternary monsoons, however, are poorly understood because paleo-monsoon studies have been heavily biased toward variations of the Quaternary monsoon on the orbital and suborbital time scales. Pre-Quaternary monsoon systems are often considered over a much longer time span, so they show more significant variations in responding to tectonically-induced geographic and topographic changes. Pre-Quaternary monsoons have so far only sporadically been mentioned in the literature for most of the geological periods, except for two better studied intervals: the Permian and Triassic where a “megamonsoon” developed on the megacontinent Pangaea, and the late Cenozoic, which led to the establishment of the modern monsoon system.

Megamonsoon of the megacontinent

As monsoons are caused by land-sea contrast in the heating rate, the ideal conditions for a monsoon system to develop exist when only one major continent and one complementary ocean exist on Earth. This was the real case around 250–200 Myr ago, during the late Permian and Triassic, when all continents

assembled into two major landmasses, Laurasia and Gondwanaland, that joined near the equator to form the supercontinent Pangaea and the super-ocean Panthalassa (Figure M35a). The extensive distribution of evaporites and many biogeographic features indicate a maximum of continentality, leading to speculation about the association of monsoon-type seasonal rains with large landmasses at that time (Robinson, 1973). Parrish et al. (1982) used the basic principles of atmospheric and oceanic circulation to reconstruct global paleo-precipitation maps for seven time intervals of the Mesozoic and Cenozoic, and found patterns of a strong summer monsoon low over Laurasia

and a winter monsoon high over Gondwanaland in the Triassic and reversed monsoon features for opposite seasons. According to these authors, the Triassic was distinguished by maximal aridity with precipitation on the supercontinent provided only by monsoons (Figure M35b). Kutzbach and Gallimore (1989) were the first to use numerical modeling to explore the “megamonsoon of the megacontinent.” Applying a low-resolution general circulation model to the idealized Pangaea (Figure M35a), they found extreme continentality with a hot summer and cold winter, and large-scale summer and winter monsoon circulations (Figure M35c,d). At the same time, Crowley et al. (1989) used

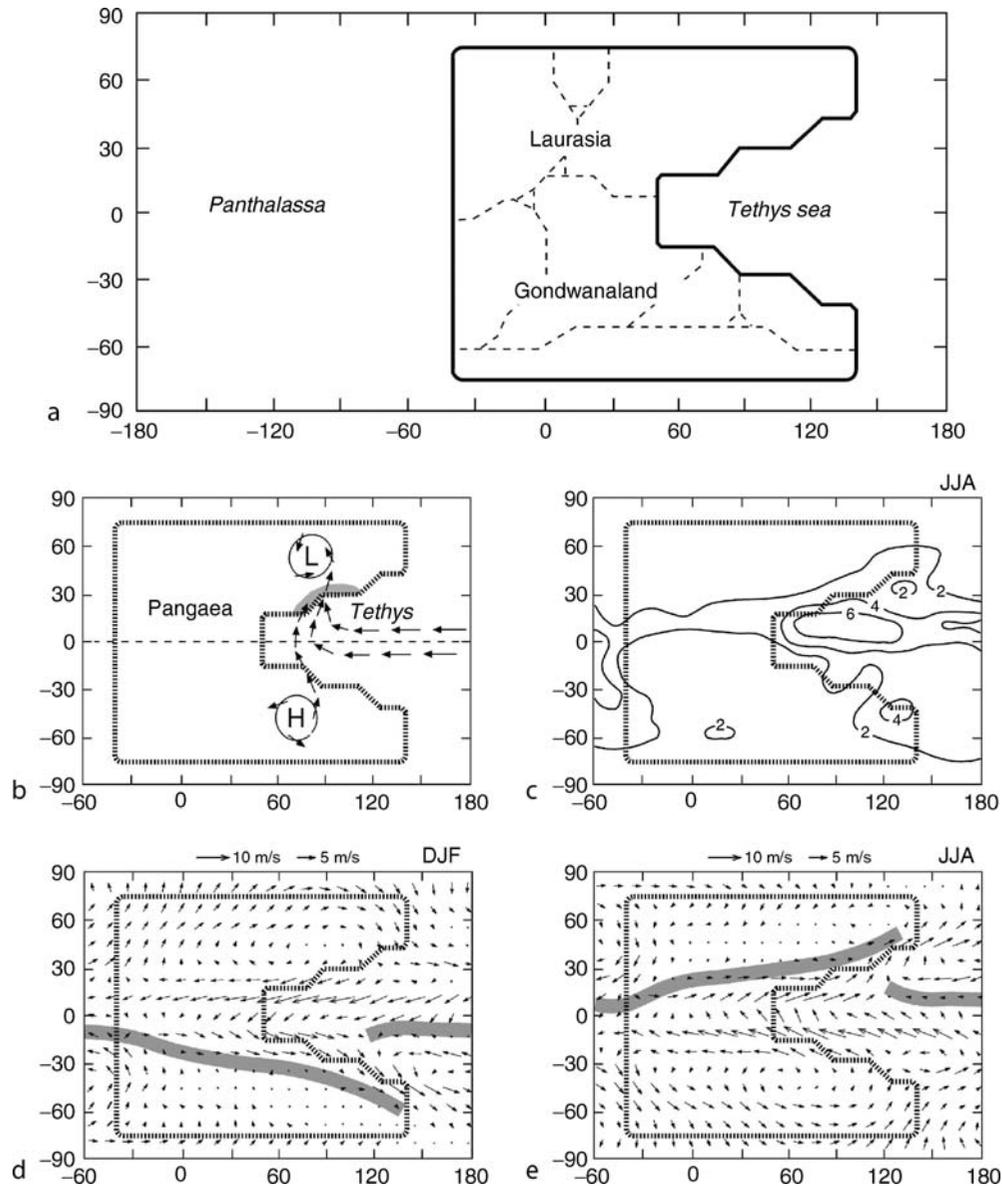

Figure M35 Megamonsoon of the Pangaea. (a) The idealized Pangaea continent. *Fine dashed lines* indicate the approximate outlines of modern landmasses (after Kutzbach and Gallimore, 1989). (b) Schematic diagram illustrating monsoonal circulation in northern summer. *Arrows* show surface winds, stippling indicates heavy seasonal rains (modified from Parrish and Peterson, 1988). (c) Modeled precipitation rate (mm d⁻¹) on Pangaea for summer. (d), (e) Modeled surface winds on Pangaea for winter (d) and summer (e), note the seasonal reversal of the wind direction. The *gray bar* shows the poleward limit of summer monsoon over land and the Intertropical Convergence Zone over ocean (modified from Kutzbach and Gallimore, 1989).

energy balance modeling (EBM) to study the late Permian climate. Both modeling results show an extremely wide annual range of temperature (50°C) for hinterland and strong monsoon circulation over Pangaea.

The geological record of the “megamonsoon” was found from the upper Triassic of North America: the Newark and related basins in the east and the Colorado Plateau in the west

(Figure M36a). Late Triassic lacustrine deposits from the Newark Basin, New Jersey, which were about 10°N in the monsoon-prevalent tropics at that time, display clear evidence of monsoon-driven seasonality and lake level fluctuations (Olsen, 1986). Part of the sequence consists of micro-laminated mudstones (varves) with 0.2–0.3 mm thin couplets of alternating light and dark layers, implying significant seasonal contrast

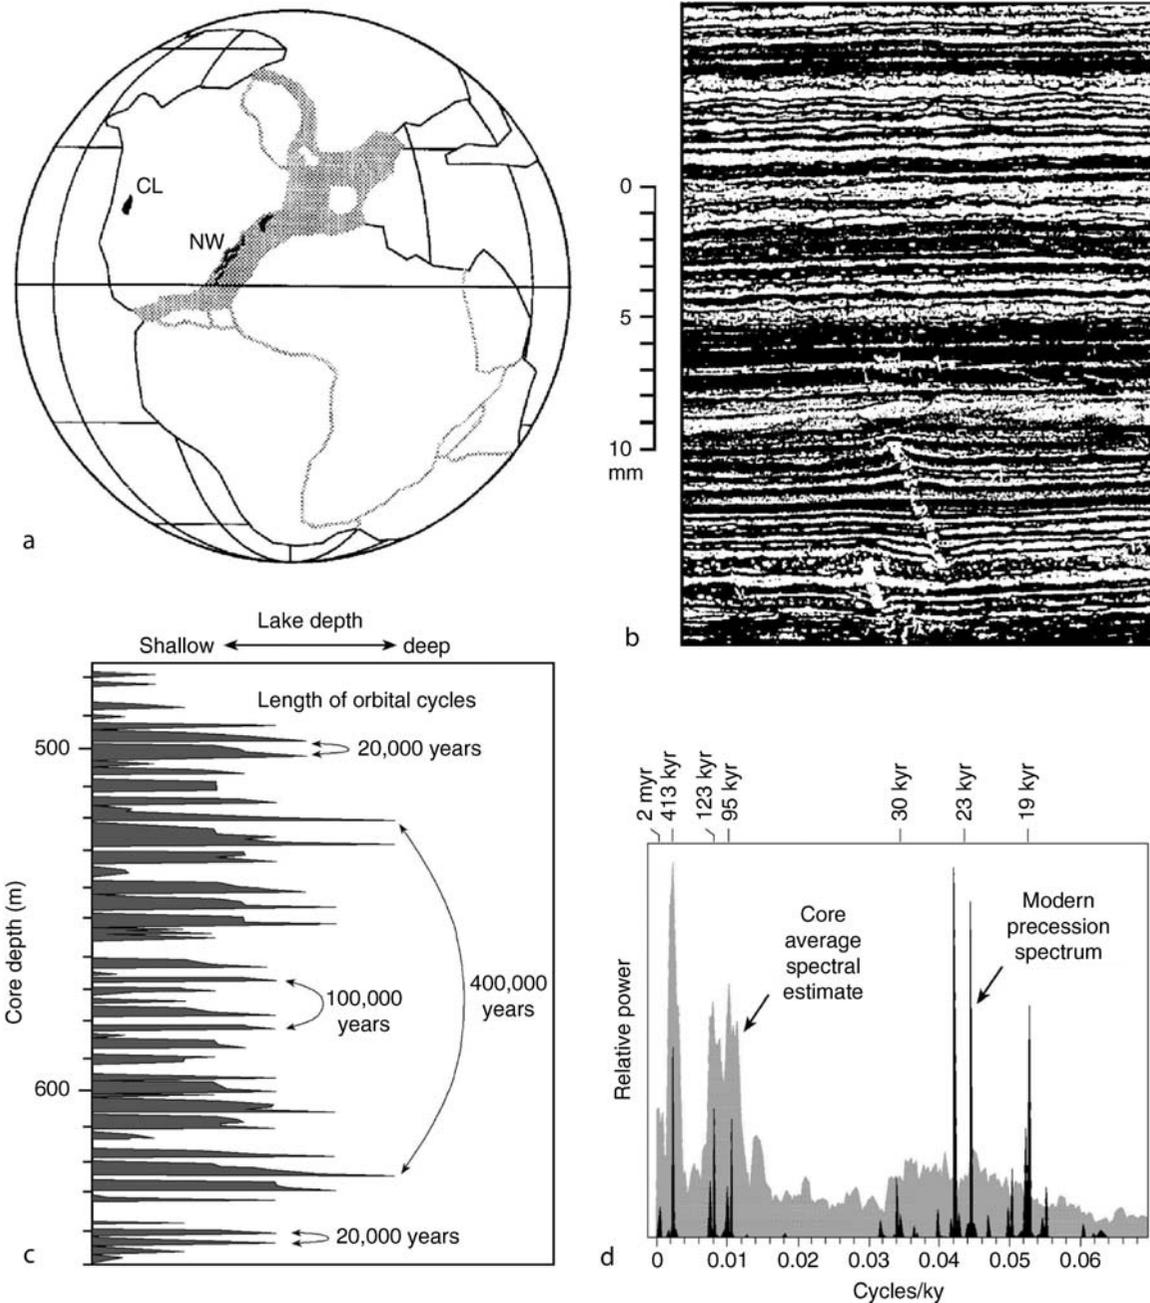

Figure M36 Late Triassic monsoon records from North America. (a) Locations of the Colorado Plateau with the Chinle Formation (CL) and, to the east, a chain of rifted basins containing the Newark Supergroup (NW). (b) Photograph of microlaminated mudstone showing organic-rich/carbonate-rich couplets as annual varves. (c) Lake-level fluctuations revealed in a section of the Newark lake sediments, showing 20-kyr, 100-kyr, and 400-kyr cycles. (d) Average spectral estimates of sediment cycles in the Newark Basin against the modern precession spectrum. (Modified from Olsen and Kent, 1996 and Ruddiman, 2001).

(Figure M36b). Detailed studies including spectral analyses on the nearly 7,000 m long section reveal a full range of precession-related periods of lake level change: the 20-kyr precession cycles, and 100-kyr and 400-kyr eccentricity cycles which modulate the amplitude of precessional cyclicity (Figure M36c,d). All these cycles are characteristic of the tropical response to orbital forcing and support a monsoon-climate origin of lake level change, whereas the absence of obliquity cycles preclude the possibility of direct linkages to high-latitude climate systems (Olsen and Kent, 1996). Similar records of the Pangaean “megamonsoon” were also found in the Chinle Formation, Colorado Plateau, on the tropical western margin of the supercontinent (Figure M36a; Dubial et al., 1991). During the Pangaean interval, eolian, playa deposits and evaporates were widespread on the Colorado Plateau, but the Chinle formation represents an unusually wet episode with well-developed fluvial and lacustrine deposits and paleosol sequences, indicating abundant moisture brought about by enhanced monsoon circulation and strong seasonality.

Establishment of the modern monsoon system

The modern Asian-Australian and African monsoons cover most of the Eastern Hemisphere, and fundamental questions in Cenozoic paleoclimatology ask when the modern monsoon system was established and how it has evolved since then. Three tectonic factors have been proposed to exert a control over the evolution of Asian monsoon circulation: plateau uplift, sea-land distribution, and closing of oceanic gateways. Continuous records of the monsoon history provided by Deep Sea

Drilling Project/Ocean Drilling Program (DSDP/ODP) cruises to the Arabian, Mediterranean and South China Seas, as well as from the Loess plateau in central China, have been used to verify the various tectonic hypotheses (Sun and Wang, 2005).

Tectonic forcing and numerical modeling

1. **Plateau uplift.** GCM experiments on the modern land-sea distribution indicate that strong monsoons can be induced by solar forcing only when the elevation of Tibet-Himalaya has reached at least half that of today (Prell and Kutzbach, 1992). A number of studies in the late 1980s investigated the climatic consequences of uplift (e.g., Ruddiman et al., 1989) and found that uplift may have been responsible for both the global cooling and significant strengthening of the Asian monsoon system in the late Cenozoic. According to the prevalent hypothesis, uplift of the Tibetan Plateau intensified around 8 Ma and caused enhanced aridity over the Asian interior and the onset of the Indian and east Asian monsoons (Figure M37a, Prell and Kutzbach, 1997; An et al., 2001). However, this cognition is challenged by the new discovery of Miocene loess (Guo et al., 2002) and other evidence that indicates an older age (see below).
2. **Sea-land distribution.** The results of Atmospheric General Circulation Model (AGCM) simulation by Ramstein et al. (1997) indicate that the Paratethys, an epicontinental sea stretching over Eurasia 30 Ma ago, had progressively receded during the Miocene, resulting in major continentalization of the Asian interior and enhancement of monsoon circulation. They consider the retreat of the Paratethys Sea as important as the uplift of the Himalayan/Tibetan Plateau

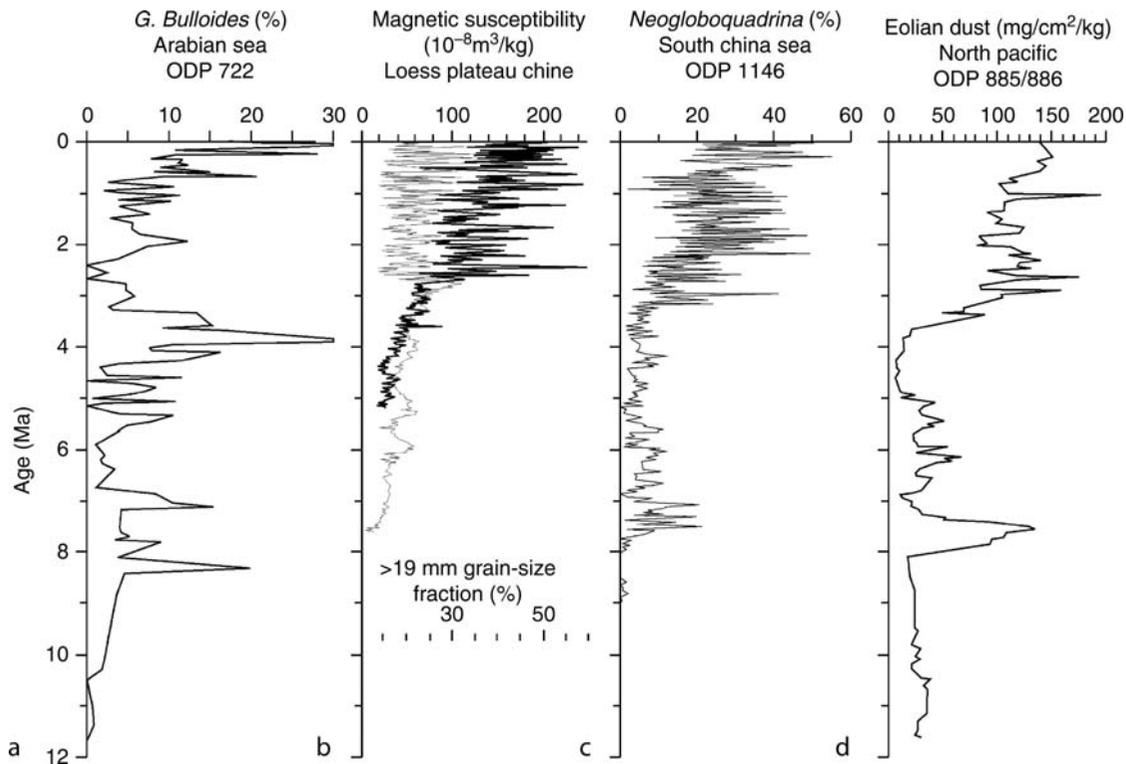

Figure M37 Records of Asian monsoon and aridity evolution over the past 12 Myr. (a) *Globigerina bulloides* % (>150 μm), ODP Site 722, Arabian Sea; (b) Magnetic susceptibility (thin line) and grain size fraction (thick line) from the Loess Plateau (An et al., 2001); (c) *Neogloboquadrina dutertrei* %, ODP Site 1146, South China Sea (Wang et al., 2003); (d) Dust flux ($\text{mg cm}^{-2} \text{ kyr}^{-1}$), ODP sites 885/886, north Pacific (Rea et al., 1998).

for development of the Asian monsoon. As the shrinkage of the Paratethys Sea occurred during the Oligocene-late Miocene, its effects on the monsoon may have lasted from 30 to 10 Ma, significantly earlier than the 8-Ma date implied by the uplift hypothesis.

3. **Oceanic gateways.** An oceanic circulation model reveals that the “closure” of the Indonesian seaway 3–4 Ma ago could be responsible for east African aridification (Cane and Molnar, 2001). The northward drift of the Australian Plate may have switched the source of the Indonesian Throughflow current from the warm South Pacific to the relatively cold North Pacific waters. This would have decreased Sea Surface Temperatures (SSTs) in the Indian Ocean and would have subsequently reduced precipitation over east Africa, as well as the overall strength of the Indian summer monsoon as recorded in marine deposits.

All of these three factors are believed to be significant in the development of the modern monsoon, but their relative roles remain unclear. To single out the role played by each of the factors, many more long-term sequences and better constraints on the timing of the tectonic and climate events are needed.

Geological records

Studies on the long-term evolution of the Asian monsoon started with ODP Leg 117 to the Arabian Sea in 1987. A sudden increase in the cool-water planktonic foraminifer *Globigerina bulloides* in sediment cores of Leg 117 around 8.5 Ma ago was considered by Kroon et al. (1991) as indicating the onset of monsoon-related upwelling (Figure M37a). This date is very close to the rapid ecological transition from C3-dominated to C4-dominated vegetation around 7.4–7.0 Ma, as revealed by the $\delta^{13}\text{C}$ data of pedogenic carbonates from northern Pakistan in the Himalayan foreland. These were interpreted as evidence for the origin or intensification of the Asian monsoon system (Quade et al., 1989). In addition, the dating of the extensive faults on the Tibetan Plateau suggests a significant uplift/extension period at about 8 Ma. On the basis of these findings and GCM simulations, Prell and Kutzbach (1992) hypothesized that uplift of the Tibetan Plateau to at least

half of its present height at ~8 Ma caused the intensification of the Asian monsoon.

In the Chinese Loess Plateau, the base of the loess-paleosol sequences dated to about 2.6 Ma was previously taken as indicating the initiation of the East Asian monsoon (Liu and Ding, 1993). Later, Chinese scientists found that the Red Clay underlying the loess sequence was also of wind-blown origin and indicative of monsoon transport (Table M4), so the history of eolian deposits of the Loess Plateau should be extended to 7–8 Ma (Figure M37b; An et al., 2001). Since the uplift of the Tibetan Plateau can lead to enhanced aridity in the Asian interior and to intensification of the Asian monsoon system (Kutzbach et al., 1993), a nearly concurrent beginning of both the Indian Ocean upwelling and dust accumulation in central China about 8 Ma ago has been interpreted as marking the onset of the Indian and East Asian monsoons, which in turn implies a significant increase in the altitude of the Plateau (An et al., 2001). However, the recent discovery by Guo et al. (2002) of a Miocene loess sequence from Qinan, western Loess Plateau, has further extended the Chinese dust history. Like the Pleistocene loess, the Miocene loess evinces enhanced aridity in the dust source areas and energetic winter monsoon winds required for dust transport, whereas paleosols point to increased moisture supply by summer monsoon winds. A total of 231 interbedded loess-paleosol layers, representing a nearly continuous history of eolian dust accumulation from 22 to 6.2 Ma, indicates that large source areas of eolian dust and energetic winter monsoon winds existed since early Miocene, at least 14 Ma earlier than previously thought (Table M4).

Noticeable climate change from arid to humid climatic conditions in East China occurred as early as around the Oligocene/Miocene boundary. The synthesized data from oil exploration and stratigraphic studies indicate that a broad aridity belt stretched across China from west to east during the Paleogene, particularly in the Paleocene, before it contracted to Northwest China in the Neogene (Figure M37), suggesting a transition from a planetary to monsoonal system in atmospheric circulation over the region. This climate transition, now confirmed by abundant paleobotanical/palynological and lithostratigraphic data, may further imply that monsoonal moisture brought westward from the ocean to East

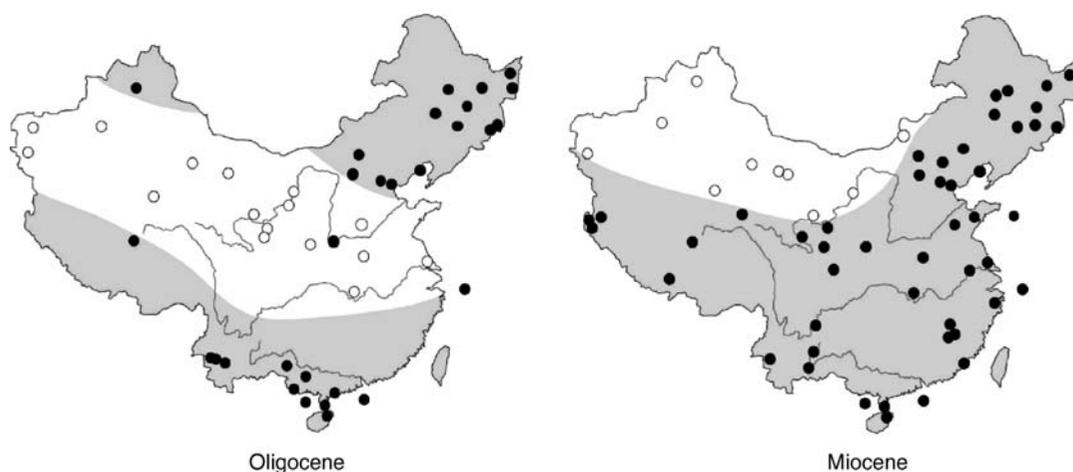

Figure M38 Distribution of arid climate zones in China based on paleobotanical and palynological data: (a) Oligocene; (b) Miocene. *Open dots* denote humid vegetation, *filled dots* denote arid vegetation. The Paleocene and Eocene patterns are similar to those of the Oligocene, while Pliocene and Pleistocene patterns are close to those of the Miocene. The drastic change between the Oligocene and Miocene implies the beginning of the modern East Asian monsoon system (Sun and Wang, 2005).

Table M4 Development of the dust history in the Loess Plateau, China

Deposits	Age	Reference
Loess-paleosol sequence	0–2.6 Ma	Liu and Ding, 1993
Red clay	2.6–8 Ma	An et al., 2001
Qinan loess sequence	6.2–22 Ma	Guo et al., 2002

China as a response to the reorganization of the climate system about 24 Ma ago was probably caused by an enhancement, if not the first establishment, of the East Asian summer monsoon (Sun and Wang, 2005). The loess-paleosol sequence at Qinan supports the Oligocene/Miocene climate transition. The existence of the Asian monsoon at about 16–14 Ma has been reported from northern Thailand, where middle Miocene mammalian faunas were found to have adapted to a monsoon-styled wet climate.

Sedimentological data from ODP Leg 116, Bay of Bengal also imply the intensification of uplift-induced monsoon in the early Miocene. Although the dramatic $\delta^{13}\text{C}$ increase of total organic carbon in Bengal Fan sediments at ca. 7 Ma supports the development of the monsoon in the Himalayan foreland at this time, the sediment accumulation records are in conflict with the 8 Ma uplift model. Accumulation rates at several DSDP/ODP Sites were high for the 17–7 Ma old Bengal Fan, but decreased from 7 to 1 Ma with the clay mineral assemblages indicating reduced physical erosion and strengthened chemical weathering (Derry and France-Lanord, 1997). No significant change in sediment accumulation around 8 Ma has been found at any ODP Leg 184 sites in the South China Sea (Wang et al., 2000). On the other hand, if using the planktonic foraminifer *Neogloboquadrina dutertrei* as an indicator of the East Asian monsoon and enhanced productivity in the South China Sea, its abundance peaks at 7.6 Ma and 3.2 Ma at Site 1146 on the northern slope correspond well to the Indian monsoon records (Figure M37c; Wang et al., 2003).

The dust record also indicates that the Asian monsoon system has a longer history and greater variability both in space and in time than previously thought. In the Miocene sequence of Qinan, two intervals are distinguished by higher dust accumulation: 15–13 Ma and 8–7 Ma (Guo et al., 2002). These might represent periods of enhanced aridity in the source areas, an interpretation supported by pollen data from Yumen, north-east of Tibet. Increased aridity over Asia around 8–7 Ma also explains a peak in dust accumulation rate in the North Pacific (Figure M37d; Rea et al., 1998).

Monsoon evolution in geological history

The number and geographic coverage of the monsoon records decrease with increasing age, resulting in relatively deficient knowledge of the pre-Quaternary monsoon history. Although it may be premature to discuss the evolution of the monsoon system through the entire geological history, the examples of the Pangaeian and late Cenozoic times provide convincing evidence that tectonically-induced changes in sea-land distribution and in topography have played the primary role in controlling the monsoon system over the 10^6 – 10^7 year and longer timescales. Tracing back the entire Phanerozoic history, the monsoon system strengthened with increased size of continents and increased altitude of mountains. With the collapse of the megacontinent, for example, the “megamonsoon” circulation over Pangaea was subsequently replaced by a basically zonal circulation (Parrish et al., 1982). The late paleozoic American

Appalachians (estimated average altitude of 4,500 m) and the European Variscan (2,000–3,000 m) in Pangaea might have played a role similar to the late Cenozoic Himalaya-Tibet in the intensification of the concomitant monsoon circulation (Fluteau et al., 2001).

The development of polar ice-sheets is another major control of the monsoon system. Clemens et al. (1996) found a non-stationarity in the phase of the summer monsoon system relative to a growing Northern Hemisphere ice volume over the past 3.5 Myr. During the initiation and the growth of the Northern Hemisphere ice sheets, the phase of strong monsoons moved away from the phase of maximum ice volume and systematically drifted in a similar pattern over the past 2.6 Myr. An intensified winter monsoon resulting from the growth of the boreal ice sheet was also reported from the Chinese loess records (Liu and Ding, 1993). Accordingly, the nature of the monsoon system in the ice-house vs. hot-house Earth must have been different, and the transition between hot- and ice-house regimes can be of paramount importance for reconstructing the monsoon history.

A trustworthy reconstruction of the monsoon history depends on the proxies adopted. Care is necessary to evaluate how the monsoon proxies that were developed for the Quaternary period can be applied to the earlier geological past. It is equally crucial to distinguish monsoon proxies from those driven by other factors. An example is the late Miocene development of C4 vegetation, exhibited by a $\delta^{13}\text{C}$ shift in pedogenic carbonates, which was considered by Quade et al., (1989) as a signal of the onset of the Indian monsoon when first found in Pakistan. Since many subsequent findings have occurred in various continents, this $\delta^{13}\text{C}$ shift has been re-interpreted as representing a large-scale vegetation change caused by decreased CO_2 concentration on the globe (Cerling et al., 1997).

Regardless of all the complexity, paleo-monsoons are increasingly important in pre-Quaternary studies. Climate variations throughout geological history have been driven not only by higher latitudes where ice-sheets develop but also by lower latitude factors, especially by the monsoons.

MONSOONS, QUATERNARY

Definition

The word “monsoon” is from the Arabic word “mausim,” meaning *season of winds*, which is often applied to the seasonal reversals of the wind direction along the shores of the Indian Ocean and surrounding regions, especially in the Arabian Sea. The prevailing winds blow from the southwest during half of the year and from the northeast during the other (Figure M39).

Monsoons are driven by the land-sea thermal contrast as the continent heats up and cools down faster than the ocean. Thus, in summer, land reaches a higher temperature than the ocean and the hot air over the land tends to rise, creating an area of persistent low pressure. This produces an extremely constant wind blowing toward the land. Associated rainfall is generated as the moist ocean air is diverted upward by mountains, which causes cooling, and in turn, condensation. In winter, the land cools off quickly, but the ocean retains heat longer. The warmer air over the ocean rises, creating a low pressure area and a breeze from land to ocean. Because the temperature difference between the ocean and land is less than in summer, the winter monsoon winds are weak and variable. Monsoons are similar to sea breezes, but they are much larger in extent, stronger, and are more constant.

Monsoon systems

As monsoons have become better understood, the definition has broadened, indicating climatic systems in which the precipitation is largely confined to the warm season. Monsoons

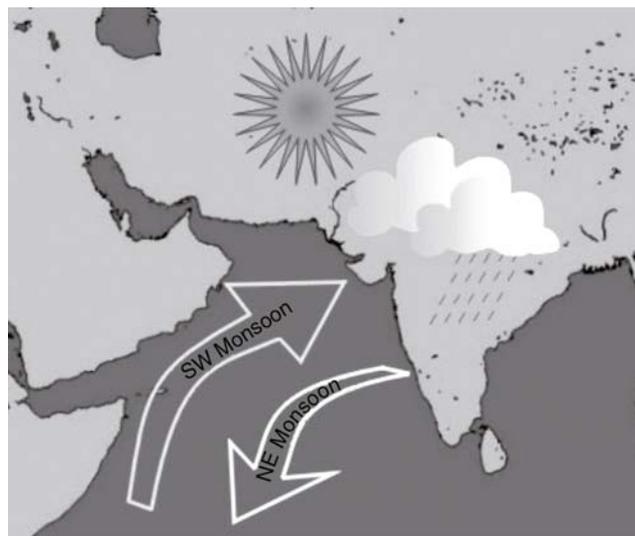

Figure M39 Asian monsoon circulation marked by the southwest or summer and northeast or winter monsoon winds. The Indian landmass receives maximum solar insolation during the summer monsoon months (June–September).

now include almost all of the phenomena associated with the annual weather cycle within the tropical and subtropical parts of Asia, Africa, Australia, North America and the adjacent seas and oceans.

The southwest or summer monsoon occurs from June to September, marked by wet and strong winds, providing maximum rainfall to the Asian landmass. The northeast or winter monsoon season ranges from December to early March, during which time the winds are dry and weak, and precipitation is reduced over the land. However, Australia and Southeast Asia receive enough rainfall during the winter monsoon. The North American monsoon occurs from mid-July to September, affecting mainly southwestern parts of the United States. The Indian or Asian monsoon, which affects South and Southeast Asia as well as northern Africa, is the best known and most regular of the world's monsoons, and one of the most spectacular features of the tropical climate system, affecting ~60% of world population between 30° N and S latitudes.

The Indian monsoon system

The Indian monsoon system is believed to have evolved in the late Oligocene or early Miocene, and appears to have had a major shift in its intensity and seasonal duration ~8.5 Ma BP. (e.g., Gupta et al., 2004). Rapid changes in the monsoon in the late Quaternary and the Holocene are documented in numerous papers based on proxies from marine records of the summer monsoon winds (Schulz et al., 1998; Gupta et al., 2003), cave deposits that record precipitation in Oman (Neff et al., 2001; Fleitmann et al., 2003), peat deposits that indicate humidity and temperature (Hong et al., 2003), runoff in the Bay of Bengal (Kudrass et al., 2001), and fluvial sediments indicating the intensity of rainfall (Sharma et al., 2004; also Figure M40). Strong monsoon events had a potentially dramatic effect on the fluvial systems (Goodbred and Kuehl, 2000), the terrestrial and marine fauna and flora, and human populations in Asia during the Holocene (past 10,000 years) (Gupta et al., 2003; Gupta, 2004).

Across the Asian region, the effects of the monsoon are preserved in numerous proxies that include tree rings, soils, ice, lake deposits, peat deposits, cave deposits and marine sediments. Paleoproxies provide evidence of slow changes in the monsoon related to solar insolation, and evidence of abrupt, multi-decadal to millennial scale events throughout the Quaternary and the Holocene.

Quaternary changes

As the climate entered the glacial-interglacial mode during the Quaternary, the Indian monsoon system also underwent parallel changes (e.g., Schulz et al., 1998; Leuschner and Sirocko, 2003). For instance, the intervals of cold spells in the North Atlantic have been found to be aligned with intervals of weak summer monsoon (e.g., Schulz et al., 1998), during which time the winter monsoon strengthened (Fontugne and Duplessy, 1986). The summer monsoon oscillated with millennial-scale variability (the Dansgaard-Oeschger (D-O) and Heinrich events), concentrated at periodicities of ~1,100, 1,450, 1,750 and 2,300 yr during the last glacial (Naidu and Malmgren, 1995; Sirocko et al., 1996). This pattern is almost similar to that of changes in the Greenland ice cores (Schulz et al., 1998; Leuschner and Sirocko, 2003) (also Figure M40).

Despite numerous assertions, the origins of millennial-scale (sub-Milankovich or sub-orbital scale) abrupt changes in the

monsoon remain elusive. Conceptual and numerical models indicate that these climate changes could originate in the tropics (e.g., Hoerling et al., 2001) or in the North Atlantic (Bond et al., 2001). Changes in tropical sea surface temperatures over the Indian and Pacific Oceans are capable of producing changes in the North Atlantic Oscillation in coupled climate model simulations, resulting in warmer temperatures associated with the positive phase of the North Atlantic Oscillation (Hoerling et al., 2001). Other changes linked to the hydrological cycle, such as changes in the quantity of water vapor in the atmosphere, or vegetation-driven greenhouse gases (Stott et al., 2002), could produce a cooling effect that is amplified at high latitudes. Alternately, the North Atlantic could drive the observed changes in the tropics (Bond et al., 2001).

Holocene variability

Repeated occurrences of millennial-scale weak and strong phases of the Indian summer monsoon characterize the Holocene record (Figure M41). The summer monsoon was stronger in the early Holocene, which is evident in the enormous Ganges-Brahmaputra sediment discharge (Goodbred and Kuehl, 2000), rapid speleothem growth reported in Oman (Burns et al., 2001) and the dominance of conifers and broad-leaved trees in the Central Higher Himalayas (Phadtare, 2000). During the period between ~10,400 and 5,500 cal yr BP, Northern Hemisphere temperatures peaked and the Indian, Southeast Asian and African monsoons reached their maximum – the so-called “Holocene Climatic Optimum.”

The early Holocene monsoon maximum was interrupted by an abrupt cooling peak ~8,200 cal yr BP. (Alley et al., 1997), during which time the summer monsoon over the Indian subcontinent and tropical Africa weakened (Gasse, 2000). Successive shifts towards drier conditions in northern Africa and Asia intensified after ~5,500 cal yr BP. (Overpeck et al., 1996; Gasse, 2000), which contributed to the termination of ancient civilizations in the region. Sustained drought due to aridification led to societal collapse of the Egyptian and Mesopotamian civilizations at around 4,200 cal yr BP. (Weiss et al., 1993; Cullen et al., 2000). The evaporation dropped during the arid phase in India (Sharma et al., 2004), and the Indus Valley civilization transformed from an organized urban phase to a post-urban phase of smaller settlements with southward migration of the population (Allchin and Allchin, 1997; Staubwasser et al., 2003; Gupta, 2004).

The summer monsoon was weakest from ~2,500 to 1,500 cal yr BP. in the late Holocene (Anderson et al., 2002; Gupta et al., 2003). During the Medieval Warm Period (AD. 900–1400), the summer monsoon strengthened (Gupta et al., 2003) whereas during the most recent climatic event, the Little Ice Age (AD. 1450–1850), there was a drastic reduction in the intensity of the summer monsoon (Gupta et al., 2003).

Centennial to millennial-scale changes and forcing mechanisms

Previous studies have demonstrated that the interannual variability of the Indian summer monsoon is controlled by the Eurasian snow cover (Bamzai and Shukla, 1999) and the amplitude and period of El Niño Southern Oscillation (ENSO) (Krishna Kumar et al., 1999). Long term variability in the Indian summer monsoon on millennial scales may be attributed to solar forcing (Neff et al., 2001; Fleitmann et al., 2003) and

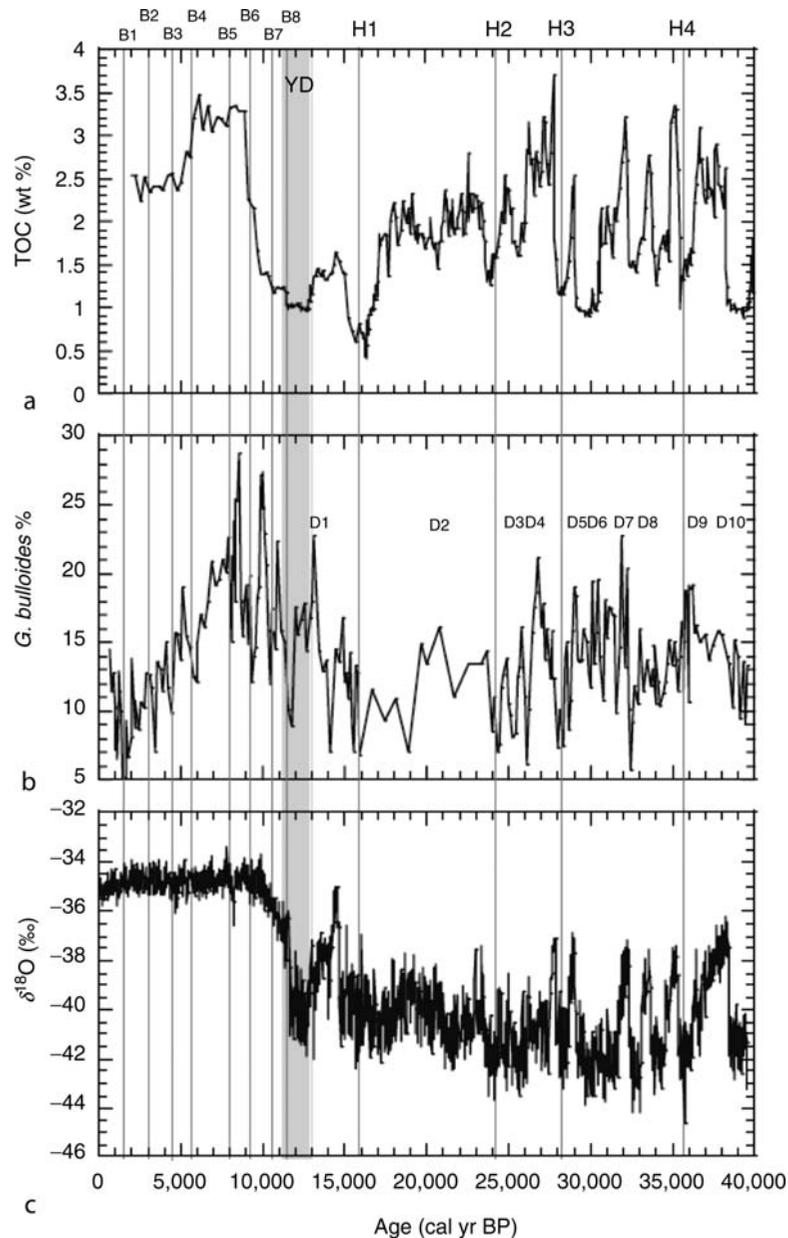

Figure M40 Summer monsoon proxy record for the late quaternary from the Arabian Sea. glacial interglacial boundary conditions (Burns et al., 2001). Major monsoon fluctuations on decadal to centennial scales during the Holocene have been attributed to changes in surface boundary conditions (Overpeck et al., 1996) and the North Atlantic climate due to changes in the North Atlantic Deep Water production (Gupta et al., 2003), and solar activity (Neff et al., 2001; Gupta et al., 2005).

The extent/duration of the snow and ice cover has been suggested as a cause of monsoon variability due to the albedo feedback of snow and ice-fields (Shukla, 1987). Increased albedo of

snow delays the seasonal heating cycle over Asia and thus delays and weakens the summer monsoon. Previous workers have also suggested that fluctuations in the monsoon intensity may be forced by variations in the tropical land-surface boundary conditions (Gasse and van Campo, 1994). Increased summer monsoon strength may lead to denser vegetation cover in Central Asia that reduces surface albedo of the region, increasing the land-sea thermal contrast and thus the summer monsoon strength.

Stuiver and Braziunas (1993) suggested that solar variability could be an important factor affecting climate variation during

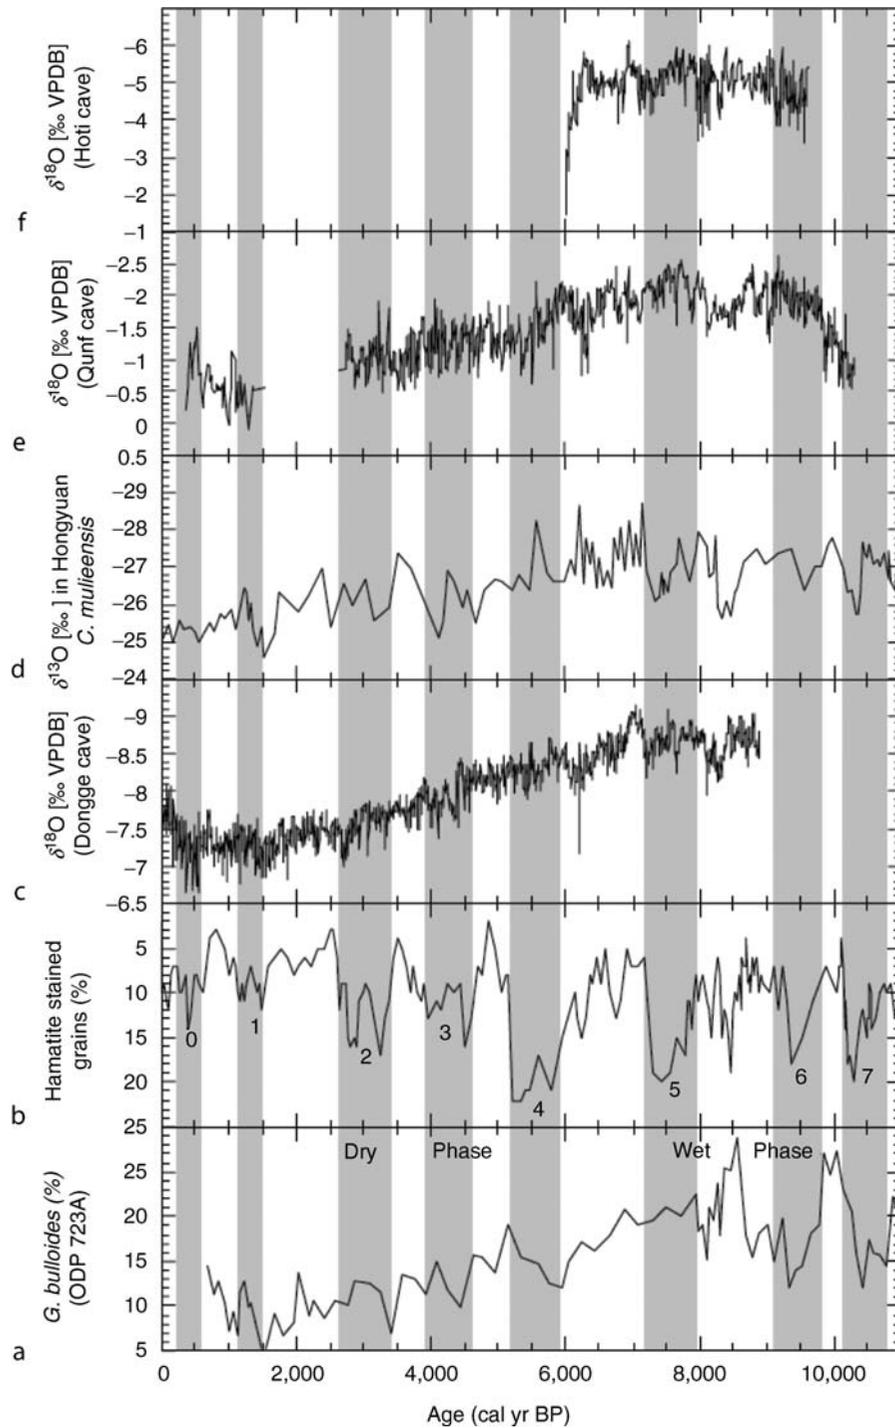

Figure M41 Visual correlation between proxy records. (a) *G. bulloides* percent from ODP Hole 723A, Arabian Sea (Gupta et al., 2003); (b) hematite % in core MC52 in the North Atlantic (Bond, et al., 2001); (c) oxygen isotope record from Dongge Cave, southern China (Wang et al., 2005); (d) Hongyuan peat deposit (Hong et al., 2003), (e) Qunf Cave $\delta^{18}\text{O}$ (Fleitmann et al., 2003), and (f) Hoti Cave $\delta^{18}\text{O}$ (Neff et al., 2001). the Holocene on the basis of analysis of ^{14}C records from tree rings. The production rates of cosmogenic nuclides (^{14}C and ^{10}Be) that reflect changes in solar activity appear to be closely correlated to Bond Cycles (Bond et al., 2001). Although the

exact process by which global climate and solar forcing may be linked is not clearly understood, variations in ultraviolet radiation and cosmic ray flux may trigger abrupt climate changes by altering the heat budget of the stratosphere

(van Geel et al., 1999) and changing the atmosphere's optical parameters and radiation balance (Kodera, 2004). The summer monsoon intensity has been positively related to changes in solar insolation not only at the Milankovitch scale (Clemens et al., 1991; Leuschner and Sirocko, 2003), but also at decadal and centennial scales, as documented by various recent studies (Wang et al., 1999; Neff et al., 2001; Gupta et al., 2005). For example, Gupta et al. (2005) observed a relation between intervals of low sunspot activity and low intensity of the summer monsoon during the Holocene.

Solar variability may lead to changes in the circulation pattern of the atmosphere and may amplify the variability of the oceanic circulation. Model results have explained the mechanism of the dynamic response of atmospheres to solar forcing (Shindell et al., 2001). A recent study from the Arabian Sea suggests that even small changes in solar output can cause pronounced changes in the tropical climate, emphasizing the importance of a sun-monsoon link (Gupta et al., 2005).

Conclusions

Summer monsoon variability has important implications on the human population of the Asian-African region as the summer monsoon winds bring rainfall to most parts of the region, thus enhancing agricultural productivity. During the early Holocene, when the summer monsoon intensity was high, several Asian rivers were in their full vigor, and plants and animals were domesticated in the Indian subcontinent along the banks of the River Indus and its tributaries. However, prolonged droughts after the beginning of the arid phase (~5,000 cal yr BP) in the Indian subcontinent led to population dislocation, widespread migration, and state collapse of the Harappan Civilization. Some people resorted to modifying their dwelling environments by developing new strategies to optimize the utility of available water rather than migrating to safer places. It appears that the hydrological changes in South Asia had the greatest effect on human settlements, as opposed to the theory that temperature changes controlled the migration of the population. Intervals of weak summer monsoon and cold spells in the North Atlantic coincided with low sunspot activity during the Holocene, indicating that the response of both the tropics and high latitudes to solar variability was direct. The monsoon could be sensitive to relatively small changes in solar forcing. The sun-monsoon link can be explained by a direct solar influence on the Intertropical Convergence Zone that controls monsoonal precipitation. It can thus be concluded that solar variability plays an important role in driving multidecadal to millennial-scale changes in monsoon climate.

MORAINES

A moraine is a glacial landform created by the deposition or deformation of sediment by glacier ice. Many different types of moraine exist, reflecting the many different processes by which glaciers deposit and deform sediment and the many locations and environments within the glacier system where

deposition can occur. Moraines are composed of till, which is also highly variable, as its characteristics depend on the characteristics of the debris supplied by the glacier as well as on the processes and environment of glacial deposition.

The morphology and sedimentology of moraines can be used to reconstruct the characteristics of former glaciers. Their distribution reflects the geography of former glaciers and glacial process environments. Sediment characteristics reflect the source location of the debris: supraglacial debris is characteristically angular, while basally derived debris is typically faceted, subrounded and striated. Structures within moraines can reveal seasonal and long term variations in processes of sedimentation.

Moraines are classified both genetically according to the process by which they are created and geographically according to their position within the glacier system. The principal processes by which moraines are created are the release of debris from ice by meltout and the deformation of proglacial or subglacial sediments by ice motion. Supraglacial moraines include lateral moraines, medial moraines and inner moraines. Subglacial moraines occur parallel or perpendicular to ice flow or in irregular patterns. Ice marginal moraines occur around the edges of glaciers and are defined by their position as either lateral or frontal moraines. Moraines marking the maximum extent of a glacial advance are referred to as terminal moraines. Moraines deposited at successive positions of the margin during a period of progressive retreat are recessional moraines. Marginal moraines at existing glaciers are typically ridges of sediment resting partially on the edge of the glacier. Upon deglaciation, ice-cored moraines lose their ice support and therefore tend to shrink in size and may become structurally unstable. Marginal moraines may be several tens of meters in height, tens or hundreds of meters across, and may stretch for hundreds of kilometers around the margins of large ice sheets.

Moraines provide long-term storage within the glacier sediment transfer system, and a supply of debris to the proglacial zone. Sediment flux within glaciated basins is very sensitive to the position of glaciers relative to their moraines. When glaciers lie behind marginal moraines the bulk of sediment produced at the margin can go into storage in the moraine belt and not reach the proglacial region. When glaciers have no marginal moraines, sediment passes directly into the proglacial system. Moraines can also focus meltwater discharge, localizing fluvial processes and causing moraine-dammed lakes. These lakes are potentially unstable and pose a serious threat of catastrophic flooding. Bennett and Glasser (1996) and Benn and Evans (1998) provide a useful review of this topic.

MOUNTAIN GLACIERS

Mountain glaciers are constrained by the topography of the underlying bedrock. They can assume a wide variety of forms such as cirque glaciers and valley glaciers, which generally have unidirectional flow, and ice caps, which usually sit atop peaks and flow radially from central summit locations. Often, ice caps contain outlet glaciers at their bases. Mountain glaciers occupy the upper altitudes of many ranges on all the continents except Australia (although they also occur in New Zealand and New Guinea), and are most extensive on the Tibetan Plateau, in Southern Alaska, and in the South American Andes. In fact, 70% of all the world's tropical mountain glaciers are located in the Peruvian Andes. Mountain glaciers around the Gulf of Alaska cover an area of 32,400 square miles, about 13% of the world's ice coverage, and include some of the largest glaciers outside the polar regions. In general, the closer to the equator a glacier is located, the higher the elevation, since the 0°C isotherm (temperature at which ice ablates) increases in altitude with decreasing latitude. Thus, Alaskan and high Canadian mountain glaciers currently exist at altitudes as low as 3,000 meters above sea level (m a.s.l.), while some mountain glaciers near the equator, such as those on Huascarán in Peru (9° S) and Kilimanjaro in Tanzania (3° S), can only survive at altitudes greater than 5,500 m a.s.l. In the tropics, these glaciers are vital for the local populations since they are often important sources of drinking water and hydroelectric power.

Tropical mountain glaciers often occur in regions that are affected by strong seasonal variations in precipitation (for example, monsoon environments), thus wet and dry seasons are recorded as easily discernable layers. Because these glaciers are relatively small (compared with the polar ice sheets) and lie close to the 0°C isotherm, they can respond quickly to variations in temperature and effective moisture, and thus serve as reliable "barometers" of climate change. For these reasons, in the last 20 years mountain glaciers, particularly ice caps, have become valuable sources of information about past climate change and thus have placed the current global climate change in perspective. The length of the climate record contained in a mountain glacier is constrained primarily by two things: the net accumulation of snow each year, and the temperature of the

glacier at its base. A glacier that contains a climate record that covers several millennia often (but not always) occurs in regions where the annual snowfall is relatively low (less than a meter per year), but more importantly the temperatures are cold enough that the base of the ice is frozen to the bedrock. This prevents the removal of annual layers from the bottom, which is very important since ice is compressed during burial, and more annual layers are contained in smaller increments with depth. Mountain glaciers in such environments can be found in the highest altitudes of the Andes Mountains, the Tibetan Plateau, the Alaskan and Canadian Arctic region, and of course in the mountain ranges in Antarctica and Greenland. Temperate glaciers, in which some of the ice (usually at the base) is above the pressure melting point, usually contain shorter records of climatic and environmental variation, and these occur at lower altitudes and latitudes.

The clearest evidence for the current major climate warming comes from the tropical glaciers, recorded in both the ice core records and in the drastic and accelerating retreats of both total area and total ice volume. The recent warming trend has contributed greatly to the accelerating rates of mountain glacier retreat, especially in the climatically stable tropics where the average intraseasonal temperature change is usually no greater than 1–2°C. For example, the Qori Kalis Glacier in Peru now retreats on average over the last 15 years more than 60 meters per year, more than 10 times faster than during the first 15 years of measurement starting in 1963. Similarly, the ice on Mount Kilimanjaro, Africa, which covered ~4.3 square miles in 1912, only covers 0.94 square mile today. If the current rate of retreat continues, the perennial ice on Kilimanjaro will disappear within the next 15–20 years, the first time in the past 11,000 years that Kilimanjaro will be devoid of ice (Thompson et al., 2002). The documentation of this can be seen in the two photos in Figure M42 taken in 1912 and in 2000.

Dramatic mountain glacier retreat is also observed at high latitudes. The glaciers in southern Alaska are experiencing very high rates of precipitation and runoff, up to 400 cm yr⁻¹. Recent work suggests that melting and calving of Alaskan glaciers make up about one-half of the total global glacial contribution to sea level rise (Arendt et al., 2002). However, while the glaciers of Alaska are retreating due to marked warming in this region, some glaciers in Norway and Sweden which had been advancing because of the

Figure M42 The ice cap on Kilimanjaro in Tanzania (3° S) in 1912 (left) and in 2000 (right).

more northerly trajectory of storms that bring higher snowfall have since 1999 have also begun to retreat as the temperature rise has started to over shadow the increase in winter snowfall.

The rapid retreat of the world's mountains glaciers causes grave concern for three reasons. First, they are the world's "water towers," and their loss threatens water resources necessary for hydroelectric production, crop irrigation, and municipal water supplies for many nations of the world. The ice fields constitute a "bank account" that was built up over thousands of years, and is drawn upon during dry times to feed and energize populations downstream. The current melting is cashing in on that rapidly dwindling bank account. Second, these ice fields contain paleoclimate histories that are unattainable elsewhere and, as the ice fields melt, the records preserved therein are lost forever. The records are needed to discern how climate has changed in the past in these sensitive regions and to assist in predicting future change. Finally, one of the important aspects of glacier retreat on a global scale is the potential contribution that it makes to sea-level rise.

MOUNTAIN UPLIFT AND CLIMATE CHANGE

Fossil shells in 400 million year old limestone near the arid, 8.8 km high summit of Mount Everest provide clear evidence for large-scale uplift of the Himalaya. South of the range crest, the southern flank of the Himalaya descends to near sea level and receives several meters of rain from the southeastern monsoon each summer. To the north, the Tibetan Plateau rises to an average elevation of 5 km and experiences a semi-arid climate.

The spatial juxtaposition of these contrasting physiographic regions and their strikingly different climates raise two fundamental questions: how does mountain uplift affect climate and climate change; and to what extent does climate change affect the uplift of mountain belts? Everyday experience indicates that mountains affect weather and climate. Clouds gather around mountain summits, rainfall is commonly greater at higher elevations, and precipitation is typically reduced downwind of mountain ranges. The provocative contention that climate could affect the growth of mountain ranges (Molnar and England, 1990) has motivated recent research efforts to explore the potential interactions between

climate, erosion, and tectonics. Numerical models that link geodynamic deformation with climate and erosion predict that gradients in climate can drive analogous spatial gradients in erosion, which, in turn, can modulate where deformation occurs within an orogen (Willett, 1999; Beaumont et al., 2001). Such reasoning suggests that the direction from which prevailing winds bring moisture into a mountain belt could ultimately determine the patterns and rates of strain and rock uplift within the orogen. Testing of these predictions has only recently begun, but synthesis of geodetic, geophysical, geological, climatic, and geomorphic data are beginning to provide insights on the nature, magnitude, and rates of the interactions that affect the Earth's surface and its deformation.

Initially, the impact of mountain uplift on climate and climate change is described. Subsequently the potential effects of climate on mountain uplift and evidence for such interactions are discussed.

Mountain uplift and climate

Orographic precipitation

Orographic precipitation refers to the impact that topography exerts on the distribution of precipitation. In the simplest form, mountain ranges cause enhanced rainfall on the upwind side of a range and generate decreased rainfall on the downwind flank. As air masses move across a landscape, mountains present topographic barriers that force diversion of the air mass through some combination of flow over the crest of the mountains and flow around its flanks. Two competing characteristics of air masses determine precipitation where moisture-laden air encounters mountainous topography (Roe et al., 2002). First, if relative humidity is constant in a static column of air then the moisture content decreases as temperature decreases with height (at a rate of $\sim 6.5^\circ\text{C km}^{-1}$). This lowered moisture content promotes decreasing precipitation at higher elevations (Figure M43). Second, as wind pushes moist air masses toward the flanks of mountains, the air is forced upslope, causing a convergence of moisture in the air column. The cooling that occurs as the air is lifted upslope increases the relative humidity. When combined with moisture convergence, the cooling leads to saturation and to rainfall of the moisture in excess of saturation (Roe et al., 2002). Hence, as air masses rise up the flanks of a mountain range, rainfall commonly increases (Figure M43). On the downwind side, as descending air masses warm adiabatically, their relative humidity drops and rainfall abruptly decreases, thereby creating a rain shadow.

Both the amount of moisture in an approaching air mass and the height of a given mountain range have finite limits. Two competing effects serve to determine the rainfall distribution. As more and more water is wrung out of the air due to orographic rainfall on upwind flanks of ranges, the reduced amount of remaining atmospheric moisture reduces the rainfall potential at higher elevations. In contrast, the steepening of slopes that characterizes the upper reaches of mountains (Brozovic et al., 1997) causes more rapid moisture convergence and tends to increase rainfall potential. The net result is that, for ranges of modest relief ($\sim 1\text{--}2$ km), rainfall tends to increase near the range crest, whereas for ranges with high relief (>3 km) rainfall can decrease on the upper parts of the windward flanks. The latter effect is well illustrated in the Himalaya, where the peak monsoonal precipitation of $4\text{--}5\text{ m yr}^{-1}$ occurs several kilometers below and >10 km to the south of the range crest (Figure M44). By 10 km north of the Himalayan crest, monsoonal rainfall has dropped to $<1\text{ m yr}^{-1}$, and at altitudes exceeding ~ 6.5 km, precipitation is negligible (Harper and Humphrey, 2003).

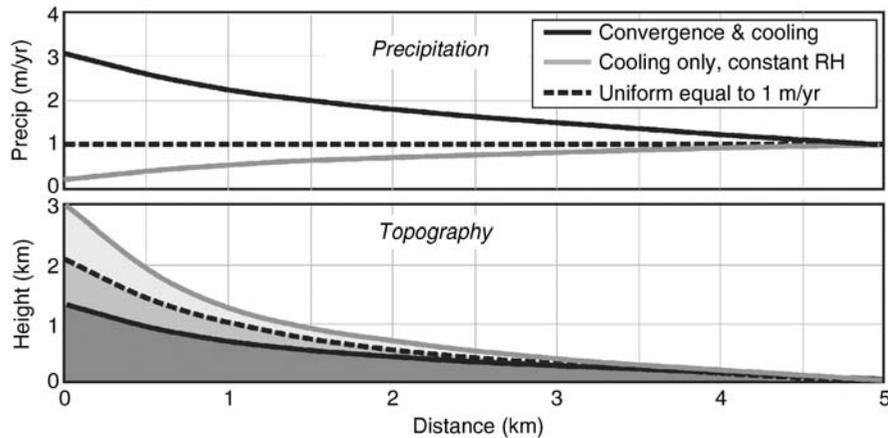

Figure M43 Orographic precipitation for a range experiencing rock-uplift rates of 2 mm yr^{-1} . (a) *Top*: Theoretical predictions of orographic precipitation with the range crest on the left of each panel. With increasing altitude (moving from right to left), air masses cool as they expand. If relative humidity (RH) is held constant, the air holds less moisture and produces less rainfall (“cooling only” curve *light gray line*). Wind blowing toward a mountain range causes vertical convergence of air masses and increases water content. Convergence and cooling increase RH, driving condensation and enhancing rainfall (the orographic effect *heavy, black line*). *Bottom*: Trends in rainfall with distance from the range crest affect equilibrium river profiles, such that river incision balances rock-uplift rates. With less rain toward the divide (cooling-only curve), the river channels are steeper and the height of the range crest is 50% greater than in the absence of orographic feedbacks, which tend to lower the range crest and channel gradients (*heavy black line*). Note the nearly 3-fold difference in ridge height between the “cooling-only” case and the “convergence and cooling” case. (Modified after Roe et al., 2002.)

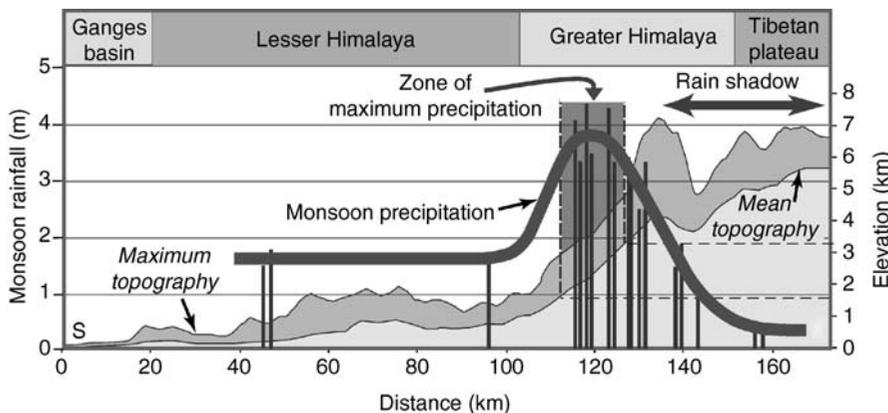

Figure M44 Example of orographic precipitation in the central Nepalese Himalaya. Orographic lifting caused by monsoonal storms from the Indian Ocean that impinge on the Himalaya enhances rainfall. The greatest rainfall occurs at $\sim 2,500 \text{ m}$ elevation, where the summertime maximum precipitation reaches $\sim 4 \text{ m yr}^{-1}$. Loss of moisture as the air masses cross the Himalaya creates a striking rain shadow to the north with only $\sim 10\%$ as much rain. (Modified from Burbank et al., 2003.)

As climate changes, the presence of mountains induces non-linear changes on orographic precipitation. For example, the typical average atmospheric cooling of $5\text{--}6^\circ\text{C}$ during glacial maxima dictates that air masses will, on average, hold less moisture. Such a reduction means that the total precipitation will be reduced overall and the zone of maximum rainfall may be moved farther from the range crest in ranges with high relief. As even less moisture creeps over the range crest, rain shadows can deepen. Although few reliable proxies exist for rainfall during glacial times, an observed steepening of regional glacial snowline gradients across high ranges like the Himalaya (Williams, 1983; Pratt et al., 2002; Burbank et al., 2003) implies an enhanced orographic effect on precipitation during glacial times.

Air mass trajectories

Mountain ranges represent physical barriers to air masses blown toward them. Two behaviors are commonly observed as air masses encounter topography: some air flows up and over the crest of the range, whereas some is diverted around the range margins. The balance between these two effects is determined by the height and lateral continuity of the range and by wind strength. Even when flowing over the mountains, much air flow is funneled through the lowest topography. Ranges with isolated high summits present less effective barriers than do more plateau-like ranges. Hence, volcanic arcs will cause less diversion than block uplifts. For example, both the Cascades of Washington and the Sierra Nevada of California are oriented nearly perpendicular to the prevailing storm tracks off the Pacific Ocean. Whereas isolated

volcanic peaks in the Cascades rise to elevations $>3\text{--}4$ km, many mountain passes lie below 2 km and much moisture funnels through these passes. The regional patterns of past glacial snowlines (a function primarily of precipitation and temperature) show that, similar to today, moisture was funneled up the major drainages during glacial climates (Figure M45). Although the Sierra Nevada also has summits rising to ~ 4 km, the passes along its crest are commonly >3 km in elevation, thereby creating a formidable barrier across the path of approaching storms and leading to diversion around the range's southern and northern ends. Similar to other ranges forming block-like barriers, the moisture that does penetrate the Sierra Nevada tends to be funneled along major river valleys (Burbank, 1991).

The impact of an individual range on regional climates can alter during climatic changes. As ice sheets accumulate at high latitudes during glacial times, the average position of the jet stream and the intertropical convergence zone migrates latitudinally. At the same time, storm trajectories also change with respect to ranges that could potentially block or divert them. As a consequence, the impact of mountainous topography on precipitation patterns will change coevally with major climatic variability, as storm tracks, total atmospheric moisture, and wind strength are altered.

Continentality and fringing ranges

As an air mass flows over ocean to land, it leaves its major source of evaporative moisture behind. Once over land, the normal extraction of moisture via rainfall commonly causes a progressive drying of the air mass, such that downwind regions will become increasingly dry, unless new moisture sources are added. Thus, farther inland on large land masses, continentality increases as the distance from major moisture sources grows.

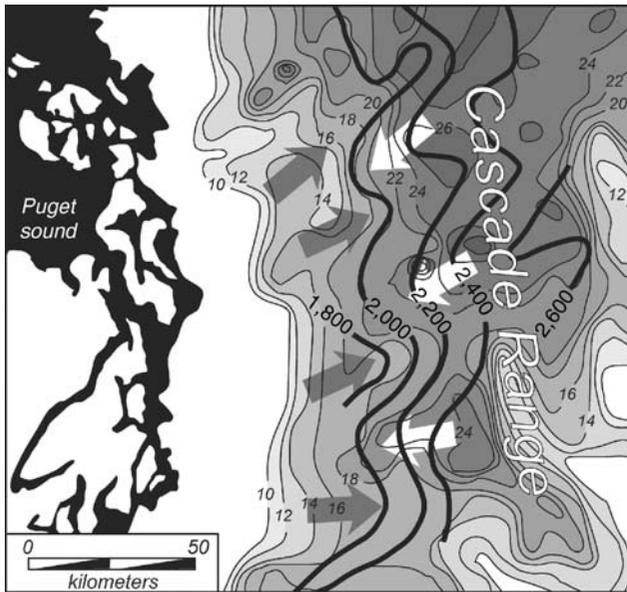

Figure M45 Pattern of glacier snow lines during the past glaciation as reconstructed from the height of cirques in the northern Cascade Range, Washington. The re-entrants (dark arrows) in the snowline elevations (heavy contours) correspond primarily with low topography along river drainages, whereas the salients (white arrows) correspond primarily with higher topography. River valleys funnel more moisture to the interior of the range, thereby lowering snowlines. (Modified after Porter, 1977.)

For example, central Asia's isolation from major moisture sources creates continental deserts in mid-latitude regions that normally experience temperate climates. Aridification of this region occurred at least 20 Ma ago (Guo et al., 2002) and was undoubtedly enhanced by the growth of the Himalaya that blocked northward moisture transport from the Indian Ocean.

The existence of fringing mountain ranges along the margins of continents can augment the magnitude of continentality. If the mountains are oriented across major storm trajectories, orography can efficiently extract moisture in the near-coastal region and create residual air masses that are even more depleted in moisture than they would be in the absence of coastal topography. Thus, north-south-oriented ranges like the Andes, Cascades, and Sierra Nevada have a larger impact on downwind continentality than do east-west-trending ranges like the Utiyas, European Alps, or Pyrenees that are oriented more parallel to prevalent storm trajectories. Even these storm-track-parallel ranges enhance continentality, however, because air masses diverted around their flanks travel a longer path and lose more moisture than they would in the absence of the range.

Plateau growth and monsoons

Summer monsoons, which can drop several meters of rainfall over 2–4 months, are one of the world's most dramatic climatic phenomena. The contrast in the heat capacity of water versus soils results in differential responses to seasonal changes in insolation. During summer months, terrestrial areas warm more rapidly than the oceans, causing lowered atmospheric pressure over the land as air masses warm, expand, and vertically ascend. The consequent lateral atmospheric flow from surrounding higher pressure zones over the oceans draws water vapor toward the continental interiors. Once over land, release of latent heat during precipitative condensation warms the surrounding air even more and creates a positive feedback by lowering atmospheric pressure over the land still further and enhancing the regional pressure gradient and resultant landward flow. Thus, differential heating and release of latent heat during rain storms can create a monsoon, an intensified summer precipitation cycle over continents.

Summer monsoons exist over northern Australia, the Amazon, and western Africa, but the Asian monsoon is the best known and typically the strongest. Much of the strength of the Asian monsoon derives from the presence of the Tibetan Plateau. The largest plateau on Earth, the Tibetan Plateau encompasses ~ 2.5 million km^2 , an area about one-third the size of the continental United States, and averages 5 km in elevation (Fielding et al., 1994). Although summertime temperatures in Tibet are cool by most human standards, Tibet is the warmest place on Earth at 5 km elevation. Because soils absorb, retain, and re-radiate heat much more effectively than does air, the Tibetan Plateau represents a hot island surrounded by an otherwise cool atmosphere at 5 km above sea level. This warmth drives the summertime low-pressure system over southern Asia and is the pump that primes and modulates the strength of the Asian monsoon.

Numerical simulations reinforce this contention (Kutzbach et al., 1993), although definition of a specific altitudinal threshold or areal extent required to trigger a strong monsoon remains uncertain. Nonetheless, the causative linkage of a high and wide plateau to development of a strong Asian monsoon underpins interpretations that use geologic indicators of the onset of a strengthened monsoon as predictors of the timing of major

uplift of the Tibetan Plateau (Quade et al., 1989; Harrison et al., 1992; Molnar et al., 1993).

The growth of the Tibetan Plateau represents a clear case in which tectonically-driven surface uplift (i.e., an increase in mean elevation) has caused fundamental changes in regional climates. Moreover, the 5 km high topography of Tibet presents a physical barrier that impacts global patterns of atmospheric circulation and affects regional climates throughout the Northern Hemisphere (Kutzbach et al., 1993).

Active mountain building and climate change

The CO₂-weathering hypothesis suggests that weathering of silicate rocks can extract CO₂ from the atmosphere, thereby reducing the amount of greenhouse gases and causing global cooling (Raymo and Ruddiman, 1992). Such a reaction can be chemically expressed as:

in which calcium silicate combines with atmospheric CO₂ and creates calcium carbonate which is then precipitated and sequestered in oceans. Although drawdown of atmospheric carbon dioxide should happen all the time due to such a weathering process, the uplift of mountains is proposed to accelerate chemical weathering rates because rapid mechanical denudation in mountains will provide abundant fresh mineral surfaces for chemical attack. This theory, therefore, links orogenesis with changes in mineral weathering rates, greenhouse gases, and ultimately global temperature.

The growth of the Himalaya and secondarily of the Andes during the late Cenozoic (Raymo et al., 1988) has been cited as a potential trigger for enhanced rates of CO₂ drawdown and global cooling. These ranges are characterized by mechanical erosion rates averaging >1 mm yr⁻¹; rates far exceeding those at which rocks are converted to soils through chemical and mechanical weathering. The primary way in which these ranges sustain long-term erosion rates of this magnitude is via landslides involving bedrock, because soil-related processes are too slow (Burbank et al., 1996). Such landsliding persistently exposes fresh rock surfaces that are ideal sites for chemical weathering. Chemical weathering is enhanced by two additional features of the Himalaya and Andes. First, the tropical temperatures promote more rapid rates of chemical weathering than do cooler conditions at northern latitudes. Second, these ranges are sufficiently high to be glaciated. The “rock flour” that is produced by glacial grinding is perfect grist for chemical weathering because it commonly comprises tiny, unweathered rock particles with large surface area/mass ratios.

The drawdown of atmospheric CO₂ is counterbalanced by three feedbacks. First, more than 95% of the Earth’s surface is not experiencing mountain building. Erosion rates are low (commonly <0.01 mm yr⁻¹) in such areas, and chemical weathering also proceeds slowly even in the tropics, except in areas of higher relief. These areally extensive, low rates of atmospheric drawdown may balance the high rates of drawdown predicted for areas of rapid mountain building and erosion. Second, because erosion isostatically drives rock uplift, formerly buried carbon reservoirs can be exposed to erosion and returned to the atmosphere. Third, mountain building associated with subduction can lead to metamorphic degassing of carbon-rich rocks. These mechanisms serve to increase atmospheric CO₂ concentrations.

Impacts of climate and climate change on mountain uplift

Defining uplift

The term “uplift” should be defined in an appropriate context (e.g., Figure M46). The change of elevation at any point in a landscape (surface uplift at a point) is a function of the magnitude of erosion, deposition, and vertical movement of the underlying rock. Some coupling exists among these factors: erosion or deposition should induce a compensating isostatic response, such that ~5/6 (the ratio of crustal to mantle densities) of an instantaneous change in altitude due to erosion or deposition will be recovered over time. The vertical movement of rocks, whether in response to isostasy or tectonism, can be defined as “rock uplift” and should be measured in absolute terms with respect to a reference surface, such as the geoid or sea level. Whereas such measurements may be feasible at the coast, this formal reference frame is commonly lost inland. Nonetheless, relative amounts of rock uplift can be defined by comparing offset points that were once contiguous at the same altitude. The average change of all points on a surface serves to define “surface uplift” or the change in the mean elevation of an area (Figure M46). Although some geophysicists argue that the term surface uplift should be restricted to areas of a size (~10⁴ km²) capable of inducing a response to crustal loading (England and Molnar, 1990), changes of mean surface elevation of smaller areas can provide useful geomorphic and geologic insights (Medwedeff, 1992; Talling and Sowter, 1999).

Absolute field measurement of any form of uplift at geologic time scales (>10³ yr) is commonly difficult. The widespread availability of digital elevation models allows ready determination of modern surface elevations; a comparable reconstruction of ancient elevations could require many hundreds of points. Although the science of paleoaltimetry is improving (Sahagian and Maus, 1994; Forest et al., 1999), there are few reliable or precise measures of the previous altitude of the surface or rock beneath it. Even when the amount of erosion or deposition can be specified, the vertical movement of rocks in response to isostasy or to tectonic loading is hard to measure. Whereas coastal terraces provide a means to define rock-uplift (Lajoie, 1986), for most inland sites, relative displacements of surfaces or rocks are commonly studied with respect to a reference frame defined by an assumed earlier form, such as a river gradient (Thompson et al., 2002) or the surface of a former sedimentary basin (Burbank et al., 1999; Bullen et al., 2003).

What drives surface uplift of mountain ranges?

Four phenomena can commonly cause positive changes in mean elevation. Tectonic thickening of the crust will induce a change in the mean height equal to ~1/6 of the magnitude of thickening after the crust is compensated isostatically. The commonly observed low-density root beneath contractional ranges is at least partly responsible for elevated topography above it. Replacement of high-density mantle with lower density asthenosphere will drive a similar isostatic response, but in proportion to the density contrasts between them and the thickness of the replaced mantle. Dynamic support of topography can occur when the strength of the flexed crust induces surface uplift over a flexure. For example, underthrusting of old, thick, rigid crust can generate dynamic topography. In contrast to the previous two mechanisms, which cause surface uplift, dynamic support will create a range out of isostatic equilibrium. Finally, volcanism can cause surface uplift by two mechanisms. Heating of the crust lowers its density and makes it more buoyant, whereas addition of new volcanic material to the

surface or intrusion of plutons adds to the crustal mass and causes an isostatic response. Because crustal additions occur from point sources (vents) in volcanic systems, they generate more irregular, punctuated surface uplift than non-volcanic systems, because they create isolated high peaks or volcanic cones that may be widely separated.

Surface uplift of mountain peaks (positive elevation changes) will typically result from all of the processes described above. Because volcanoes add material to the Earth's surface, rock beneath will subside in response to new volcanic loads, such that only $\sim 1/6$ of any crustal thickening will be expressed as a long-term elevation change.

Erosion can also induce peak uplift. Consider the situation in which erosion is focused in only part of the landscape, such as the valley bottoms. The removal of mass by erosion will

cause a net thinning of the crust, and although the mean elevation will decrease, the crustal thinning induces isostatic uplift (rock uplift). If uneroded, the intervening peaks will rise by an amount equal to $\sim 5/6$ of the average amount of erosion (Molnar and England, 1990). Consequently, 1 km of erosion averaged across a region could cause the mean elevation to decrease by ~ 150 m, whereas uneroded peaks could uplift isostatically >800 m (Figure M47).

The erosional system

The primary means by which climate can affect tectonics is through the influence of climate on erosion. Isostasy requires that wherever erosion removes significantly more mass from an active orogen than elsewhere, differential rock uplift will occur preferentially beneath the more highly eroded area.

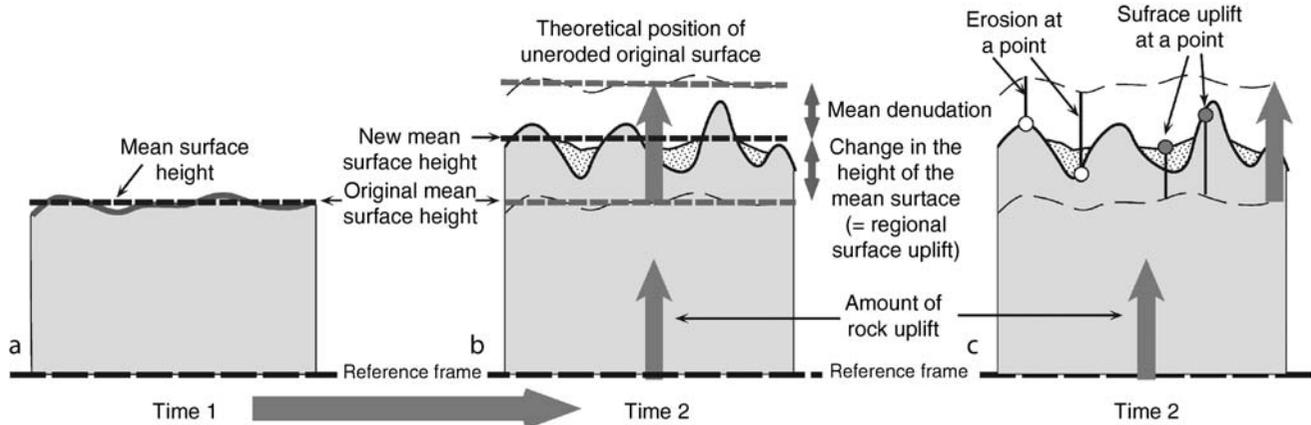

Figure M46 Definitions for aspects of "uplift." (a) Initial configuration depicting mean surface height. (b) Rock uplift (vertical arrows) represents the vertical motion of rock with respect to sea level or the geoid. "Regional surface uplift" is defined by changes in mean surface height (difference from "time 1" to "time 2"). The difference between the magnitude of rock uplift and the change in the mean surface height is the mean denudation. (c) "Surface uplift at a point" can depart from the mean surface uplift due to variations in erosion or deposition at specific sites in a landscape. (Modified after Burbank and Anderson, 2001.)

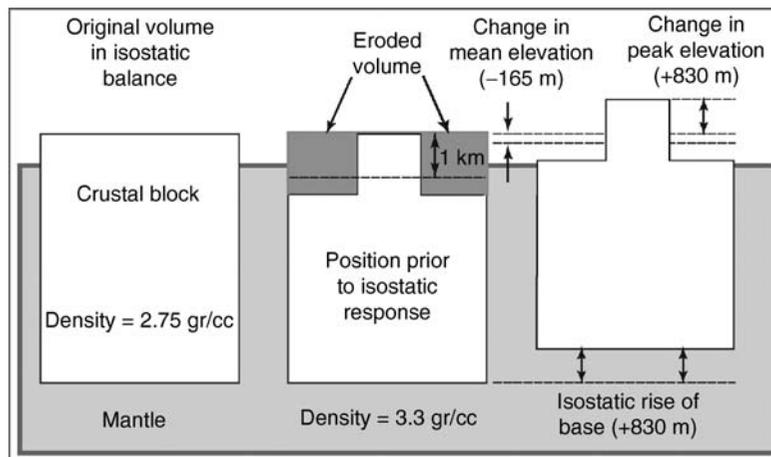

Figure M47 Isostatic responses to erosion. *Left:* An uneroded "crustal" block in isostatic balance with surrounding denser mantle; its upper surface floats above the surface of the denser material. *Center:* Square "valleys" 1.5 km deep remove mass across $2/3$ of the top of the crustal block (average erosion equals 1 km). Rebound is artificially restrained. *Right:* Following isostatic rebound, the mean elevation decreases by ~ 165 m, whereas the base of the block and the remaining part of its uneroded upper surface rebound ~ 830 m. The amount of rebound or "rock uplift" equals the average amount of erosion (1 km) times the ratio of the density of the crustal block ($\rho = 2.75 \text{ g cm}^{-3}$) to that of the mantle ($\rho = 3.3 \text{ g cm}^{-3}$).

Because differential rock uplift usually requires faulting, differential erosion can focus tectonic activity in regions where erosion is most rapid.

A linked climate-geomorphic system underlies this feedback. From a geomorphic framework, most mountain belts consist of networks of rivers and adjoining hillslopes (Figure M48). The rivers control the rate of lowering of base level within the mountains, whereas the hillslopes respond to base-level lowering and provide a flux of sediment to the rivers. Two classes of hillslope processes can be defined based on whether they involve primarily soil or bedrock. Soil erosion processes on hillslopes include rain splash, creep, bioturbation, and shallow (soil) landsliding. Because these occur primarily within soils, they cannot proceed at rates faster than soils are produced by weathering of bedrock. The best documented studies at present indicate that the conversion of rock to regolith or soil occurs at rates of $<0.5 \text{ mm yr}^{-1}$ (Heimsath et al., 1997). Thus, if hillslopes are eroding at rates slower than this, processes that move soils downslope may be sufficient to account for all hillslope sediment fluxes. As soon as rates climb above 1 mm yr^{-1} , bedrock landslides must begin to play an important role. For bedrock landslides to occur, a hillslope must be sufficiently steep to overcome the stabilizing forces resulting from cohesion (rock strength) and gravitational normal stresses on a potential failure plane. At equilibrium, slope angles should hover around that angle required for failure: the threshold slope angle. In many rapidly eroding terrains, hillsides are long and straight, with slope angles that are commonly clustered around $30^\circ\text{--}34^\circ$, independently of variations in erosion rates $>1 \text{ mm yr}^{-1}$. These characteristics are indicative of threshold slopes poised for failure (Figure M48). Any processes that decrease cohesion or normal stresses, and increase pore pressures or shear stresses, will tend to lead to bedrock landsliding. Thus, rock weathering, heavy rainfall, or seismic shaking will all tend to trigger landslides.

For ranges whose peaks rise above the regional snowline, glacial erosion becomes an important component of the geomorphic system (Figure M49). Glaciers that slide on their beds are very effective erosive agents, capable of eroding at rates exceeding 10 mm yr^{-1} (Hallet et al., 1996). Glacial erosion is commonly defined as a function of ice velocity (Humphrey and Raymond, 1994). Because velocity typically peaks near the glacial snowline, vertical erosion is considered to be maximized in the vicinity of the snowline (MacGregor et al., 2000). When coupled with enhanced vertical erosion, rapid headward erosion by glaciers causes a flattening of the slope of the long profile of glaciers (Brocklehurst and Whipple, 2002). Although glaciers are capable of overdeepening (scouring below the level of their toes), the rate of lowering of the entire glacial profile is ultimately regulated by the rate at which the rivers erode at the glacial terminus.

Mountains of sufficient height may have their upper reaches in a frozen zone that almost never rises above freezing. Here, glaciers are cold-based and frozen to their beds, freeze-thaw activity is minimal, and the primary means of erosion is through bedrock landslides (Figure M49). In such a setting, warm-based glaciers commonly occur at lower altitudes and cause both downward and headward erosion. Meanwhile, peaks within the frozen zone become higher and narrower. These steep-like summit regions episodically collapse via large-scale bedrock landslides.

Climatic impacts on the geomorphic system and mountain topography

During the repeated, large-scale Quaternary oscillations (Shackleton and Opdyke, 1976), changing temperature and precipitation regimes caused ice sheets and mountain glaciers to wax and wane. Snowlines generally were lowered 800–1,000 m in most temperate regions during maximum glacial times (Porter, 1989). This snowline shift displaced the predicted zone of maximum glacial erosion farther down the

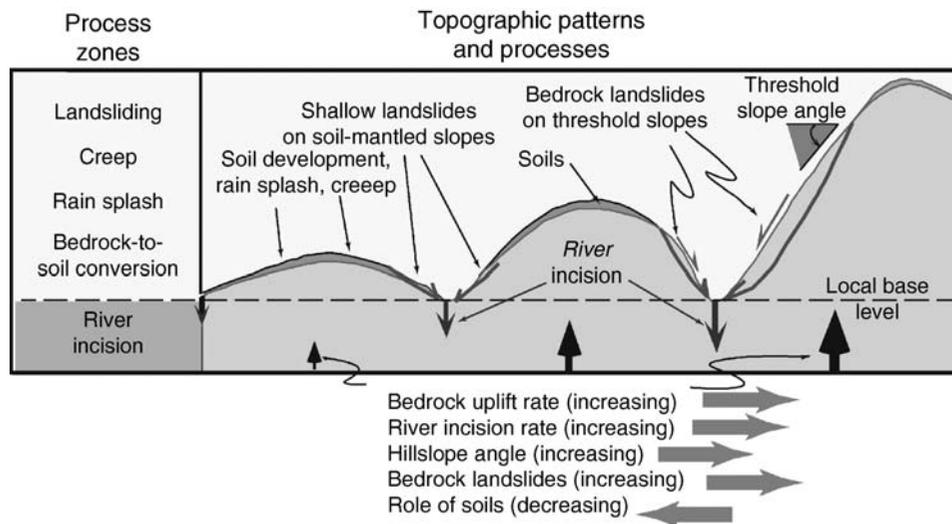

Figure M48 Hillslope and erosion processes in a steady-state, non-glaciated landscape. *Left panel:* Geomorphic process zones. River incision determines changes in local base level. Rates of rock-to-soil conversion limit the rate at which the landscape can erode (rain splash, creep, shallow landslides) in the absence of removal of unweathered bedrock. *Right panel:* Rates of relative rock-uplift increase from left to right. Assuming topographic steady-state, hillslope erosion and river incision match rock uplift rates. For slow uplift, soil processes (creep, rain splash) balance uplift rate. At higher uplift rates, shallow landslides rapidly strip soil from hillslopes. When relative rock-uplift rates exceed the rock-to-soil conversion rate, soil erosion balances uplift only if bedrock erosion, usually via landslides, also occurs. In most such landscapes, many hillslopes hover near the threshold angle for failure by landsliding. (Modified after Burbank, 2002.)

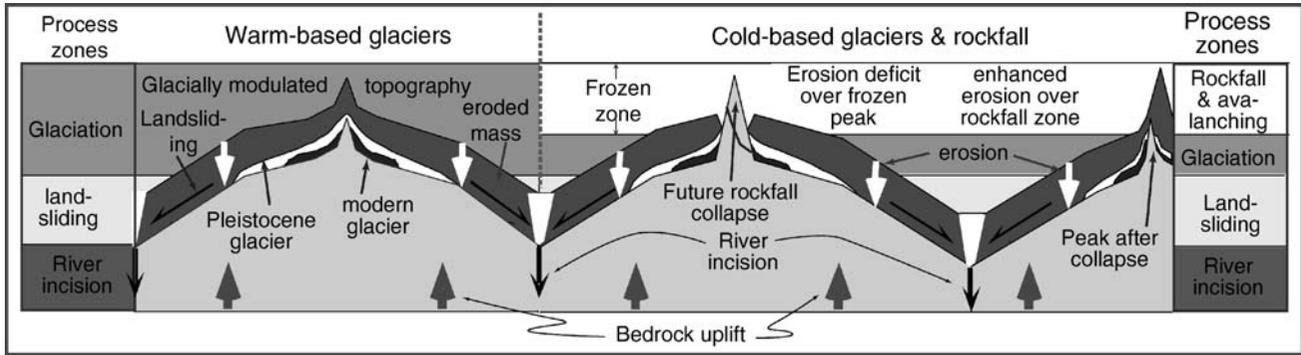

Figure M49 Erosion processes in steady-state, glaciated landscapes experiencing rapid relative rock uplift and erosion. Below the glacial limit, erosion (white downward arrows and dark gray region) via bedrock landsliding and river incision balance rock uplift (dark arrows along base). *Left panel:* Warm-based glaciers slide on their beds and erode bedrock, leading to a concentration of higher altitude topography near the glacial snowline. *Right panel:* Cold-based glaciers are frozen to their beds and, the absence of freeze-thaw cycles prevents erosion in the frozen zone. As warm-based glaciers continue to erode at lower altitudes, rock uplift steepens the summit regions, making them more unstable, and causing massive landslides. (Modified after Burbank, 2002.)

mountain flanks and was responsible for the low-gradient glacial troughs that exist downstream of modern glaciers. The vertical and lateral excavation of these troughs lowers base level and steepens adjacent valley walls, thereby promoting accelerated lowering of the ridges between glacial valleys. During glacial times, therefore, the average height of the glaciated parts of mountains should be lowered due to enhanced erosion of both valleys and ridges.

Changes in hydrology and sediment loads also affect fluvial erosion during climate changes. For any given climatic state, a river tends toward a graded condition, whereby its channel slope and width are adjusted to transport the sediment supplied to it from hillslopes. For a given discharge, steeper and narrower channels allow more sediment to be transported downstream. The longitudinal profiles of rivers typically show systematic downstream decreases in channel slope with increasing drainage area. The concavity (θ) of many river systems is defined by the relationship of channel slope (S) to drainage area (A): $S = kA^{-\theta}$, where k is a constant (Whipple et al., 1999). For most rivers, channel concavity hovers around 0.4–0.5. The constant k can be conceptualized as a ratio between rock uplift and climate or hydrology. If rock uplift rates increase, channel steepness should also increase, whereas if climatic conditions enhance erosiveness, channel steepness decreases (Whipple et al., 1999). In general, climatic conditions that lead to higher discharges will promote erosion and cause the entire stream profile to become less steep (Figure M50).

Sediments transported by rivers abrade the channel bed through repeated impacts. In the absence of sediment, rivers cannot erode efficiently, whereas too much sediment will cover the bed of the river and protect it from further erosion (Sklar and Dietrich, 2001). For underloaded rivers, i.e., where the sediment supply is much less than the transport capacity, a climatically-induced increase in the sediment supply may promote more rapid channel erosion. Irrespective of the cause (changing sediment or water discharge) of a lower channel slope, unless there is a compensating change in drainage spacing or rock strength, hillslopes and ridge crests will be lowered as well, and the mean elevation of a range should decrease (Figure M50). Because climate oscillates between glacial and interglacial conditions, the erosivity of fluvial systems should oscillate as well, such that the mean elevation, mean relief, and height of the ridge crests should vary with climate.

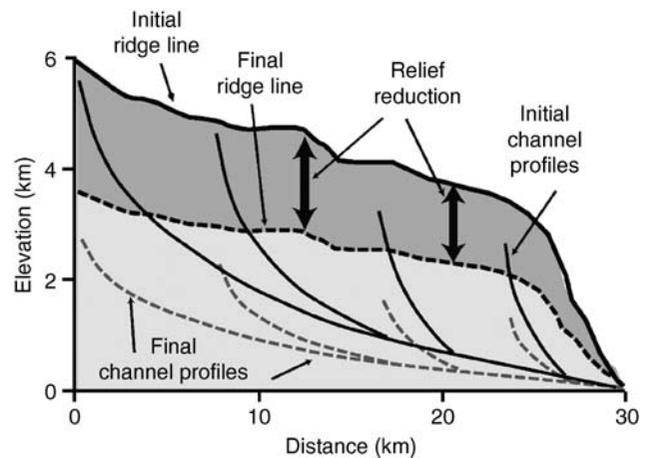

Figure M50 Predicted changes in river-channel and ridge-crest profiles that result from a sustained change from a less to more erosive climate state or from a regime of more rapid to slower rock uplift. More erosive climates increase discharge to each channel, thereby enhancing their ability to erode and lower river profiles. Because only a small fraction of a landscape typically lies between the channel head and ridge crest, a decrease in the channel gradient causes ridge lines to lower as well. (Modified after Whipple et al., 1999.)

The rapidity of climate change, however, often outpaces the response time of river systems (Whipple, 2001), such that the hillslopes and rivers will always tend to be somewhat out of equilibrium.

Because glaciers are very effective erosional agents, their presence will create a different mountain topography than would occur on the same range in the absence of glaciers. Two attributes influence glacial effects on topography. First, the focusing of bedrock erosion by glaciers at the altitude of the glacial snow line causes a lowering of mean elevation at that level. Second, as climate changes, the glacial snowline shifts altitudinally up or down, causing a synchronous shift in the zone of maximum glacial erosion. The well known elongate glacial troughs of alpine terrains are excavated by this mechanism. In comparison to the topographic profiles of rivers, glaciers produce high-altitude low-gradient profiles that extend

upward to the base of the cirque headwalls. Because the headwalls occupy only a small fraction of the landscape, the glacial troughs cause a concentration of landscape area in the altitude range defined by climatically-driven variations in snowline (Figure M51) (Brozovic et al., 1997). The net results of climatically-driven snowline variations are a lowering of the mean elevation, a focusing of land area near the snowline, and development of isolated horns or summits formed by coalescence of cirques. These summits may act as topographic “lightning rods” where storms gather along their flanks (Brozovic et al., 1997). The additional snow fed into the nearby glaciers would be expected to cause them to erode even more effectively.

Although reconstruction of the paleoaltitude of past mountain belts is difficult and typically contains large uncertainties (100s of m), changes in the flux of sediments from a mountain belt can be assessed through examination of the sedimentary record in basins adjacent to ranges. An enhanced sediment flux can occur either because erosion is occurring with greater efficiency compared to the past or because the rates of tectonic fluxes into an eroding mountain belt have increased. Compilation of sedimentation-accumulation rates from basins around the world indicate that both the volume and grain size of sediments has significantly increased since ~2–4 Ma (Zhang et al., 2001). The global synchrony of this change indicates that tectonics cannot be the cause: only climate change could cause such a pervasive and synchronous response. Whereas one might expect expanded glaciations to drive increases in erosion rates (Hallet

et al., 1996), many of the studied basins are not bounded by glaciated ranges. Instead, it is proposed that strongly oscillating Late Cenozoic climates have imposed such abrupt and frequent changes in precipitation, vegetation, and temperature that the landscape was always out of equilibrium and susceptible to rapid erosion (Zhang et al., 2001).

Steady-state orogens, topography, and climate

Conceptually, in a convergent mountain range, the flux of rock into an orogen could be balanced by the efflux through erosion, such that a steady-state mass would be maintained (Willett and Brandon, 2002). In a topographic steady state, the mean height and relief of the range would also remain steady through time. In such a condition, erosion by rivers, hillslopes, and glaciers must be adjusted so that they collectively erode at the same rate as rock moves into the orogen through tectonism. Steady-state topography requires a tectonic influx, because by itself the isostatic response to erosion will always result in a reduction in the mean height of a range. Given the rate of climatic change and the response time of geomorphic systems to approach equilibrium, orogenic topography should oscillate between higher and lower mean elevation and relief. Thus, at short time scales ($<10^5$ yr), steady state would never be strictly attained. However, if the average topography remained steady at time scales exceeding the primary glacial cycles (10^5 yr), the topography could be considered to be in a steady state.

Recent numerical models suggest that climate can play a major role in shaping orogens and determining where strain is focused within an orogenic belt (Beaumont et al., 1992; Willett, 1999). The models suggest that, in the absence of erosion, a convergent orogen will simply widen and thicken over time. If moisture is advected into the orogen from one side, the resultant asymmetric erosion causes profound changes in the shape of the orogen, precipitation patterns, and distribution of thickening and strain. Both the topographic divide and the zone of maximum crustal thickening shift away from the moisture source, whereas the region of maximum strain shifts toward the moisture (Figure M52). These changes all result from the preferential focusing of erosion on only one side of the orogen.

At a large scale, the predicted impacts of climate on orogenic growth may be well displayed by the Himalayan-Tibetan Orogen. Strong climatic contrasts exist on the northern and southern margins of the Tibetan Plateau. In the south, the Asian monsoon delivers 3–5 m of rain over the summer months to the southern flank of the Himalaya (Barros et al., 2000). In the north, generally arid to semi-arid conditions prevail along the margins of the Tarim Basin and the Hexi Corridor. After ~50 Myr of the ongoing Indo-Asian collision, 1,000s of km of convergence have been absorbed within the orogen. Accommodation of the converging crust can occur by thickening and widening, removal of mass through erosion, or lateral escape of mass out of the pathway of collision. The monsoon’s highly effective removal of mass from the Himalayan side of the Tibetan Plateau suggests that a near steady state may prevail there (Beaumont et al., 2001). Many of the major Himalayan structures that were active 10 million years ago are still active today, and the zone of active deformation has not significantly widened. In contrast, on the arid northern side of the Tibetan Plateau, extensive northward expansion of the Plateau has occurred during this same interval. Both northward propagation of active thrusting and the incorporation, shortening, and thickening of the former northern foreland has enabled large scale

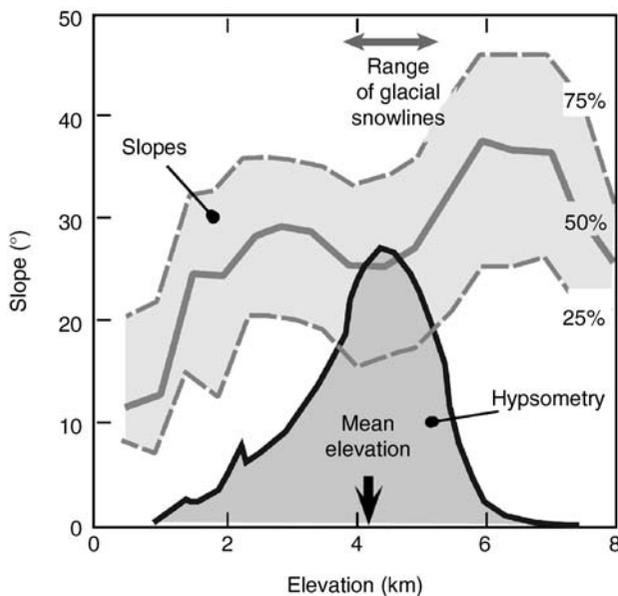

Figure M51 Hypsometry (altitude versus frequency) and mean hillslope angles of a glaciated Himalayan region. In glaciated regions above 3 km, much of the topography is concentrated between 4 and 5 km – a range coinciding with the altitudinal range of glacier snow lines between interglacial and glacial times. Glacial erosion is most efficient near the snow line, where ice flows fastest. Such altitudinally-dependent erosion focuses more topography near that altitude. Hillslope angles are steep in the zone just below the glaciers (<3.5 km) where bedrock landsliding occurs, but become more gentle in the altitude range where most glaciers occur, before steepening again in the headwalls and higher altitudes where cold-based glaciers prevail. (Modified after Brozovic et al., 1997.)

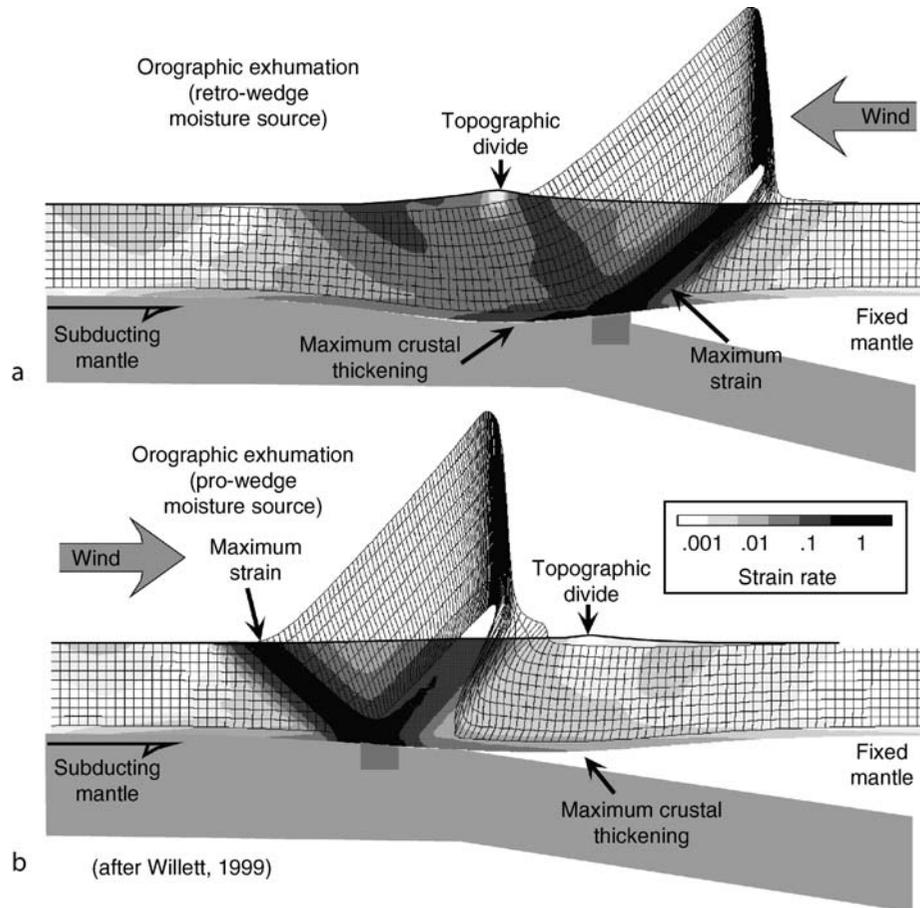

Figure M52 Contrasting magnitudes of geometries of erosion, strain, and crustal thickening resulting from the direction in which storms approach an orogen. In both cases, the tectonic framework is identical, with two blocks of continental lithosphere colliding and with the mantle lithosphere detaching on one side of the orogen. In each case, erosion and crustal strain are concentrated on the side from which moisture approaches the orogen, whereas the topographic divide and zone of maximum crustal thickening move away from the moisture source. The erosion resulting from greater rainfall on one side of the orogen creates fundamental contrasts in deformation patterns, despite the identical tectonic framework. (a) Moisture enters the orogen from above the retro-wedge side (the non-subducting side). (b) Moisture approaches from the pro-wedge side. (Modified after Willett, 1999.)

accretion of new mass into the northern edge of the Tibetan Plateau. The apparent steady state on one flank of the Himalayan-Tibetan Orogen and its obvious absence on the other flank support the prediction that large scale climatic contrasts exert a controlling influence on patterns of orogenic deformation (Willett, 1999).

Summary

Mountain ranges impact climate and climate change through multiple mechanisms, including the control of the pathways moisture follows across the landscape, patterns of orographic precipitation as storms impinge on the flanks of mountains, the enhancement of summer monsoons, and the magnitude of continentality. The chemical composition of the atmosphere and, in particular, the concentrations of CO_2 may be affected by rates of mountain building, whereby rapid mountain growth causes high rates of mechanical weathering and enhances the extent of glaciation – both of which serve to provide fresh rock surfaces for chemical weathering.

Climate can also exert some surprising controls on mountain topography and orogenic growth. In nonglaciated mountains, a

coupling exists between river erosion, bounding hillslopes, and climate. Rates of river downcutting control both local base-level lowering and incipient changes in the angle of hillslopes. Increased discharge during wetter climates will promote more rapid fluvial erosion and lower stream gradients. The flux of sediment off slopes represents the primary means of denudation in most orogens. As climate changes, precipitation variations alter hillslope pore pressures, change stable hillslope angles, and ultimately cause variability in hillslope sediment fluxes. When climates are wetter or more erosive, the mean altitude and relief of ranges should be lowered.

In glaciated ranges, glacial erosion commonly limits the mean height of mountain ranges by removing much of the topography above the snow line. Climatically-induced variations in the glacial snow line cause changes in the elevation of maximum glacial erosion and tend to define an altitudinal range within which most topography is concentrated. Overall, glaciated ranges will have lower mean elevations than would nonglaciated ranges under the same tectonic conditions.

In convergent orogens, gradients in erosion can cause gradients in crustal strain. Increased moisture on one flank of a

range will tend to increase erosion on that side and induce more rapid deformation in the underlying rock. Whereas a simple isostatic response can restore ~80% of the eroded mass, if rock is entering a convergent orogen from the side, then a steady state topography can be maintained at time scales ($>10^5$ yr) exceeding those of major climatic cycles.

NEAREST-LIVING-RELATIVE METHOD

The nearest-living-relative (NLR) method represents a standard and powerful tool in paleoclimatology and paleoecology. It uses the climatic or ecologic characteristics of the NLRs of fossil taxa or assemblages to estimate the paleoclimatic or paleoecologic conditions under which the fossil taxa or assemblages lived. Since the NLR method is based on the assumption that the climatic or ecologic characteristics of a fossil taxon or assemblage are similar to those of its nearest living relative, it is largely restricted to the Cenozoic. The paleobotanist Oswald Heer (1809–1883), who is also considered to be one of the founders of paleoclimatology, was probably the first to use this technique in order to estimate climate parameters for the Tertiary based on fossil floras (see *History of Paleoclimatology*). Since that time, numerous qualitative and quantitative variations of the NLR method have been developed, some of them based on fossil taxa, others based on fossil assemblages, all of them, however, have their specific advantages and limitations.

Qualitative techniques

The qualitative indicator taxon approach may be viewed as the classic variation of the NLR method: individual indicator taxa are used to derive information about the paleoenvironment or about paleoenvironmental trends. For instance, the modern bivalve species *Mytilus edulis* tolerates hyposaline conditions; hence, mass occurrence of *Mytilus* in a Cenozoic shell-bed may indicate brackish or varying salinities. Similarly, an increase in abundance of Lauraceae (laurel family) or Arecaceae (palm family) leaves in a sequence of fossil floras is typically interpreted as reflecting a warming trend since today both families show a predominantly tropical to subtropical distribution.

Although very simple and rapid to apply – at least if the ecology and climatology of the NLRs of the fossil taxa are known – this qualitative indicator taxon approach has serious limitations. First, it provides only qualitative and not quantitative data. Second, the accuracy and reliability of the paleoenvironmental information depends on the taxonomic level to

which the NLR of a fossil taxon can be determined and on the stratigraphic or evolutionary age of the fossil taxon. Typically, more detailed information can be extracted from fossil taxa if their NLRs can be identified not only on the family but also on the genus or even species level. The accuracy, however, to which the NLR of a given fossil can be determined, is a function of the evolutionary and stratigraphic age of the fossil. Angiosperms have their major radiations in the Cretaceous and Paleogene. Correspondingly, the NLR of Neogene angiosperms can mostly be identified on the genus level, Pleistocene angiosperms on the species level. The situation is completely different for mammals, which show important radiations in the Neogene and Pleistocene. Hence, the NLRs of many early Pleistocene mammals can only be identified on the family or genus level. A third shortcoming of the qualitative indicator taxon approach is its sensitivity to taphonomic effects since the presence or absence of certain indicator taxa may not only be controlled by paleoclimatic or paleoenvironmental change but also by taphonomy. For instance, Lauraceae are quite common in European Paleogene leaf floras but are rare in pollen floras due to differential degradation processes. For the same reason, angiosperms are rare in Cenozoic wood floras since their trunks and branches decay more rapidly than those of conifers. Finally, it should be emphasized that the qualitative indicator taxon approach is not a well-defined, objective and reproducible technique. The same fossil flora or fauna may hence lead to different interpretations if analyzed by different scientists.

Instead of indicator taxa, it is possible to use fossil indicator assemblages to obtain qualitative paleoenvironmental information. This qualitative indicator assemblage approach is particularly common in Quaternary research: pollen diagrams of sedimentary sequences are interpreted as a succession of characteristic vegetation types; from the vegetation succession, a qualitative or semi-quantitative climate trend or climate curve may then be derived. The technique can be applied to all kinds of fossil assemblages but it makes more rigorous assumptions than the qualitative indicator taxon approach. In the qualitative indicator assemblage approach, it is required that the NLRs of fossil taxa and of fossil assemblages are identified correctly and that both the fossil taxa and the fossil assemblages have

climatic or environmental requirements similar to those of their modern analogues. Hence, the qualitative indicator assemblage technique is more restricted in its applicability than the qualitative indicator taxon approach. In general, it works quite well in the Quaternary but becomes increasingly less reliable in the Neogene. In addition, it is even more sensitive to taphonomy than the indicator taxon approach because transportation and fossilization processes may heavily influence the composition of a fossil assemblage.

Quantitative techniques

Both the indicator taxon and indicator assemblage techniques may also be used in a more systematic and objective way in order to obtain quantitative paleoclimate or paleoenvironmental data. Grichuk (1969) was the first to develop Heer's indicator taxon approach into a well-defined methodology that allows determination of absolute climate estimates from fossil floras; his technique was later modified into the so-called "coexistence approach" and adapted to modern computer technology (Mosbrugger and Utescher, 1997). A similar methodology was developed by Atkinson et al. (1987) for beetles and applied to Quaternary beetle faunas. All these techniques are quite similar (Figure N1). Given a fossil fauna or flora with taxa A to Z for which the NLRs A' to Z' are known, if the climatic (or ecologic) tolerances of the modern taxa A' to Z' (e.g., concerning the various climatic parameters such as mean annual temperature, mean temperature of the warmest month, etc.) are known, then by overlapping all these tolerances the "coexistence interval" can be determined for any environmental or climatic parameter. This coexistence interval is interpreted to bracket the real climatic or environmental parameter value under which the fossil fauna or flora lived. The climatic resolution of the methodology can be improved if the various climatic parameters such as mean annual temperature, mean annual precipitation, etc. are not considered independently but if the multidimensional climatic spheres, which describe the climatic tolerances of the modern taxa A' to Z', are calculated and overlapped (e.g., Kühl et al., 2002).

All these quantitative techniques have found wide application in paleoclimatology and proved very useful and reliable in Cenozoic paleoclimate reconstructions (e.g., Utescher et al., 2000; Mosbrugger et al., 2005). Unfortunately, they suffer from similar shortcomings as the qualitative indicator taxon approach. However, the method becomes virtually independent from taphonomy if many taxa are included in the analysis. For instance, if some taxa are missing in the fossil fauna or flora

for taphonomic reasons, this will only influence the width of the resulting coexistence interval (cf. Figure N1) but the new interval will still bracket the real value. Similarly, the simultaneous consideration of many taxa will allow statistical tests to determine if some modern taxa have changed their climatic tolerances as compared to their fossil relatives. For instance, in Figure N1, the NLR taxon C' forms a climatic outlier with respect to parameter I, i.e., the climatic tolerance of C' does not overlap with the climatic tolerances of the other NLRs of the fossil flora/fauna. This clearly indicates that the climatic tolerance of modern taxon C' does not reflect the climatic tolerance of fossil taxon C. From many such analyses it turns out that all modern relict taxa, such as the conifer genus *Sequoia*, that today have a very restricted distribution, as compared to the distribution area of the fossil taxon, are not very useful in paleoclimate reconstructions.

A variety of assemblage-based methods that allow quantitative estimates of paleoclimate or paleoenvironment parameters also exists. The modern analogue technique may serve as an example. In a first step, a calibration dataset has to be established. For this purpose, many modern assemblages covering a wide range of climatic (or ecologic) conditions are characterized with respect to their climatic (or ecologic) requirements. Then for a given fossil assemblage, a certain number (e.g., 1–5) of the best "modern analogues" are picked from the calibration dataset; the climatic characteristics of these modern analogues are averaged and the mean value is used as a paleoclimate estimate for the fossil assemblage. The classic transfer functions may be viewed as just another variety of the quantitative assemblage-based methods.

The limitations of these techniques are similar to those described for the qualitative indicator assemblage approaches: the NLRs of the fossil taxa and of the fossil assemblages have to be identified and it is assumed that both fossil assemblage and its modern analogue have similar climatic or environmental requirements. Hence, quantitative assemblage-based paleoclimate reconstructions are again largely restricted to the Quaternary, with rapidly increasing uncertainties further back in time. Calibration of the modern data set and taphonomy play a crucial role in these techniques. It has to be kept in mind that there are fossil assemblages, such as the Pleistocene mammoth steppe, which have no close modern analogues. In addition, taphonomic filter processes may strongly influence the relative abundance of taxa in a fossil assemblage and thus hamper the identification of the nearest living relative assemblage.

Summary

The nearest-living-relative method exists in numerous taxon- and assemblage-based variations and is still one of the most powerful approaches to obtain qualitative and quantitative paleoclimate (or paleoenvironment) information. Taxon-based approaches relying only on the presence-absence of taxa are less sensitive to taphonomy than assemblage-based approaches, which typically also rely on the relative abundance of taxa. Stratigraphically, taxon-based methods are limited to periods after the time when the major evolutionary radiation of the respective taxon group occurred; typically, they cannot be applied to pre-Cenozoic times. In contrast, assemblage-based techniques are mostly restricted in their application to Quaternary sequences.

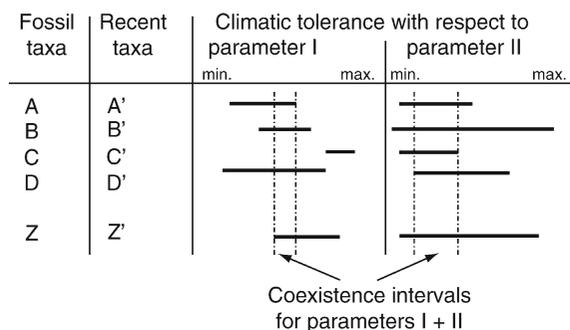

Figure N1 General concept of quantitative indicator taxon approaches. Taxon C' forms a climatic outlier (further explanation in the text).

NEOGENE CLIMATES

Introduction

The Neogene includes the Miocene and Pliocene epochs, which span 23.03–5.33 and 5.33–1.81 million years ago, respectively Loureus et al., 2004. The Neogene witnessed several major paleoclimatological changes. In general terms, the Neogene went from a warm climatic optimum in the late early Miocene through rapid cooling during the middle Miocene, to the onset of Northern Hemisphere Glaciation (NHG) in the Pliocene.

The Miocene

During the Miocene, especially the middle Miocene, the Earth went through several major changes – both climatic and tectonic. The climatic transition involved gradual cooling, starting about 15 million years ago, and establishment of major ice sheets on Antarctica by 10 million years ago (Zachos et al., 2001), as well as significant changes in global carbon cycling and deep ocean circulation. Initially, researchers argued for minimal continental ice from sometime in the Cretaceous to the Miocene, with a transition to so-called “icehouse” conditions in the middle Miocene. However, evidence now exists in support of the development of glacial conditions in the early Oligocene, with waxing and waning of global ice volume occurring through the Oligocene and early Miocene. Trends in microfossil stable oxygen isotope composition provide evidence for several glacial intervals during the Miocene (e.g., Miller et al., 1991). However, a period of global warmth followed a major glacial episode at the Oligocene/Miocene boundary, resulting in a reduced latitudinal temperature gradient and higher average surface water and deep-water temperatures (Zachos et al., 1997, 2001). At the height of the climatic optimum

(17–15 million years ago) deep-water and high-latitude surface water temperatures were as much as 6 °C warmer than today (Shackleton and Kennett, 1975; Savin et al., 1975). The most dramatic climatic change that occurred during the Miocene took place around 15 million years ago, during the middle Miocene, at which time there was evidence for rapid deep-water cooling and east Antarctic ice-sheet expansion (Figure N2). Evidence from ice-rafted debris indicates that glaciation in the Nordic seas and Arctic regions began in the late Miocene. During the late Miocene, glaciers reached sea level in both the North Atlantic and North Pacific, resulting in the deposition of ice-rafted debris across both these oceans.

There are several different hypotheses concerning the cause of the Miocene climatic optimum and the following cooling. One of these hypotheses involves changes in atmospheric CO₂ content, with an elevated *p*CO₂ possibly responsible for the global warmth in the late early Miocene optimum. Evidence for Neogene *p*CO₂ variability comes from different sources. Evidence regarding a possible organic carbon control on *p*CO₂ can be found in the stable carbon isotope composition of microfossils that live on the ocean floor. In the middle Miocene, there is a positive shift in the stable carbon isotope composition of marine carbonates, which is associated with organic carbon-rich deposits around the Pacific, such as the Monterey Formation (Vincent and Berger, 1985). Increased upwelling is thought to be the major cause for this increased organic carbon burial and subsequent CO₂ removal. The increase is followed by a positive shift in the stable oxygen isotope composition of marine carbonates, indicating a cooling associated with decreased levels of *p*CO₂. However, Raymo (1994) suggested that the primary cause of decreasing *p*CO₂ during the Miocene was due to changes in rates of continental chemical weathering. Based on a strontium isotope record, Raymo (1994) argued for increasing silicate chemical weathering rates as the primary mechanism of CO₂ removal. The enhanced weathering rate has been attributed to a major phase of deformation of the Himalayan orogen that occurred about 21–17 million years ago. On the other hand, reconstructions of the evolution of atmospheric *p*CO₂ during the Miocene that are based on the carbon analyses of diunsaturated alkenones and planktonic foraminifers from deep-sea sediment cores show no link between atmospheric *p*CO₂ and climate change during the late early and middle Miocene (Pagani et al., 1999). Another cause of the late early Miocene climate optimum and East Antarctic ice expansion in the middle Miocene could be the opening of the Drake Passage between South America and the Antarctic Peninsula. The opening of the Drake Passage had a great effect on Southern Ocean circulation.

Several different hypotheses tie Miocene climate change to deep-water circulation patterns (Wright et al., 1992 and references therein). Based on stable carbon and oxygen isotope records from the Atlantic, Pacific, Indian and Southern oceans, middle Miocene growth of the East Antarctic Ice Sheet was controlled by the interplay between Northern Component Water, Southern Component Water and a water mass originating in the eastern Tethys (Wright et al., 1992; Flower and Kennett, 1995). According to Wright et al. (1992) a combination of the relatively warm Northern Component Water and Tethyan water masses about 20–16 million years ago produced a significant meridional heat transport that warmed the deep ocean by several degrees. At around 16 million years ago, deep-water temperatures cooled after the fluxes of Northern Component Water and Tethyan outflow water were reduced, allowing the deep oceans to be ventilated by only Southern Component

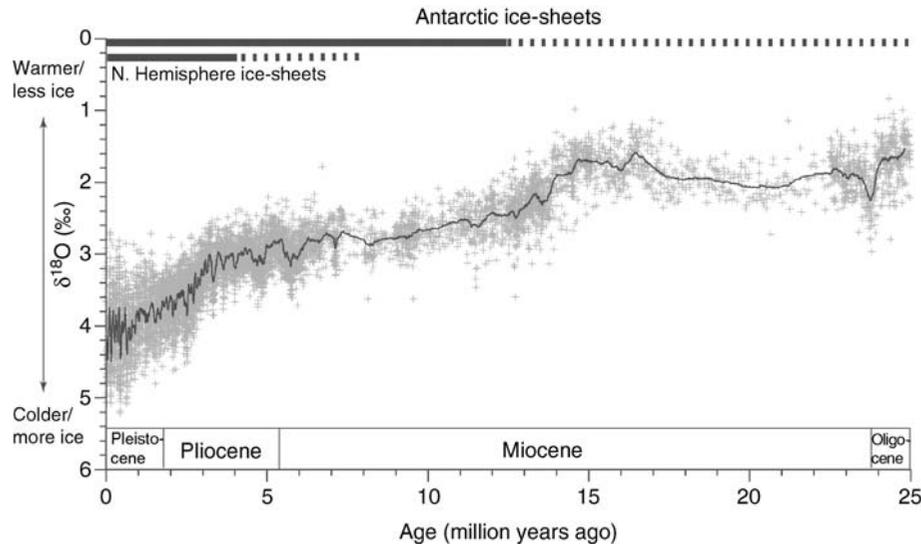

Figure N2 Trends in global climate change during the Neogene. The data shown are based on deep-sea stable oxygen isotope records ($\delta^{18}\text{O}$) from more than 40 Deep Sea Drilling Project and Ocean Drilling Program sites (Zachos et al., 2001). The stable oxygen isotope composition of bottom-dwelling foraminifers reflects changes in global ice-volume and/or changes in deep-water temperature. Solid black line corresponds to heavily smoothed values of raw data (grey crosses). Increases in $\delta^{18}\text{O}$ values correspond to climatic deterioration, i.e., larger global ice-volume and/or cooler deep-waters (after Zachos et al., 2001).

Water. Flower and Kennett (1995) suggested that with the cessation of Tethyan outflow around 14 million years ago, Southern Component Water production increased, thereby reducing the meridional heat transport and making an expansion of the East Antarctic Ice Sheet possible. Hence, reconstructions of the production rates of warm and cold deep-water masses suggest that the middle Miocene cooling and growth of the East Antarctic Ice Sheet were controlled by changes in ocean circulation.

The latest Miocene, during the Messinian stage (7.12–5.32 million years ago, Berggren et al., 1995) was a time of major climatic and paleoceanographic change. Large anhydrite/gypsum deposits from the Messinian are found around the Mediterranean region, suggesting that the Mediterranean Sea was desiccated during this time period. During the late Miocene, the connections between the Atlantic Ocean and Tethyan Ocean (a precursor to the Mediterranean) were through the Rifian Corridor in Morocco and the Iberian Portal in Spain. These passages allowed the inflow of Atlantic waters in to the Paleo-Mediterranean to replenish evaporative loss in this basin. With the progressive closure of the two straits that connected the Paleo-Mediterranean with the Atlantic, the Paleo-Mediterranean became isolated and desiccated (e.g., Benson et al., 1991; Hodell et al., 1994). This led to what is called the Messinian salinity crisis. The desiccation of the Paleo-Mediterranean affected oceanic salinity by removing an estimated 6% of dissolved salts from seawater. The cause of the Mediterranean salinity crisis was probably the interplay between tectonic changes, glacio-eustatic changes and climate changes within the Paleo-Mediterranean.

The Pliocene

The early Pliocene (~5–3 Ma) seems to be the most recent time period of sustained global warmth. During the mid-Pliocene (~3 Ma), prior to the onset of Northern Hemisphere glaciation, global mean temperatures may have been as much as 3.5 °C warmer than at present (Raymo et al., 1996). Much evidence comes

from the mid-Pliocene, when high-latitude sea surface temperature increases suggest strong thermohaline circulation.

The reasons for mid-Pliocene warmth are not yet clear. Crowley (1996) summarized several possible reasons: changing CO_2 levels, orographic effects related to late Cenozoic uplift and/or changes in meridional heat transport due to, for example, closure of the Central American Isthmus. Recent studies call on a combination of two main factors to explain Pliocene warmth: increased atmospheric CO_2 levels and enhanced thermohaline circulation. Because CO_2 is a “greenhouse” gas, changes in Pliocene atmospheric CO_2 levels could be the cause of the mid-Pliocene warmth. Raymo et al. (1996), for example, suggested that atmospheric CO_2 levels during the mid-Pliocene were on average about 35% higher than the pre-industrial value. CO_2 estimates for the mid-Pliocene come from different sources. Among these are studies of the carbon isotopic composition of marine organic matter (Raymo et al., 1996), stomatal densities in leaves (Van der Burgh et al., 1993) and the carbon isotope difference between surface and deep waters (Shackleton et al., 1992). However, the results from these different techniques show little increase in $p\text{CO}_2$ for the Pliocene.

In addition to changes in atmospheric CO_2 levels, change in ocean heat transport, i.e., thermohaline circulation is one of the major mechanisms used to explain past time intervals of greater warmth, like that of the mid-Pliocene. The thermohaline circulation plays a significant role in regulating global climate by redistributing heat and moisture and influencing the rate of CO_2 exchange between the ocean surface and deep-ocean. At present, the thermohaline circulation is composed of two major water masses: North Atlantic Deep Water (NADW) and Antarctic Bottom Water (AABW). NADW is produced in the northern North Atlantic and spreads towards the south, influencing other ocean basins. AABW, which is mainly produced in the Weddell Sea and Ross Sea, spreads towards the low latitudes in all ocean basins. The overturning cells of NADW and AABW are interrelated, which means that the relative

abundance of these water masses in ocean basins can be modified by a change in production rate of only one of them. However, there are problems associated with holding changes in ocean heat transport responsible for greater warmth (Crowley, 1996). One of them is the need to identify the factors responsible for changes in ocean circulation. Another is that increased heat transport would decrease low-latitude sea-surface temperatures (SST). Cooler tropical SSTs during past warm periods are matters of controversy. Raymo et al. (1996) presented evidence suggesting that the mid-Pliocene (~3 Ma) warmth was related to increased NADW production, in addition to slightly increased CO₂ levels. Although increased NADW production might be responsible for increased warmth in the North Atlantic, it is not clear how this would result in global warmth. Changes in thermohaline circulation primarily redistribute heat over the planet.

The initiation of NADW production occurred during the Neogene. Data from deep-sea cores suggests that NADW was being formed during parts of the middle Miocene (~17–11 million years ago) and that the flux of NADW increased in the late Miocene (~11–5 million years ago), approaching modern values in the early Pliocene (~5–3 million years ago). There are two major hypotheses for the cause of the initiation of NADW. One is that the shoaling and subsequent closure of the Central American Seaway allowed the North Atlantic to become saline enough for the formation of NADW (Maier-Reimer et al., 1990). The other is that changes in the sill depth of the Greenland-Scotland Ridge (Wright and Miller, 1996). Based on modeling studies, Mikolajewicz and Crowley (1997) suggested that the initiation of NADW might have been related to the closing of the Central American Seaway, but that the depth of the Greenland-Scotland Ridge controlled its outflow.

Paleoceanographic studies in the western equatorial Atlantic, the eastern equatorial Pacific and in the Caribbean indicate that the closure of the seaway between North and South America resulted in a distinct reorganization of ocean circulation starting at about 4.6 million years ago (Haug and Tiedemann, 1998). The emergence of the Panamanian Isthmus intensified the Gulf Stream and introduced warm, saline water masses to the high northern latitudes. Evaporative cooling of this warm, saline water mass would result in the formation of NADW. However, Kim and Crowley (2000) suggested, based on an ocean general circulation model, that the increased NADW production could be a consequence of Pliocene warming rather than a primary cause. Their results indicate that a warming over the Southern Ocean produces lower rates of sea ice formation and southern ocean deep-water outflow. This in turn, leads to an increase in NADW outflow in the Southern Ocean and an increase in poleward heat transport in the North Atlantic. Kim and Crowley further postulated that due to the greater sea ice area in the Southern Ocean, this region would be more sensitive to the inferred slightly higher CO₂ levels during the mid-Pliocene.

Onset of Northern Hemisphere Glaciation

The initiation of major NHG seems to have been the culmination of a longer-term high-latitude Cenozoic cooling that began in the early Eocene and is marked by the first indications of ice sheets in Antarctica about 36 million years ago. The long-term cooling brought the climate system of Earth to a critical state for ice-sheet buildup in the Northern Hemisphere. The glaciation of Greenland and the Arctic is believed to have begun in the late Miocene. Small amounts of ice-rafted debris (IRD)

are detected in Nordic Sea sediment cores back to about 11 million years ago (Jansen et al., 2000 and references therein). The timing of the onset of NHG varies to some extent between different regions. Although the initiation of major glacial intervals probably occurred close to the middle/late Miocene boundary, major glacial events are not apparent in the Nordic seas until just before 3 million years ago. An intensification of glacial conditions is recorded at about 3.3 million years ago. The onset of large-scale NHG is dated at approximately 2.75 million years ago on the Vøring Plateau and 3.3 million years ago on the Iceland Plateau (Fronval and Jansen, 1996; Jansen et al., 2000). The different timing probably reflects different responses of the Greenland Ice Sheet versus ice-sheets in northern Europe. IRD with an origin from the Laurentide Ice Sheet seem to appear around 2.74 million years ago. In general, enrichment of the stable oxygen isotope composition of benthic foraminifers suggests that there was significant deep-water cooling and an increase in global ice volume after 3.2 Ma (Tiedeman et al., 1994; Shackleton et al., 1995) (Figure N2).

Several different causes for the onset of NHG have been suggested. One theory attributes the onset of NHG to a decline in the concentration of atmospheric CO₂. This would reduce the amount of heat trapped in the atmosphere and lead to cooling. Changes in atmospheric CO₂ could arise from increased productivity or from a longer-term decline in CO₂ due to the burial of organic carbon and chemical weathering. It has also been hypothesized that the final closing of the South American Seaway was linked to the onset of NHG. The strengthened northward flow of warm, salty water would suppress sea-ice formation. With a reduced sea-ice cover, more moisture from the ocean would be available to the surrounding landmasses and trigger the growth of large ice sheets there. Haug and Tiedemann (1998), for example, proposed that increased atmospheric moisture supply was a necessary precondition for ice-sheet growth, which was then triggered by changes in the Earth's orbital obliquity. A contrasting argument is that increased deep-water formation could have worked against the initiation of NHG as greater heat transport to high latitudes would have tended to prevent ice-sheet formation.

The geological record shows strong evidence that the thermohaline circulation in the early Pliocene weakened as a response to the onset of Northern Hemisphere Glaciation (e.g., Raymo et al., 1992, 1996). Based on the stable carbon isotope composition in benthic foraminifera from the Atlantic and Pacific oceans, Raymo et al. (1992) associated the gradual cooling between 3 and 2 Ma with an increased suppression of the formation of NADW. Data from the eastern Pacific (Shackleton et al., 1995) shows an in-phase relationship between colder periods and those having decreased NADW formation during the Pliocene. It has been argued that tectonic changes such as the closing of the Central American Seaway, uplift of the Himalayan and Tibetan Plateaus, and deepening of the Bering Strait are too gradual to account entirely for the rapid onset of NHG. Although tectonic changes may have brought the global climate to a critical threshold, the rapid variations in Earth's orbital parameters and thus insolation are more likely to have triggered the intensification of NHG (e.g., see Lourens and Hilgen, 1997). Long-term periodic variations in the Earth's orbital parameters seem at least partially to have controlled the onset of NHG (see *Astronomical theory of climate change*).

NITROGEN ISOTOPES

Introduction

Nitrogen, element number five in the Periodic Table, is a limiting nutrient to primary production (i.e., plant growth) on the continents and in the ocean (Dugdale and Goering, 1967). Phytoplankton productivity is generally high where fixed (i.e., soluble) nitrogen concentrations are elevated and low where they are diminished. Because primary productivity influences climate, via the uptake of atmospheric carbon dioxide, and is the precursor to petroleum deposits, it is important to understand nitrogen cycling in the environment. The stable isotopes of nitrogen, ¹⁴N and ¹⁵N, representing, respectively, 99.63% and 0.37% of nitrogen atoms in the solar system, provide a powerful tool for elucidating the processes that transfer nitrogen between reservoirs because many of them cause large isotopic fractionations that can be measured with a mass spectrometer.

The global nitrogen cycle

The largest reservoir of nitrogen on the planet is rocks, which contain 1.9×10^{11} Tg (10^{12} g) of nitrogen (Wada and Hattori, 1990). Nitrogen in rocks is not very reactive and therefore has a very long residence time. The largest available pool of nitrogen is atmospheric dinitrogen gas (N_2), consisting of 3.9×10^9 Tg N (Wada and Hattori, 1990). For comparison, the total amount of nitrogen contained in all plants and animals on the continents is 1.5×10^4 Tg N and in the ocean is 4.7×10^2 Tg N, both very much smaller than the reservoir of nitrogen in the atmosphere. While some specialized microbes are able to convert N_2 gas into ammonia (NH_3) – the biologically useful form of nitrogen – by a process called nitrogen fixation, most primary producers require fixed nitrogen in the form of nitrate (NO_3^-) or ammonium ion (NO_4^+). The pool of nitrate in the ocean is 5.7×10^5 Tg N and that of ammonium ion is 7×10^3 Tg N (Wada and Hattori, 1990).

The marine nitrogen cycle is complex and not well understood (Codispoti, 1995). Current estimates indicate that the total of all oceanic sinks for nitrogen are larger than combined sources by 75% (Codispoti and Christensen, 1985) but uncertainties of a factor of two to four exist regarding the magnitude of each. Sources of fixed nitrogen to the ocean are (a) nitrogen fixation ($30\text{--}130$ Tg N yr^{-1}), (b) atmospheric deposition ($30\text{--}83$ Tg N yr^{-1}), and (c) river runoff ($13\text{--}24$ Tg N yr^{-1}) (Wada and Hattori, 1990). Sinks of nitrogen in the ocean are (a) microbial denitrification, the conversion of nitrate to N_2 gas with its subsequent loss to the atmosphere ($25\text{--}180$ Tg N yr^{-1}), (b) burial in marine sediments (20 Tg N yr^{-1}), and (c) exports of organic nitrogen to the continents via fish catches, guano deposition, and atmospheric transport ($10\text{--}20$ Tg N yr^{-1}) (Codispoti and Christensen, 1985).

While the combined exports of nitrogen substantially exceed combined imports in the above tally, recent studies indicate that nitrogen fixation rates may have been drastically underestimated by a factor of two or more (Gruber and Sarmiento, 1997; Karl et al., 1997; Zehr et al., 2001). So the marine nitrogen cycle may be approximately in balance. Nevertheless future studies are needed to better constrain the sources and sinks of nitrogen in the ocean.

Nitrogen isotope ratios

Nitrogen isotopic ratios are typically measured on gaseous nitrogen (N_2 or N_2O) in a dual-inlet mass spectrometer. Very high precision, on the order of 0.01% or better, is obtainable using this technique. The isotope ratio of a sample is reported relative to that of a reference standard and reported in delta notation in units of per mil (‰), where one per mil is one-tenth of one percent, or one part per thousand, according to Equation (1):

$$\delta^{15}N = \left(\frac{^{15}N/^{14}N_{\text{sample}}}{^{15}N/^{14}N_{\text{standard}}} \right) - 1 \times 1,000/‰ \quad (1)$$

Atmospheric nitrogen (N_2) is the reference standard for nitrogen isotopic analyses and has a $\delta^{15}N$ value defined as 0‰.

The biologically-mediated reduction reactions that convert nitrogen from nitrate (NO_3^- , +5 oxidation state) to nitrite (NO_2^- , +3) to nitrous oxide (N_2O , +1), to nitrogen gas (N_2 , 0), and to ammonia (NH_3 , -3) are faster for ^{14}N than for ^{15}N as a result of higher vibrational frequency of bonding to ^{14}N than to ^{15}N (Owens, 1987). This results in products that are

^{15}N -depleted (i.e., have a lower $^{15}N/^{14}N$ ratio and lower $\delta^{15}N$) relative to the substrate. If the substrate reservoir is either closed or has inputs and outputs that are slow relative to one of the reduction processes then the reservoir will become enriched in ^{15}N . An example is the oxygen-depleted sub-surface water of the eastern tropical Pacific Ocean where high rates of denitrification cause large ^{15}N enrichments of the nitrate pool on the order of 1% (or 10‰) (Cline and Kaplan, 1975). Denitrification in low-oxygen regions of the ocean, such as the eastern tropical Pacific and the Arabian Sea cause the $\delta^{15}N$ value of the ocean nitrate reservoir to be high ($\sim 5\%$) relative to the atmosphere and to terrestrial nitrogen (Wada et al., 1975; Sigman et al., 1999).

During the reduction of N_2 to NH_3 by nitrogen fixing bacteria in the ocean, atmospheric nitrogen ($\delta^{15}N = 0\%$), which is already isotopically-depleted relative to ocean fixed nitrogen, is further depleted, resulting in organic nitrogen with a $\delta^{15}N$ value of -2.7% (c.f., Sachs and Repeta, 1999 and references therein). In regions of the ocean where nitrogen fixation is extensive, such as in the subtropical north Pacific (Liu et al., 1996; Karl et al., 1997) and in the Mediterranean Sea (Sachs and Repeta, 1999), $\delta^{15}N$ values are low in both phytoplankton and fixed nitrogen relative to global ocean average values.

Oxidation reactions that convert ammonia to N_2O , NO_2^- and NO_3^- during nitrification also result in isotopic fractionation (Mariotti et al., 1981; Yoshida et al., 1989).

Diagenetic alteration of nitrogen isotope ratios

Early diagenetic (i.e., decomposition) reactions in marine sediments can severely alter the isotopic composition of sedimentary organic nitrogen. This is critical to consider when attempting the interpretation of nitrogen isotopic ratios in whole sediment because the effect of diagenesis can be as large as the primary signal that is sought. For example, the diagenetic overprint of sedimentary nitrogen isotopic values typically ranges from 3–8‰ in sediments overlain by well-oxygenated water (Altabet and Francois, 1994; Sachs and Repeta, 1999), while the total range of isotopic variation is typically less than 5‰. The problem of diagenetic alteration of sedimentary $\delta^{15}N$ values is less of a concern in sediments overlain by oxygen-depleted water (Altabet et al., 1999; Sachs and Repeta, 1999).

One means of circumventing the issue of diagenesis is to measure nitrogen isotopic ratios on molecular fossils, or “biomarkers.” These molecules have a known source and, if found intact, are unlikely to have been altered isotopically. Chlorophyll and its decomposition products, chlorins, are ideal for this purpose because they are produced by all primary producers and persist in sediments for millions of years (Sachs and Repeta, 1999). Algal culture studies indicate that chlorophyll $\delta^{15}N$ values reflect those of the host alga with a constant isotopic depletion of 5.1‰ (Sachs et al., 1999). Methods for purifying chlorins for nitrogen (and carbon) isotopic analysis are described in Sachs and Repeta (2000).

Conclusion

Nitrogen isotopic ratios provide a powerful tool for evaluating processes within the nitrogen cycle and for reconstructing changes in the cycling of nitrogen through time. Because multiple nitrogen transformation reactions occur simultaneously in any environment, with some leading to nitrogen isotopic enrichment and some to isotopic depletion of the reservoir

of interest, it can be difficult to discern the most important processes. Nitrogen isotopes are therefore most useful in environments where one or more transformation processes can be ruled out.

NORTH ATLANTIC DEEP WATER AND CLIMATE CHANGE

Modern North Atlantic deep water

Together, the atmosphere and oceans transport $\sim 5\text{--}6$ PW (PW = 10^{15} W) of heat away from the tropics toward each pole in response to the latitudinal imbalance between incoming solar and outgoing long-wave radiation. In the Atlantic Ocean, net ocean heat transport is northward in both hemispheres, with a maximum of ~ 1.3 PW across northern middle latitudes (Ganachaud and Wunsch, 2000). This transport is dominated by the meridional overturning circulation, which transforms warm surface currents (moving predominately northward) into cold deep waters (moving predominately southward). The main product of this transformation is North Atlantic Deep Water (NADW), which forms poleward of 50°N and fills much of the Atlantic between ~ 1 and 4 km depth below sea surface. NADW formation is thus associated with the release of a great deal of heat to the high northern latitude atmosphere.

Modern NADW is ventilated in two main regions of wintertime deep convection: the Greenland Sea (producing Greenland Sea Deep Water) and the Labrador Sea (producing Labrador Sea Water) (Figure N3). In general, three factors may contribute to convective instability: cooling, increased salinity (lack of freshwater input, or active salinification due to sea ice formation), and winds/storminess. Sea ice also leads to the formation of dense Arctic shelf waters that entrain warm Atlantic waters. The resulting Arctic Intermediate/Deep Water mixes with Greenland Sea Deep Water to form the dense overflows that pass southward on each side of Iceland (Denmark Strait Overflow Water to the west, and Iceland-Scotland Overflow Water to the east). Each overflow

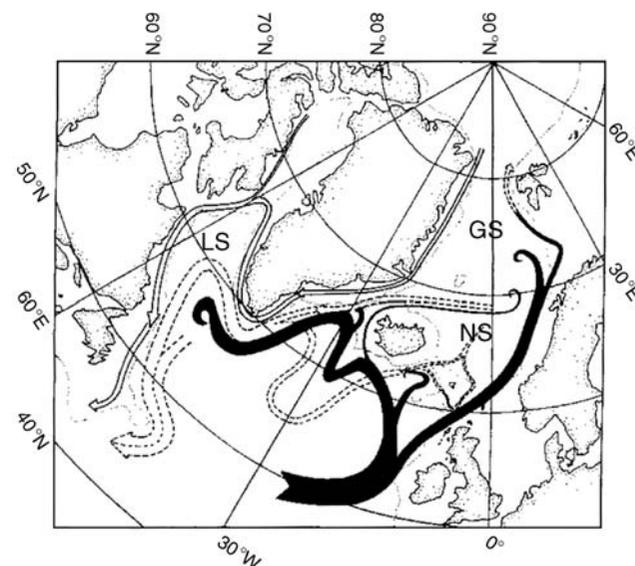

Figure N3 Schematic diagram of modern NADW formation, after McCartney and Talley (1984). Warm ($>4^\circ\text{C}$) surface currents are shown in black, and dense deep waters are dashed. The curled ends of the warm currents indicate sinking. Also shown are cold surface currents (open arrows). Labels denote the Labrador Sea (LS), Greenland Sea (GS), and Norwegian Sea (NS).

amounts to roughly 3 Sverdrups ($Sv = 10^6 \text{ m}^3 \text{ s}^{-1}$), and several additional Sv are entrained south of the sills as geostrophy concentrates the net flow into a western boundary current (Hansen and Østerhus, 2000). Labrador Sea Water adds perhaps another 5 Sv, yielding a total of 15 ± 2 Sv of NADW exiting the North Atlantic (Ganachaud and Wunsch, 2000). The overflows mainly contribute to NADW properties below 2 km depth while the less-dense Labrador Sea Water mainly affects the 1–2 km range.

Hydrographic time series indicate that fluxes of the various NADW components have varied slightly over recent decades (Dickson et al., 1996; Hansen et al., 2001). Changing patterns of surface salinity and winds may suppress deep convection in one region while enhancing it in another. Analogous but larger scale changes are believed to have occurred in the distant past, with dramatic impacts on climate.

Last Glacial Maximum

The importance of the North Atlantic's wind-driven circulation in explaining the climate of the last ice age was hypothesized by James Croll well over a century ago, but the abyssal circulation did not receive attention until much later. Weyl (1968) proposed that Pleistocene glaciations were initiated by reduced NADW formation and expanded sea ice coverage, with both being caused by lower sea surface salinities in the North Atlantic. Early reconstructions of Last Glacial Maximum (LGM, ~ 21 ka) North Atlantic surface temperatures based on assemblages of planktonic organisms suggested that polar waters and sea ice expanded southward, as expected if the warm, upper branch of the meridional overturning circulation was restricted. Reduced NADW has since come to be regarded as a response to (and amplifier of) glaciation, rather than its ultimate cause (Rahmstorf, 2002).

Most of what is known about the past distribution of NADW is based on paleonutrient proxies. Modern NADW is low in dissolved nutrients like phosphate and nitrate because it is formed from surface waters that have been stripped of these constituents by photosynthetic activity. In contrast, Atlantic deep waters of southern origin (Antarctic Bottom Water (AABW) and Circumpolar Deep Water (CDW)) are

formed from waters that contain abundant nutrients. Deep Atlantic nutrient distributions therefore reflect the spatial extent of these water masses and give some indication of "aging" (via the collection of nutrients remineralized from decomposing organic matter that rains from above) and mixing processes.

Since there is no way to directly measure past phosphate or nitrate distributions, nutrient proxies are relied upon for paleoceanographic reconstructions. One such proxy is $\delta^{13}\text{C}$, a measure of the ratio between ^{13}C and ^{12}C in the dissolved inorganic carbon (DIC) pool. The preferential uptake of ^{12}C during marine photosynthesis leaves low-nutrient surface waters, such as those that form NADW, enriched in $\delta^{13}\text{C}$ (Kroopnick, 1985) (Figure N4). The $\delta^{13}\text{C}$ of DIC is recorded by the $\delta^{13}\text{C}$ of benthic foraminiferal calcite (Duplessy et al., 1984), offering a way to reconstruct the distribution of NADW through time. Another important nutrient proxy is dissolved Cd, which is highly correlated with phosphate in the modern ocean. Some phytoplankton use Cd as a micronutrient and others may incorporate it incidentally during the uptake of other nutrients. The Cd concentration of seawater is reflected in the Cd/Ca ratio of benthic foraminiferal calcite (Boyle, 1992), again offering a method for tracing paleo-NADW. Discrepancies sometimes exist between $\delta^{13}\text{C}$ and Cd/Ca, however, pointing to complicating factors such as air-sea carbon exchange, benthic foraminiferal microhabitat effects, and calcite undersaturation or dissolution. Care must therefore be exercised when interpreting changes recorded by just one proxy.

Benthic foraminiferal $\delta^{13}\text{C}$ and Cd/Ca provide a relatively detailed picture of deep Atlantic water mass geometries during the LGM. Below ~ 2 km, both proxies indicate higher nutrient concentrations during glacial times, consistent with reduced NADW production (Boyle, 1992; Oppo and Lehman, 1993; Samthein et al., 1994; Curry and Oppo, 2005; Marchitto and Broecker, 2006). High $\delta^{13}\text{C}$ and low Cd/Ca values at intermediate depths (above ~ 2 km) suggest that NADW was partially replaced by a shallower water mass dubbed Glacial North Atlantic Intermediate Water (GNAIW). This apparent shoaling of northern source deep waters allowed high-nutrient

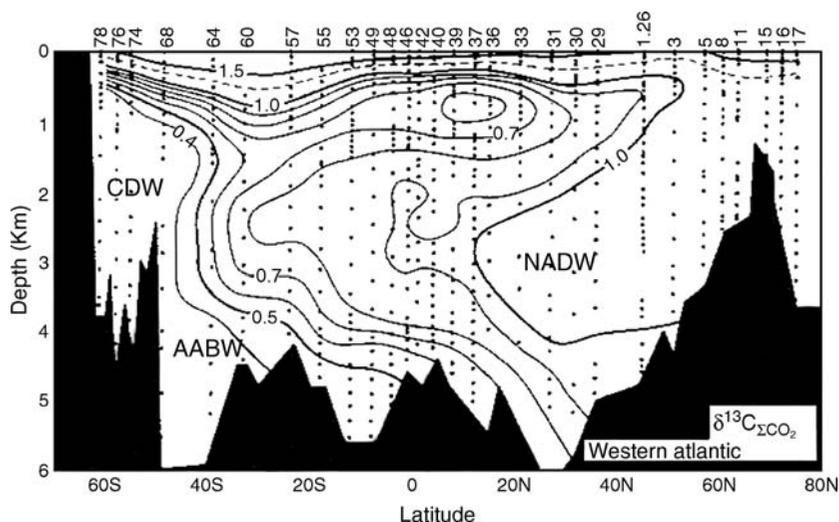

Figure N4 Section of modern seawater $\delta^{13}\text{C}$ in the western Atlantic Ocean, after Kroopnick (1985) (reprinted with permission from Elsevier). High values trace the southward flow of NADW, which mixes with low- $\delta^{13}\text{C}$ AABW and CDW. Dots indicate locations of samples, and numbers along the top axis indicate GEOSECS station numbers.

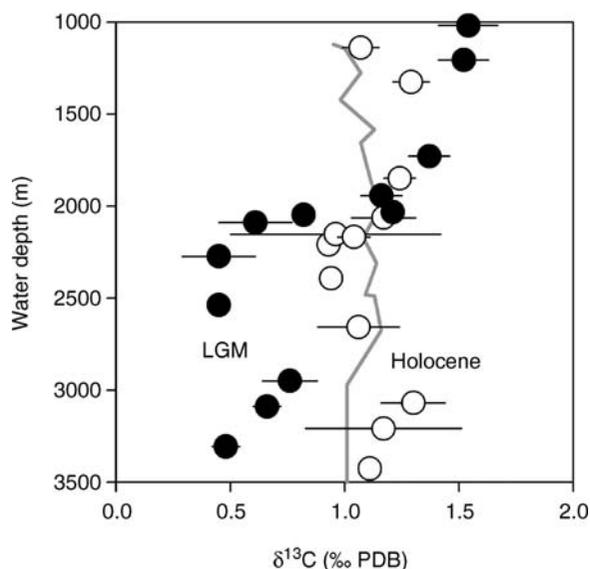

Figure N5 Vertical profiles of North Atlantic (>40° N) benthic foraminiferal $\delta^{13}\text{C}$ for the Holocene (open circles) and LGM (filled circles) (Oppo and Lehman, 1993; Marchitto et al., 2002). LGM data have been shifted upward by 120 m to account for the glacial lowering of sea level. Also shown are nearby modern seawater measurements (gray line) (Kroopnick, 1985). The LGM nutricline at ~2,000 m separates high- $\delta^{13}\text{C}$ GNAIW from low- $\delta^{13}\text{C}$ AABW/CDW.

southern source deep waters (AABW and/or CDW) to penetrate farther into the North Atlantic (Figure N5). Two additional paleonutrient tracers, Ba/Ca and Zn/Ca, support this view (Lea and Boyle, 1990; Marchitto et al., 2002).

Ocean circulation models suggest that reduced sea surface salinities and greater sea ice cover in the glacial North Atlantic could cause not only a shallower mode of deep water production (GNAIW), but also a shift in its production site to south of Iceland (Ganopolski et al., 1998). This change in deep convection sites would reduce ocean heat transport to higher latitudes even if the rate of deep water production was unchanged. The question of rate cannot be addressed with paleonutrient data alone, since their distributions depend on additional factors such as initial sea surface (“preformed”) values, biogeochemical cycling, and water mass mixing. One method that can potentially be used to assess actual flow rates is the ^{14}C age difference between coexisting benthic and planktonic foraminifera, which is an estimate of the time elapsed since the deep water mass was last in contact with the atmosphere (“ventilation age”). Mixing with old (poorly ventilated) AABW/CDW must be accounted for, however, to isolate any true aging of northern source waters. Limited LGM measurements are consistent with older waters in the deep (~3–4 km) Atlantic (Robinson et al., 2005), but the impact of mixing has not been well constrained. An additional complication for benthic-planktonic ages arises from temporal variations in the ^{14}C content of the atmosphere, a problem that can be avoided by obtaining paired ^{14}C and U-series dates on deep sea corals (Robinson et al., 2005). $^{231}\text{Pa}/^{230}\text{Th}$ patterns in marine sediments have been used to argue that LGM GNAIW must have been exported to the Southern Ocean at a rate similar to today, otherwise more Pa (which is less particle reactive than Th) would have been scavenged out of the water column within the Atlantic (Yu et al., 1996). The differential behavior of Pa and Th is dependent on

particle flux and composition, however, adding uncertainty to rate estimations.

A promising method for reconstructing the rate of the meridional overturning circulation is paleo-geostrophy. The northward flowing limb of the North Atlantic overturning is geostrophic, i.e., the flow is balanced by a horizontal pressure gradient and the Coriolis force. The strength of the flow can therefore be calculated from the magnitude of the pressure gradient. Above some “level of no motion” (where isobars are horizontal) the pressure gradient must be accompanied by lateral changes in density. Because benthic foraminiferal $\delta^{18}\text{O}$ is influenced by both temperature and salinity, it is a good recorder of density in waters warmer than ~5°C, allowing paleo-geostrophic calculations to be made. Lynch-Stieglitz et al. (1999) showed that Gulf Stream transport through the Florida Straits was only ~15–18 Sv during the LGM. Today the flow is ~30–32 Sv, with the wind-driven subtropical gyre accounting for ~17 Sv and the rest being due to meridional overturning. Since it is unlikely that the gyre circulation was slower during the LGM (models do not support weaker winds), this suggests that the overturning was either very weak, or was accomplished in a way that did not draw surface waters northward through the Florida Straits.

Although benthic foraminiferal $\delta^{18}\text{O}$ has also been used to infer deep ocean paleotemperatures, the influence of seawater $\delta^{18}\text{O}$ (which is related to both salinity and global ice volume) has been difficult to quantify. Fortunately, independent methods for separating temperature and salinity have recently become available. Initial indications from benthic foraminiferal Mg/Ca (a temperature proxy) are that the deep equatorial Atlantic was ~3–4°C colder during the LGM than during the Holocene, consistent with a greater influence of AABW (Martin et al., 2002). Semi-direct estimates of salinity and seawater $\delta^{18}\text{O}$ can also be made by analyzing glacial-age waters that have been partially preserved as sediment pore waters. When combined with benthic foraminiferal $\delta^{18}\text{O}$, these measurements suggest that the LGM deep Southern Ocean was much saltier and denser, but not discernibly colder, than the deep North Atlantic (Adkins et al., 2002). This is very different from the modern relationship (AABW colder and fresher than NADW), indicating a major change in the thermohaline properties of the deep circulation. All deep waters appear to have been formed close to the freezing point, with salinity dominating the deep stratification.

Dansgaard-Oeschger cycles and Heinrich events

During the last ice age, temperatures over Greenland and in the North Atlantic repeatedly and abruptly switched between cold stadials and warm interstadials, with a periodicity of approximately 1,500 years (Dansgaard et al., 1993). Broecker et al. (1985) suggested that these Dansgaard-Oeschger (D-O) cycles could have been caused by switches between “weak NADW” and “strong NADW” states, driven by oscillations in North Atlantic salinity. The first convincing evidence for a millennial-scale change in NADW flow was during the Younger Dryas (~13–11.6 ka), a brief return to glacial-like conditions in the middle of the last deglaciation. Benthic foraminiferal Cd/Ca and $\delta^{13}\text{C}$ imply a sharply reduced presence of NADW in the deep western North Atlantic at this time (Boyle and Keigwin, 1987). NADW suppression during the Younger Dryas may have been caused by an input of Laurentide Ice Sheet meltwater into the North Atlantic via the St. Lawrence River. Paleonutrient records (Keigwin

and Boyle, 1999; Boyle, 2000) and benthic foraminiferal faunas (Rasmussen et al., 1997) now suggest that NADW production was also reduced during D-O stadials and enhanced during interstadials (Figure N6). There is evidence for an opposite response (reduced during interstadials) for GNAIW (Zahn and Stüber, 2002), suggesting that stadials resembled the LGM state while interstadials approached the Holocene state. Some deep waters may have continued to form in the Norwegian-Greenland Seas during stadials because of brines resulting from sea ice formation (Dokken and Jansen, 1999).

Various ocean circulation models support the hypothesis that even small freshwater forcing can abruptly switch NADW between different equilibrium states (Rahmstorf, 2002). These models exhibit hysteresis behavior, whereby the system flips rapidly from strong to weak/no overturning, or vice versa, after crossing some surface salinity threshold. Furthermore, the overturning can be bistable, meaning that it can exist in either state for a given range of freshwater forcing. Glacial boundary conditions may narrow the hysteresis loop, such that a smaller range of salinity forcing is required to cause abrupt switches. Periodic or quasi-periodic salinity “triggers” may result from internal ice sheet dynamics (iceberg calving) (Schmittner et al., 2002) or possibly solar variations. When combined with white-noise salinity variability, the required magnitude of salinity forcing is further reduced, a phenomenon known as stochastic resonance (Alley et al., 2001).

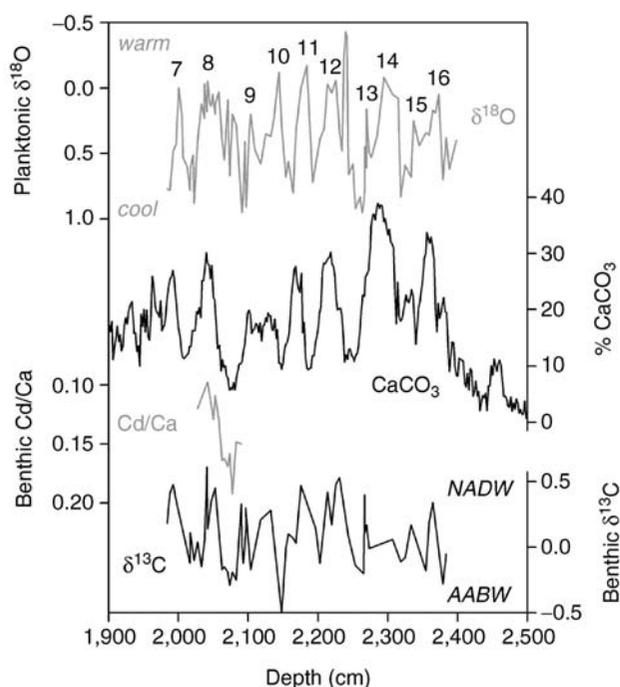

Figure N6 Last ice age climatic and deep water indicators from Bermuda Rise (~4,600 m) in the western North Atlantic (Keigwin and Boyle, 1999). Planktonic foraminiferal $\delta^{18}\text{O}$ shows warmings coincident with Dansgaard-Oeschger interstadials (numbered). Benthic foraminiferal $\delta^{13}\text{C}$ increased during interstadials, suggesting stronger production of NADW. Cd/Ca measurements across one stadial-interstadial transition are consistent with this (note reversed scale). Low bulk percent CaCO_3 during stadials may have been due, in part, to dissolution by corrosive AABW.

Some models' glacial responses may be grouped into three states: “warm” or strong NADW (interstadials), “cold” or weak GNAIW (stadials), and “off” (Heinrich events) (Rahmstorf, 2002). Heinrich events, which occurred during stadials every 6–10 Kyr, are marked by widespread ice-rafted debris layers believed to have resulted from ice sheet surging. The modeled Heinrich state thus results from a much larger freshwater (iceberg) forcing than in the normal stadial state. There is good paleonutrient evidence for reduced NADW during Heinrich events (Boyle, 2000; Elliot et al., 2002), and at least some GNAIW sites show strong nutrient enrichments (Zahn and Stüber, 2002). $^{231}\text{Pa}/^{230}\text{Th}$ measurements from Bermuda Rise suggest that the meridional overturning circulation was nearly or completely shut down during Heinrich event 1 (McManus et al., 2004).

Northern Hemisphere glaciations (past 3 Myr)

Composite records of deep ocean $\delta^{18}\text{O}$ indicate that significant Northern Hemisphere glaciations commenced during the late Pliocene, at ~3 Ma. Deep ocean $\delta^{13}\text{C}$ gradients suggest that a gradual weakening of NADW began around this time (Ravelo and Andreasen, 2000), probably as a response to (and amplifier of) surface cooling and freshening. The divergence of Nd isotopic values between the North Atlantic and Southern Ocean since ~3–4 Ma is consistent with this weakening (Frank et al., 2002). On the 41 Kyr scale of late Pliocene glacial-interglacial cycles, NADW was generally weakest during glaci- als and progressively deteriorated toward the Pleistocene. Glacial suppression of NADW intensified after ~1.5 Ma and was most severe during the 100 Kyr cycles of the mid-late Pleistocene (since ~0.9 Ma) (Raymo et al., 1997). GNAIW has appeared during glaciations (intermittently) since at least the early Pleistocene (McIntyre et al., 1999).

On a finer temporal scale, there appear to be lags between Pleistocene glacial cycles and NADW production changes (Wright and Flower, 2002). During glacial initiations, NADW initially strengthened as ice sheets began to grow, likely in response to increased salinities. The resulting continued sea surface warmth may have supplied excess moisture for the expanding ice. At least several millennia passed before reduced salinities caused NADW suppression and North Atlantic cooling. A similar (but opposite) progression seems to have occurred during deglaciations: GNAIW initially weakened due to meltwater addition, with NADW resumption and surface warming occurring several millennia later. Hence, NADW production changes have played an important role in modifying the character of glacial-interglacial transitions.

With still higher temporal resolution, it is apparent that the millennial scale variability characteristic of the last glaciation was also present during prior glaciations. Ice rafting events have been associated with NADW reorganizations since at least the early Pleistocene (Raymo et al., 1998). During the late Pleistocene (past 0.5 Myr), millennial-scale sea surface variability was strongest when ice sheets exceeded a certain threshold size (McManus et al., 1999). Benthic $\delta^{13}\text{C}$, however, suggests that NADW reductions occurred during intervals of cooling and ice rafting regardless of their magnitude, implying that rapid deep circulation changes may occur without large Northern Hemisphere ice sheets.

Earlier Cenozoic history

On longer timescales, tectonics played an important role in the broad evolution of NADW. Prior to the global cooling of

the Plio-Pleistocene, a relatively cold NADW mass (loosely defined) could only form at very high latitudes, such as in the Norwegian-Greenland Seas. During the early Cenozoic, a shallow Greenland-Scotland Ridge prevented any such waters from filling the open Atlantic. Attempts to date the onset of NADW formation, presumed to coincide with an opening in this barrier, have relied on two main methods: reconstructing deep ocean $\delta^{13}\text{C}$ gradients and identifying sedimentation patterns created by deep flow. It has been proposed that an early Oligocene initiation coincided with the formation of the Southeast Faroes Drift (Davies et al., 2001). Accumulation on Feni Drift also began around this time, though its link to NADW production is not straightforward. The opening of Drake Passage (probably during the Oligocene) may have also established the ocean dynamics necessary to sustain a meridional overturning circulation, thereby amplifying the cooling and glaciation of Antarctica (Toggweiler and Bjornsson, 2000). The transition of deep Southern Ocean $\delta^{13}\text{C}$ from low Pacific-like values toward high North Atlantic values during the early-middle Miocene (~ 20 – 15 Ma) has been interpreted as the first appearance of substantial NADW (Wright and Miller, 1996). The formation of other major North Atlantic drifts around this time may or may not be related to increased NADW flow.

Another tectonic change that affected NADW formation was the closing of the Isthmus of Panama. Although the closure began ~ 13 Ma, the gateway was not shallow enough to strongly impact NADW until ~ 4.6 Ma (Haug and Tiedemann, 1998). By this time, the flow of relatively fresh Pacific waters into the Atlantic was minimized, allowing the North Atlantic to become saltier. This excess salt intensified the production of NADW, which may have contributed to early Pliocene warmth. The stronger northward flow of warm waters may have also preconditioned the Northern Hemisphere for glaciation at ~ 3 Ma by supplying the requisite moisture for ice growth.

NORTH ATLANTIC OSCILLATION (NAO) RECORDS

Introduction

Natural climate variability in the Atlantic sector results from processes at work in the atmosphere and in the ocean, and interactions between the two. In general, Atlantic climate variability has been described as a function of three related components: (a) an *atmospheric* mode of variability known as the North Atlantic Oscillation (NAO), (b) an *oceanic* mode of variability known as Atlantic Meridional Overturning Circulation, and possibly (c) an *atmosphere-ocean* mode of dynamics in the tropical Atlantic (see review by Marshall et al., 2001).

The first component, the NAO, is the leading mode of atmospheric variability in the Atlantic sector and has been dubbed the regional manifestation of the Arctic Oscillation (AO) – the leading mode of large-scale atmospheric variability in the Northern Hemisphere (NH). The NAO/AO is second only to the El Niño-Southern Oscillation (ENSO) in terms of the range of its climate impacts.

Impacts

The NAO has a profound impact on both marine and terrestrial ecosystems (Stenseth et al., 2002) in the Atlantic sector and surrounding continents, stretching from the Caribbean to the Arctic and from the eastern seaboard of the United States to Siberia. In addition to temperature and precipitation, impacts of the NAO are seen in agricultural production (Souriau, 2001), yields from fisheries (Otterson and Stenseth, 2001), fertility and demographic trends of land animals (Post and Stenseth, 1998), snow depth (Beniston, 1997), water resource management (Cullen et al., 2002), hydropower generation (Visbeck et al., 2002), hurricanes (Landsea et al., 1999), and wave heights (Kushnir and Wallace, 1989; Kushnir et al., 1997). The NAO is also the major factor controlling air-sea interactions over the Atlantic Ocean; modulating the intensity and location of upwelling/downwelling centers of the Atlantic's Meridional Overturning Circulation (MOC). Furthermore, there exists the possibility that the NAO has been influenced by anthropogenically forced climate change. This has led to the suggestion that a significant NAO-related weakening of the MOC in global warming scenarios is – while contentious – a possibility (Marshall et al., 2001).

Definitions

The NAO refers to a meridional redistribution of atmospheric mass between the center of subtropical high surface pressure located near the Azores, known as the Azores High (AH), and the center of subpolar low surface pressure near Iceland, known as the Icelandic Low (IL). There is no single way to define the NAO. Techniques include one-point correlation maps that rely on identifying regions of maximum negative correlation (Wallace and Gutzler, 1981), principle component analysis using eigenvectors of the covariance matrix (Barnston and Livezey, 1987), and clustering algorithms that identify climate regimes corresponding to the peak in the probability density function (Cassou and Terray, 2001).

In general, the NAO is described as being in either a positive or a negative phase. Synchronous strengthening (positive NAO state) and weakening (negative NAO state) of the NAO centers-of-action have been shown to result in distinct, dipole-like climate change patterns between western Greenland/the Mediterranean and northern Europe/northeast US/Scandinavia (Walker, 1924; Walker and Bliss, 1932; van Loon and Rogers, 1978; Rogers and van Loon, 1979). A lower-than-normal (higher-than-normal) IL and higher-than-normal (lower-than-normal) AH result in an enhanced (reduced) pressure gradient and a positive (negative) NAO. During this +NAO (–NAO) phase, surface winds and wintertime storms moving from west to east across the North Atlantic are stronger (weaker) than usual. As a result, wetter and warmer (drier and cooler) winter conditions occur in northern Europe, Scandinavia and the east coast of the US, while cooler and drier (warmer and wetter) winters occur in eastern Canada and Greenland.

In addition to a sea-level pressure (SLP) signature, the NAO has a coherent signal in sea-surface temperature (SST) involving a tripole pattern of almost zonally-oriented anomalies with subtropical and high-latitude SSTs varying in-phase and mid-latitude SSTs varying out-of-phase (Seager et al., 2000). Figure N7 presents the classic SLP and SST pattern associated with the NAO. While the NAO reflects changes in the strength and orientation of mid-Atlantic westerlies that dictate heat and moisture flux trajectories, it is also expressed in terms of distinct North Atlantic SST, sub-surface temperature (Molinari et al., 1997; Reverdin et al., 1997) and sea-ice extent anomalies (Deser and Blackmon, 1993). During the positive phase of the NAO, SSTs in the eastern Labrador Sea, eastern Mediterranean, and subtropical Atlantic are anomalously cold by 0.5–1 °C, whereas SSTs in the North Sea and Sargasso Sea are anomalously warm by approximately the same amount (Cullen et al., 2002).

Given that there is no unequivocal method for defining the NAO, it follows that there is no universally accepted index of the temporal variability of the NAO. However, as the signature of the NAO is strongly regional, a simple NAO index has been defined as the difference between the normalized mean winter (December through March; DJFM) SLP anomalies at locations representative of the relative strengths of the AH and IL. A positive NAO index implies more meridional storm tracks while a negative NAO index implies more zonal storm tracks. It must be remembered, however, that indices of the NAO merely provide a temporal signature for the behavior of a phenomenon whose dynamics are not clearly understood.

Historical development

The NAO was first documented by the Danish missionary Hans Egede Saabye (Egede, 1745) who described it as a saw-saw in temperature between Greenland and Denmark. Sir Gilbert Walker eventually defined the NAO as a meridional alternation of atmospheric mass in the 1920s (Walker, 1924). In addition to the NAO, Walker was also the first to describe the Southern Oscillation and the North Pacific Oscillation in his attempt to forecast Indian monsoon rainfall (Brown and Katz, 1991).

Beginning with the work of Bjerknes (1964), considerable effort has been made to understand the extent to which preferred timescales apparent in observations of the North Atlantic Ocean are associated with interactions between the ocean and atmosphere. These processes can be either coupled, whereby the two systems generate important positive and negative feedbacks, or uncoupled, where communication does not lead to feedbacks. Coupled, or two-way, interactions between the ocean and atmosphere suggest the potential for a degree of predictability. Predictability resides primarily within the long-term memory of the ocean and provides the opportunity for long-range forecasting. One example, in fact the only unquestioned example, of a coupled ocean-atmosphere interaction is the El Niño-Southern Oscillation (ENSO). Like the ENSO, the NAO has been shown to have significant climate impacts. However, there is still considerable doubt as to whether the NAO is a coupled ocean-atmosphere process. The NAO is a fundamental mode of the atmosphere, that is, it appears in atmospheric general circulation models (AGCMs) with fixed surface boundary conditions, whereas the Southern Oscillation's existence is entirely dependent upon active ocean-atmosphere coupling.

Significance

Given its importance as a modulator of climate in the Atlantic sector, an increased understanding of how the NAO has varied in past centuries is of considerable interest to the climate community. However, unlike the tropics, where abundant maritime proxy climate data (e.g., coral records) are preserved for high-resolution reconstructions of ENSO variability over past centuries, extra-tropical regions such as the North Atlantic lack these primary archives for reconstruction. The best proxy archives of NAO variability come from terrestrial regions and include tree ring records from North America, Eurasia, Scandinavia, and the Middle East, documentary evidence from Europe, and ice cores from the Arctic.

The NAO has exhibited a significant trend towards more positive values over the past 30 years, steadily rising from a negative phase in the 1960s to a persistent positive phase in the early 1990s. This trend accounts for a significant portion of the wintertime (DJFM) temperature increase over Eurasia

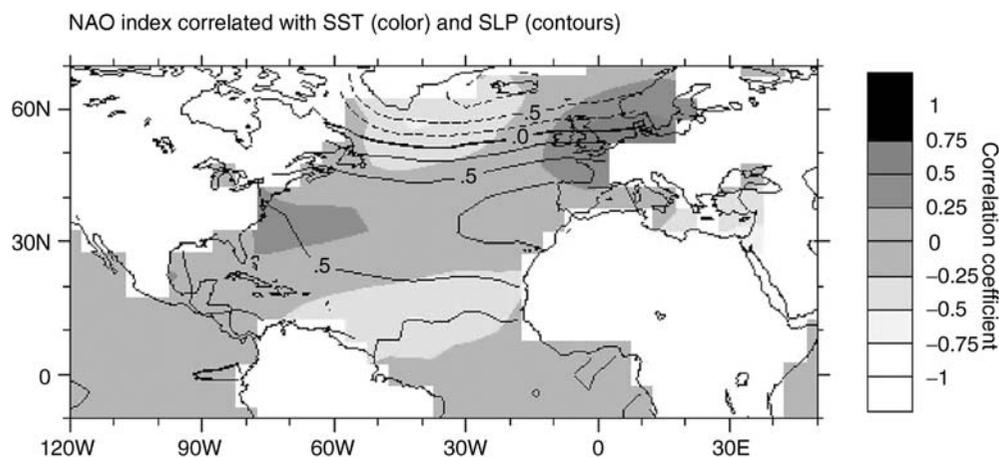

Figure N7 Correlation over the period 1865–2001 between the NAO index (Hurrell, 1995) and North Atlantic sector sea-level pressure (SLP; Kaplan, 2000) anomalies and sea-surface temperature (SST; Kaplan et al., 1998) anomalies. SLP correlation is shown as *contoured* r values (correlation coefficient) from -1.0 to 1.0 and SST correlation is shown as *shaded* r values (correlation coefficient) from -1.0 to 1.0 .

(Hurrell and van Loon, 1997). Consequently, the NAO has been introduced into the global warming debate with a search for mechanisms that could resolve whether this trend is due to anthropogenic perturbation or natural variability (Rodwell et al., 1999; Shindell et al., 1999). Coherent, large-scale changes in the NAO since 1981 were linked to recent dry conditions over western Greenland and the Mediterranean, and wetter and warmer than normal conditions in northern Europe, the northeast US, and parts of Scandinavia (Hurrell, 1995; Hurrell and van Loon, 1997). Using multivariate linear regression to quantify temperature variability associated with the NAO, it was shown that the NAO accounts for 31% of NH interannual variance (Hurrell, 1996). Moreover, the NAO accounts linearly for 0.15°C of the 0.29°C NH extratropical temperature increase for the period 1981–1994, with respect to the 1935–1994 mean. It should be noted, however, that the winters since 1995 have shown negative or neutral values – thereby interrupting the trend. In addition to being linked to widespread warming over the past three decades (Hurrell, 1996), it has been suggested that the NAO may have also played a role in maintaining climate anomalies during the Little Ice Age (Luterbacher et al., 1999, 2000; Shindell et al., 2001).

Proxy NAO records lengthen the relatively short observational record and provide the opportunity to assess both the low-frequency behavior of the NAO and the recent positive trend. Since the NAO is a natural mode of atmospheric variability, one could argue that much of the recent warming is natural and not related to the build-up of greenhouse gases in the atmosphere since the industrial revolution. This viewpoint, however, ignores the possibility that anthropogenic climate change might influence modes of natural variability, perhaps making it more likely that one phase or another of the NAO might be preferred.

Observational records

Table N1 details the most commonly used NAO indices. Most of the more commonly used NAO indices are derived from different representative SLP stations of the IL and AH. The principal component (PC) time series of the leading empirical orthogonal function (EOF) of Atlantic SLP is also commonly used. Walker and Bliss (1932) constructed the first index of the NAO using a linear combination of surface pressure and temperature measurements. Rogers (1984) constructed an NAO index beginning in 1895 using SLP anomalies from Ponta Delgados, the Azores, and Akuyreyri, Iceland. 1995) demonstrated that data from Lisbon, Portugal better captured the southern node variability of the NAO and used it along with data from Stykkisholmur, Iceland to develop an index that extends back to 1864. Figure N7 presents the correlation of the Hurrell (1996) NAO index with winter (DJFM) SLP (Kaplan et al., 2000) and SST (Kaplan et al., 1998) data. Jones et al.

(1997) further extended the NAO index back to 1821, using pressure data from Gibraltar and a composite southwest Iceland series. Jones et al. (2003) show that all of these indices are significantly correlated at interannual and decadal timescales but that choice of the southern node does make a difference.

Cullen et al. (2002) developed an SST anomaly index of the NAO, extending back to 1857, to extract the NAO-related component of Atlantic SST variability – similar in principle to the NINO3 SST-based index, which tracks ENSO in the tropical Pacific Ocean. Luterbacher et al. (1999) have developed the longest observational NAO record to date, going back to 1675, using instrumental station pressure, temperature and precipitation measurements, and proxy data. Each method has advantages and disadvantages. Indices based on station data are fixed in space and are therefore affected by small-scale transient non NAO-related weather events (Trenberth, 1984). Given the shifting of the NAO centers-of-action through the annual cycle, these indices cannot sufficiently capture the NAO over all months of the year (Hurrell and van Loon, 1997). One advantage of the PC time series approach is that it includes a larger spatial domain and hence provides a more optimal representation of the NAO pattern.

In addition to these commonly used NAO indices, several other methods for capturing temporal variability exist. During the 1950s, Namias, (1950) and Lorenz, (1951) were among the first to develop indices known as the “zonal index cycle.” These indices characterize NAO variability by looking at zonally averaged mid-latitude surface westerly wind fields. Stephenson et al. (2003) describe several less well-known NAO indices that have been developed by European scientists.

An investigation of the power spectrum of these NAO indices suggests little evidence that the NAO varies on any preferred timescale. Spectral analysis, used to quantify periodicities within time series, shows a slightly “red” spectrum (power increasing with period). There is somewhat enhanced variance on interannual (2–3 years) and decadal (8–10 years) bands as well as a trend over the last 30 years – but there are no significant peaks. Using a station-based index, Hurrell and van Loon (1997) demonstrated that the NAO index showed a greater degree of interannual variability during late nineteenth and early twentieth centuries, whereas decadal variability increased during the late twentieth century. Furthermore, Feldstein (2000) concluded that a role for forcings external to the atmosphere (i.e., the ocean) could not be ruled out despite the fact that interannual variability of the NAO arises primarily from noise. Czaja et al. (2003) caution that spectral analyses of dynamical NAO indices are not optimal for detecting the impact of the ocean.

Paleorecords

Instrumental records of the NAO, while useful in assessing seasonal and interannual variability, are not long enough to answer fundamental questions about low-frequency variability. In addition, recent observational records are not pure reflections of natural climate variability – they carry an imprint of anthropogenic forcing. As a result, a clear need exists to extend climate records back beyond the industrial era in order to understand: (a) the range of natural climate variability, (b) how quickly climate regimes can switch, and (c) how human activity might be influencing natural climate variability.

At present, paleoreconstructions are unable to accurately fingerprint the climate response to increasing greenhouse gas

Table N1 Instrumental records

Index	Season	Field	Begin
Cullen et al. (2002)	DJFM	SST	1856
Hurrell (1995)	DJFM	SLP	1864
Jones et al. (1997, 1999)	Monthly	SLP	1780
Luterbacher et al. (1999)	Monthly	SLP, SAT, P	1675
Rogers (1984)	DJFM	SLP	1874
Thompson and Wallace (2000)	Monthly	SLP	1899
Thompson and Wallace (1998)	JFM	SAT	1851

emissions as they cannot achieve the spatial (regional level) and temporal (season-specific) resolution required (Jones et al., 2001). Nevertheless, several attempts have been made to extend the NAO record back based on the rationale that large-scale climate variability can be represented successfully by integrating across a number of high-resolution “proxies” of past variability. Proxies can either be natural (physical or biological) or from a documentary source and generally act as an indicator of either temperature or precipitation or some combination of the two. The most widely used proxy for NAO reconstructions are trees, where ring density, ring width, and wood isotopic composition are generally measured. Ice cores are the second most widely used proxy, where isotope ratios, accumulation rates, and melt layers serve as proxies. Corals and stalagmites (Proctor et al., 2000) can also be used by measuring isotopic concentration, cation ratios, and growth thickness to provide an annual reconstruction; however, these records are generally restricted to the tropics and have not been widely employed as a tool for reconstructing the NAO. Whereas instrumental measurements have unique space and time coordinates, climate proxies often represent the combined influences of climatic and non-climatic factors, recorded at different times of the year depending on the type and location of the proxy. Calibration against instrumental records is critical for all proxies, and statistical regression is generally used to establish a relationship between observations of the climate in a given region and the variability of the proxy over the same time period.

Table N2 details the most commonly used NAO paleoproxy reconstructions. The longest record is that of Cook et al. (2002), extending back to AD 1400. The reconstructions of Luterbacher et al. (1999, 2002a,b) are the only reconstructions providing monthly resolution. Despite the inconsistencies between different records, this rich archive of tree rings, ice cores, and documentary data indicate that prolonged positive and negative NAO phases have occurred in the past (Appenzeller, 1998; Cook et al., 1998; Luterbacher et al., 1999; Schmutz et al., 2000; Cullen et al., 2001). This suggests that the extreme positive values of the index evident since the late 1980s are not unprecedented over the past five centuries (Luterbacher et al., 2002a,b). Proxy records also indicate that there is a degree of “intermittency” present in the NAO. This suggests the NAO does not contain a single, persistent frequency – but rather oscillates between low-frequency variability and periods more akin to white noise (Appenzeller et al., 1998). However, it should also be noted that the NAO index might simply be one particular realization of a white noise atmosphere initiating a red noise ocean response (Wunsch, 1999).

Due to the different methods, different time intervals, and different observational time series used for calibration, a direct comparison of the different indices shows little agreement before the 1820s (Schmutz et al., 2000; Cullen et al., 2001).

Schmutz et al. (2000) suggest that proxy-based NAO indices are unable to capture NAO variability in a consistent manner in the eighteenth and nineteenth centuries and speculate that the NAO includes several different circulation patterns with specific impacts on a given proxy, resulting in degrees of covariability. Prior to the twentieth century most NAO index reconstructions show an inconsistent picture and in the period before the 1820s these inconsistencies are greater.

Of the NAO records listed in Table N2, the reconstructions by Cook et al. (2002) and Luterbacher et al. (2002a,b) appear to have somewhat more consistent covariability – at least on interannual timescales. The winter (DJFM) multiproxy reconstruction by Cook et al. (2002) was constructed using tree ring and ice core data from the North Atlantic sector whereas the monthly (1659–1995) and seasonal (1500–1658) reconstructions by Luterbacher et al. (2002a,b) used both instrumental and documentary data from Eurasia. When the seasonal indices are compared, explained variances are higher in Luterbacher et al. (2002a,b) than in the Cook et al. (2002) reconstruction during and before the eighteenth century. Furthermore, Luterbacher et al. (2002a,b) suggests predominantly negative-phase NAO values before 1800, whereas Cook et al. (2002) indicate more positive-phase NAO values.

Predictability

In addition to the importance of assessing the role of increasing greenhouse gases, an improved dynamical understanding of the NAO may help provide a better understanding of NAO ocean-atmosphere dynamics as well as the potential predictability of large-scale climate fluctuations in the Atlantic sector. Current research efforts suggest a small degree of seasonal predictability of North Atlantic climate via two potential pathways. The ocean, with its significant thermal inertia, may provide one pathway for limited predictability (Rodwell, 2003). Statistical analyses have revealed that knowledge of North Atlantic (Kushnir et al., 2002) and tropical Pacific (Hoerling et al., 2001) SSTs may provide information about the NAO with a lead time of several months.

A second pathway that offers hope for improved predictability of the NAO involves links through which changes in stratospheric wind patterns might exert some downward control on surface climate (Thompson et al., 2003). The NAO is most active in the winter, a time when stratospheric circulation favors communication between the stratosphere and troposphere, which is consistent with the stratosphere as a potential mechanism. Traditionally, it was thought that the more massive troposphere was forcing the stratosphere, however, now it appears things may work the other way around. Changes in stratospheric circulation can be forced by several different mechanisms including ozone depletion, volcanic dust, and CO₂. Rising CO₂ concentrations cool the stratosphere and strengthen the stratospheric winter vortex, which

Table N2 Paleoproxy records

Reconstruction	Source	Location	Period
Appenzeller et al. (1998)	Ice core	Greenland	1648–1990
Cook et al. (2002)	Multiproxy	Northern Hemisphere	1400–1979
Cook et al. (1998)	Tree rings	North Atlantic sector	1701–1980
Cullen et al. (2001)	Multiproxy	North Atlantic sector	1750–1979
Glueck and Stockton (2001)	Multiproxy	Northern Hemisphere	1429–1983
Luterbacher et al. (2002a,b)	Instruments/documentary	Eurasia	1500–1995
Rodrigo et al. (2001)	Documentary	Spain	1501–1997

generates stronger surface winds through a complex dynamical interaction. These enhanced westerly surface winds are consistent with a positive NAO index. A statistical connection between the month-to-month variability of the NH stratospheric polar vortex and the tropospheric NAO was established several years ago (Perlwitz and Graf, 1995) and more recently it has been documented that large amplitude anomalies in the wintertime stratospheric winds precede anomalous behavior of the NAO by 1–2 weeks. (Baldwin and Dunkerton, 2001), perhaps providing some extended range predictability. Similarly, processes that affect the stratospheric circulation on longer timescales, such as reductions in stratospheric ozone, volcanic forcing, and increases in greenhouse gases, could factor into the trend in Atlantic surface climate observed over the past several decades (Gillett, 2003).

This leaves the interesting possibility that, while interannual to decadal variations in the NAO/AO exist simply because they represent a fundamental mode of climate variability, the trend may be anthropogenically forced. Using an AGCM, Shindell et al. (1999) tested the possibility that these observed trends could be simulated by realistic increases in greenhouse gas concentrations. Ultimately, Shindell et al. (1999) showed that rising greenhouse gases in an AGCM could create a trend in the NAO/AO. Greenhouse gases, therefore, may induce climate change through dynamical effects in addition to direct radiative forcing.

Conclusions

Records, both instrumental and paleoproxy reconstructions of the NAO, provide a temporal snapshot of the behavior of a large-scale climate phenomenon whose dynamics are not yet fully understood. Despite the fact that the NAO is indeed a mode of variability internal to the atmosphere, these records of the NAO exhibit low-frequency variability – both decadal variability and trends – that would not be expected from a fast acting atmospheric process. That not all of the variability associated with the NAO can be attributed to intraseasonal stochastic atmospheric processes suggests a possible role for external forcings. Furthermore, it suggests a small but perhaps useful amount of predictability.

O

OBLIQUITY

The Earth's axis of rotation is not perpendicular to the orbital plane (ecliptic). At present, there is an angle of 23.446° between the axis of rotation and the perpendicular to the ecliptic. This angle, called obliquity, governs the march of the seasons. The North Pole receives sun light during the entire boreal summer while the South Pole remains in the dark. It is the reverse for the boreal winter.

Obliquity results from the torque that the Sun and the Moon exert on the equatorial bulge of the Earth. Its value has varied from 22 to 25° over the last three million years, with a quasi-period of 41,000 years (Figure O1; Berger, 1978; Berger and Loutre, 1991). Obliquity plays a similar role in both hemispheres. Indeed, larger obliquity increases the energy received in each hemisphere during the local warm season. The highest latitudes are more sensitive to obliquity changes because the energy flux at the surface depends on the inclination of the solar beam (Berger and Loutre, 1994). Around the poles, a 1° obliquity change induces a change in the solar radiation at the top of the atmosphere by $\sim 4\%$ during summer time. Moreover, a larger obliquity reinforces the seasonal contrast in insolation because it increases the irradiance in summer and reduces it in winter. It also reduces the latitudinal contrast in annual irradiance because it increases the irradiance at mid-and high-latitudes and decreases it at low latitudes (Figure O2).

OCEAN ANOXIC EVENTS

Although black shales and carbon isotope anomalies are known from the Paleozoic, ocean crust older than approximately 150 Myr has been subducted and therefore oceanic anoxic events prior to the Mesozoic cannot be confirmed. Therefore, this discussion will focus mainly on Mesozoic events.

Mesozoic ocean anoxic events are defined based on the widespread occurrence of fine-grained sedimentary rocks that are highly enriched in organic carbon (e.g., black shales). Deposits of organic-carbon enriched strata (generally known as “black

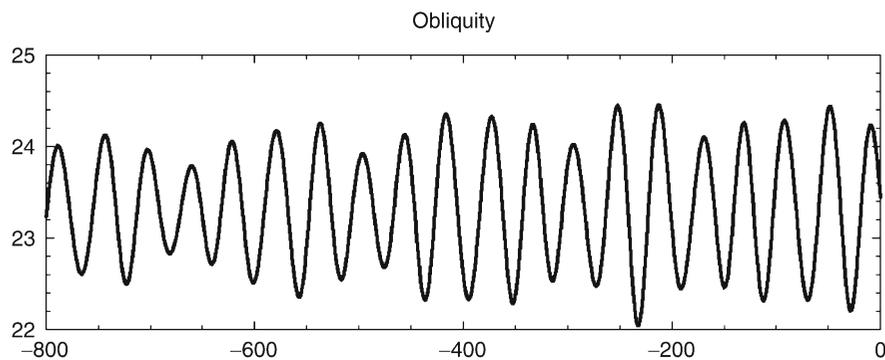

Figure O1 Long term variations of the obliquity over the last 800,000 years.

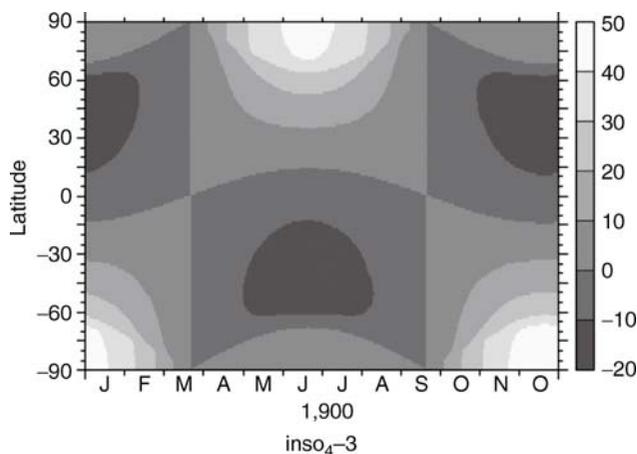

Figure O2 Variation of the mean irradiance (W m^{-2}) following an increase of the obliquity from 22 to 24° (at present-day eccentricity, $e = 0.0167$ and longitude of perihelion, $= 102.04^\circ$).

shales") were recognized as special features of the rock record early in the development of the geologic sciences because they require specific environmental conditions for formation that are not common or widespread in modern oceans. Nonetheless, these deposits store quantities of carbon sufficient to source all of the petroleum and natural gas that humans have thus far consumed, or will ever produce. In fact, it has been estimated that the highest proportion of petroleum source rocks were formed during the times in Earth history that were characterized by ocean anoxic events (Schlanger and Cita, 1982).

Based on observations of organic carbon burial rates in modern marine environments that are oxygen deficient, early black shale researchers concluded that the key factor leading to enhanced organic carbon preservation was decreased oxygen content in bottom waters (e.g., less than 1.0 ml O_2 per $\text{L H}_2\text{O}$). Oxygen deficiency was known to occur as a consequence of either (i) water column stratification, a process that prevents downward mixing of surface waters enriched in oxygen by photosynthesizing algae and/or gas exchange with the atmosphere, (ii) increases in primary production, which result in accumulation of excess decomposing organic matter and exhaustion of oxygen supply by aerobic bacteria. As the petroleum industry expanded in the twentieth century, the impetus to better understand the formation of organic carbon-enriched petroleum source rocks led to even more detailed studies of modern and ancient black shales. Following World War II, the development of research-related exploratory drilling in the ocean basins (the Deep Sea Drilling Project) resulted in a major discovery: many of the black shales known from shallower epicontinental basins could be traced to time equivalent strata in the deep sea record, suggesting that the conditions responsible for organic carbon burial and preservation had been extremely widespread, if not global, during certain intervals of Earth's history. This discovery led Schlanger and Jenkyns (1976) to propose the concept of Mesozoic oceanic anoxic events or OAEs.

The key features that first distinguished ocean anoxic events were the rapid onset, short duration ($\pm 0.5 \text{ Myr}$), and widespread distribution of highly organic-carbon enriched deposits, which suggested a profound and sudden change in the Earth's ocean-atmosphere system (Schlanger and Jenkyns, 1976; Schlanger et al., 1987). It was later shown that many of the OAEs were also

characterized by significant positive shifts in the stable isotopic composition of both organic and inorganic (carbonate) carbon contained within them (Arthur et al., 1985, 1987, 1988). This evidence indicated that the Earth's entire surface carbon reservoir had been depleted in the lighter stable isotope of carbon (^{12}C), likely due to a global increase in the burial of organic matter (which preferentially concentrates the lighter stable isotope). Had the entire global ocean turned rapidly anoxic (as suggested by the OAE term), leading to a worldwide increase in preservation of organic carbon? Alternatively, had rates of phytoplankton production dramatically risen so that the supply of organic matter sinking through the water column was so large that the respiratory demands of decomposers overwhelmed oxygen supplies, secondarily causing widespread anoxia? Was carbon burial in ocean sediments so massive that it turned the oceans into a net CO_2 sink, causing drawdown of atmospheric CO_2 and cooling of the warm greenhouse climate of the Mesozoic? Were these putative changes in marine and terrestrial environments responsible for the major changes in biodiversity revealed in fossil records spanning some of the OAEs? Lastly, what process(es) had initiated each OAE and what caused them to terminate? Such questions have been vigorously debated during almost thirty years of intensive research on these events, and although much has been learned, the largest questions remain unanswered. For this reason, Mesozoic OAEs remain one of the most actively studied examples of deep time perturbations in the Earth's ocean-climate system.

Organic carbon burial processes

The fundamental process underlying the formation of OAEs is the burial of organic carbon. Organic carbon is produced in sufficient quantities to form geologically significant accumulations mainly by primary photosynthesizers, including algae and bacteria in oceans and lakes and vascular plants on land. In most depositional environments, where oxygen is abundant, accumulating organic matter is efficiently decomposed and the CO_2 that was fixed by plants ("photosynthate") is returned to the surface reservoir with no net change in the global carbon cycle. Under certain conditions, however, where oxygen becomes limited due to a decrease in supply or an increase in demand (relative to supply), accumulating organic matter may be protected from aerobic decomposition long enough to be buried, thus preventing its remineralization to CO_2 (examples include bogs in which so much plant matter accumulates that available oxygen is consumed by respiration, or well-stratified tropical lakes and shallow seas in which a lack of seasonal overturn leads to oxygen-depleted bottom waters and improved conditions for preservation of algal organic matter). In these settings, carbon is removed from the surface short-term carbon cycle and it enters the long-term (lithospheric) carbon cycle, where it remains for timescales of millions to many millions of years. Ocean anoxic events represent extremely narrow time intervals in which large areas of the world's oceans shifted from carbon respiring to carbon preserving systems.

The exposure of organic matter to dissolved oxygen certainly exerts an important primary control on organic carbon burial rate (Hartnett et al., 1998), but it is not the only control. The main factors that regulate the rate of burial and long term preservation of organic matter in marine sediments include the rate of export production (fraction of primary photosynthate reaching the sediment), the rate of bulk sedimentation (which controls how fast organic matter is transferred into the anoxic zone within the sediment column), and the rate of organic decomposition (which is accomplished by aerobic and anaerobic microbial communities) (e.g., Arthur and Sageman, 1994;

Sageman and Lyons, 2003; Sageman et al., 2003). Although there has been much debate about the importance of production vs. preservation over the years, the current consensus views each of the aforementioned factors to be important, if not interdependent elements of organic matter burial. Their relative importance may vary from one depositional system to another.

Types of OAEs

Mesozoic OAEs occur in two major time intervals that are generally characterized by widespread development of black shales (Figure O3). Based on areal extent of organic carbon deposition and perturbation of the global carbon cycle, as reflected in carbon isotope excursions, the Toarcian event in the Jurassic (Jenkyns, 1988) and OAE Ia through III in the Cretaceous (Leckie et al., 2002) are the major designated OAEs. However, other stratigraphic intervals such as the Late Jurassic Kimmeridge Clay and Oxford Clay, or the Middle to Late Cenomanian Graneros and Greenhorn Formations (and time equivalent stratigraphic units), are also characterized by significant organic carbon enrichments, as well as some minor perturbations in the isotope record.

Although the difference between OAE and non-OAE black shales appears to be a matter of degree, the key question is degree of what? Both OAE and non-OAE black shales may exhibit spatial and temporal differences in the principal types of organic matter buried; the dominance of production, preservation, or sedimentation mechanisms; or the nature of the associated carbon isotope excursion. For example, the Toarcian event, OAE Ia, OAE Ib, OAE II and OAE III [all] contain mostly marine organic matter, but OAE Ic and OAE Id appear to be dominated by terrestrial organic material (Erbacher et al., 1996). Increase in primary production is currently viewed as the dominant mechanism driving carbon burial during OAEs in most settings. However, evidence for dominance of hydrogen-sulfide rich conditions in the deep ocean basins (e.g., Kuypers et al., 2002) combined with the recent demonstration of enhanced organic matter preservation due to sulfide-mediated hydrogenation reactions (Hebting et al., 2006) suggests that preservation may indeed also play an important role. Lastly, although the archetypal isotope excursion during an OAE is the positive shift believed to reflect greater burial of ^{12}C -enriched organic matter (e.g., OAE Ia, OAE II), some events are characterized by distinct negative shifts in $\delta^{13}\text{C}$ followed by a swing to positive values. This pattern is particularly well developed in the Toarcian event (Hesselbo et al., 2000, 2003).

Causal mechanisms for OAEs

If enhanced primary production initiates OAEs, then these events likely reflect major changes in nutrient availability. Several processes have been implicated as causal factors affecting nutrient budgets in Cretaceous seas, but none of them individually provides a satisfactory explanation for the observed features of OAEs. For example, changes in vertical circulation associated with the opening of ocean gateways has been suggested as a mechanism that might have upwelled phosphate-rich deep waters (Kuypers et al., 2002; Poulsen et al., 2003). Some investigators have suggested that micronutrients, such as reactive Fe, derived from hydrothermal activity associated with rapidly spreading ridges or emplacement of large igneous provinces may have played a role in driving OAEs (Sinton and Duncan, 1997; Kerr, 1998; Kerr et al., 2004; Leckie et al., 2002; Snow et al., 2005). This idea is quite intriguing, especially since the strontium isotope record (Figure O3) shows shifts toward less radiogenic values consistent

with global increases in oceanic volcanism and sea floor spreading during several OAEs (McArthur et al., 2001), and the ages of some large igneous provinces broadly overlap with OAEs (Wignall, 2001; Leckie et al., 2002). A terrestrial source of increased phosphorus is also a possibility given that many studies have shown changes in paleotemperature proxies consistent with significant warming during the time intervals containing OAEs (e.g., Huber et al., 2002; Norris et al., 2002; Wilson et al., 2002). Such temperature increases, initially caused by enhanced volcanic outgassing of CO_2 and global warming, could have driven up chemical weathering rates leading to greater terrigenous phosphorous input to the oceans (Föllmi, 1995). Lastly, it is clear from a comparison of the global relative sea level record and OAEs (Figure O3) that they occurred during rising sea level or highstand episodes when the area of shallow shelf seas was greatly expanded. As originally recognized by Schlanger and Jenkyns (1976), shelf sea area may have been a critical prerequisite for OAE development.

Although none of these proposed mechanisms alone explains the short-term character of all OAEs, some combination likely provides a plausible means to initiate and terminate these events. In addition, the role of phosphorus regeneration during anoxic organic matter decomposition has received increasing attention in recent years as a potential feedback mechanism for eutrophication and black shale deposition (Ingall et al., 1993; Van Cappellen and Ingall, 1994; Ingall and Jahnke, 1997; Murphy et al., 2000; Nederbragt et al., 2004). This process may have played a role in maintaining elevated organic carbon burial rates during OAEs.

Summary

Interest in OAEs was originally motivated, in part, by a desire to better understand the processes leading to formation of petroleum source rocks. As we look forward to the end of the Petroleum Era, due to occur in the next century, renewed interest in OAEs has been driven by a very different motivator: the need to better understand the processes and feedbacks involved in rapid perturbations of the Earth's biogeochemical cycles. OAEs include some of the most geologically rapid and pervasive changes of the oceans and atmosphere driven by changes in the carbon cycle, and they are associated with warm climates, rising sea levels, and possibly increased nutrient fluxes to the oceans. The development of sound environmental policy for the twenty first Century and beyond will depend on our ability to predict the response of the Earth System to anthropogenic CO_2 output, the climate warming predicted to result from this output, the increases in sea levels as continental ice sheets continue to melt, and the increase in agricultural runoff of nutrients associated with population-driven expansion of food production. Studies of Mesozoic OAEs provide a critical source of information to our ongoing effort to build accurate and predictive Earth System models.

OCEAN DRILLING PROGRAM (ODP)

History

For more than 30 years, the Ocean Drilling Program (ODP) has sent hundreds of scientists out from their universities and laboratories to the far corners of the world's oceans in search of sediments and rocks that tell the story of Earth's restless past. The ancient ocean depths, long thought to be a barren and unchanging primordial environment, have yielded their secrets of how our planet's powerful yet delicate ecosystem functions.

The Ocean Drilling Program constitutes one part of a systematic geologic investigation of the Earth that has been ongoing since the eighteenth century. It is only in the past thirty years that scientific ocean drilling conducted by ODP and its predecessor, the Deep Sea Drilling Project (DSDP) has taken

center stage as one of the main contributors to our understanding of the system that drives Earth's evolution. ODP focuses its inquiry into the physics, chemistry, and biology of the Earth's processes using two basic data collection strategies: (a) drilling holes in oceanic crust and extracting core samples and (b) inserting instruments into the holes to measure conditions such as pressure, temperature, and chemistry of the pore waters. Scientists from every major scientific specialty use all the tools available to them both in ship and shore-based laboratories to analyze samples and measurements in an effort to compile the data needed for a thorough, multidisciplinary understanding of the processes taking place in and on the seafloor.

Deep sampling of the sedimentary layer of oceanic crust actually began in 1947 with the invention of the Kullenberg piston corer which was able to penetrate to the Pleistocene and late Pliocene sedimentary layers. Through the 1950s and early 1960s, scientists were able to gather samples as old as the upper-Cretaceous (Kennett, 1982; Hay, 1988). Long piston cores provided the first evidence that sedimentary accumulations in deep sea basins are highly variable and subject to constantly changing environmental processes.

In the early 1960s, improvements in deep sea drilling technology warranted a proposal to launch a national program to drill through the Mohorovičić Discontinuity, the boundary between the crust and the mantle. The ambitious plan was to penetrate 6 km of crustal rock below the sea floor in the Pacific Ocean basin. Known as the Experimental Mohole Project, the plan was scrapped after a few test holes due to unanticipated technology problems resulting in substantial cost overruns. Even though the Project was thought to be a dismal failure, samples obtained while drilling from a floating vessel demonstrated to scientists the enormous potential value of geological explorations in oceanic crust, which covers over 70% of the Earth's surface, rather than restricting research to the continental crust.

By 1964, four U.S. oceanographic institutions (Miami University, Columbia University, Woods Hole, and Scripps) had joined together in a consortium known as the Joint Oceanographic Institutions for Deep Earth Sampling (JOIDES) and proposed to the National Science Foundation a program of continuous coring to depths of more than 1 km off the coasts of Florida and Trinidad. Deep sea sediments recovered from six drillholes contained long sequences of well-preserved microfossil assemblages useful for global stratigraphic correlations.

The Mohole Project and the JOIDES holes, as they were called, thus laid the foundation for a campaign of scientific ocean drilling that, over the past four decades, has yielded a treasure trove of core samples and downhole measurements available to scientists all over the world.

On July 20, 1968, the *Glomar Challenger*, an existing vessel modified specifically for scientific ocean drilling, set sail as the flagship of the Deep Sea Drilling Project (DSDP), initially designed as an 18-month project to drill in the Atlantic and Pacific oceans. DSDP was so successful that in the early 1970s other U.S. and foreign institutions joined JOIDES in support of the program, thus providing more stable funding for ongoing operations. DSDP continued operations for more than a decade, gradually increasing its international participation and its range of deep-sea explorations. In 1985, a new, larger, and more sophisticated scientific research vessel began operations, launching the Ocean Drilling Program, a brand new program of scientific ocean drilling. Operated by Texas A&M University, the drillship *JOIDES Resolution* is a "floating university," fitted with modern drilling

equipment as well as numerous fully-equipped laboratories for sample measurement and analysis.

ODP has explored all of the world's oceans, from the Arctic to the Weddell Sea near Antarctica, collecting sediment and rock samples, recording downhole geophysical and geochemical data, and establishing long-term borehole observatories. Since the *JOIDES Resolution* first sailed in January 1985, she has put to sea six times a year, every year with a contingent of scientists, students, drilling specialists and crew, who leave politics and national identity behind in favor of getting the job done. As of mid-2002, ODP has collected almost 700,000 feet (215 km) of cores from over 1,700 holes. Participants in the Ocean Drilling Program include 18 U.S. institutions and 22 international partners. An estimated 2,700 scientists from more than 40 nations have participated in ODP expeditions and countless more have used ODP samples and data in their research. All ODP core samples and related measurements are carefully preserved in depositories and archives and are made available for study to scientists from all countries, institutions, and disciplines.

ODP research objectives

The impetus for deep sea drilling has been to collect sediment and rock samples from oceanic crust in an effort to define and understand the evolution of the planet. One of the most fortuitous aspects of ODP is that evolving technology for scientific ocean drilling coincided with recently developed theories of continental drift, sea-floor spreading, and shifts in the planet's magnetic field. Theories of slowly drifting landmasses, known as plate tectonics, were first proposed in the early twentieth Century by Alfred Wegener, but scientists lacked the tools and technology to test his intriguing hypotheses. The advent of scientific ocean drilling has allowed the collection of data to test and confirm plate tectonics as well as many other hypotheses concerning the geodynamics of natural events like earthquakes and volcanoes, and theories of crustal age and its relationship to the magnetic properties of rocks.

From the outset, ODP researchers have sought to understand the dynamics of Earth's geophysical and geochemical processes, focusing on:

1. climate and sea level variability
2. the nature and movements of sediments and fluids in and on the oceanic crust
3. the deep structure of continental margins and mantle-crust interactions
4. the nature and functions of life forms within the oceanic crust

ODP contributions to Earth science

The Ocean Drilling Program's approach to scientific investigation derives from the recognition that Earth is a complex, multidimensional, dynamic system that is constantly changing. Some changes may be considered rapid in geologic time – for example, ice sheets can fluctuate dramatically over a few thousand years. Other changes occur so gradually that their effects are not at all apparent, even over hundreds of millennia. Geologists have learned to analyze data within theoretical models that can collapse millions of years into time scales in which changes can be described and interpreted. Although any division of the components of Earth's system is arbitrary, oceanographers must subdivide their theoretical approaches and hypotheses in order to tackle manageable scientific questions. Over the years, ODP has concentrated its

efforts within a number of broad scientific themes: climate and sea level variability; sediments, fluids, and bacteria as agents of system change; heat and mass transfer within the Earth's crust and mantle; and deformation mechanisms within the lithosphere which contribute to natural catastrophic events such as earthquakes, volcanoes, and massive landslides under the ocean.

Climate change

The Earth's climate exhibits cycles of warming and cooling as well as episodes of rapid climate change. Geologists from a wide variety of disciplines have employed an extraordinary number of investigative approaches to identify and quantify climate variability, and the various agents of change within Earth's dynamic climate system. This area of research is critical to understanding natural climate cycles, as well as impacts on local and global climate of natural and man-made perturbations in the system.

Climate is affected by atmospheric composition, planetary orbital oscillations, ocean circulation patterns and carbon flux, biological productivity and evolution, land surface alterations, sea-level fluctuations, and the global distribution and volume of ice. Climate change in turn impacts many of these factors such that a feedback system exists between physical, chemical, and other ecosystem elements (Figure O4). Identifying cause and effect relationships requires data from widely diverse geographic locations and from as many time periods as possible.

One method for measuring climate change comes from examining stable isotopes of oxygen, carbon, and nitrogen, and the presence of particular elements within microfossils in sediment deposits. The ratio of oxygen isotopes and the concentration of certain elements in the fossils vary predictably with the temperature at which the animals lived. These measurements allow scientists to extrapolate their findings to make predictions about

other parts of the climate system, such as the waxing and waning of ice volume over time (Lear et al., 2000).

Variations in carbon deposition is another indicator of climate change, since biologic productivity and turnover varies with climate, and rates of biological activity can be measured in depositions of biogenic sediments of the deep sea. The degree of preservation of organic carbon in sediments is controlled both by rates of productivity and degree of oxygenation of the bottom waters.

Plate tectonics, popularly known as continental drift, has also been implicated in major climatic variation due to alterations in the distribution of freshwater and heat transport in the global ocean. Through cores obtained from ocean drilling, scientists have identified shifts in ocean currents, seawater salinity, and rates and pathways of heat transport due to the reconfiguration of oceans and continents, particularly the opening and closing of oceanic gateways. One example is the closure of the Central American Seaway, near Panama, which initially resulted in climate warming but ultimately led to major ice sheet development in the Northern Hemisphere (Haug et al., 2001).

Fluctuations in sea-level are also seen as indicators of shifts in the global climate. While local sea-level changes can be the result of sediment shifting and plate movement, global sea-level fluctuation is usually the result of changes in the global volume of ice, and is directly associated with variations in atmospheric and ocean temperatures. ODP has drilled a number of sites, particularly in the New Jersey continental shelf and Bahama Islands, in an effort to identify those sea level variations that are the result of local effects versus those that result from global climate change.

Large shifts in climate can also occur as a result of catastrophic natural events. An event such as a volcanic eruption or a meteor striking the Earth can produce sufficient change in the composition of the atmosphere to cause an overall warm-

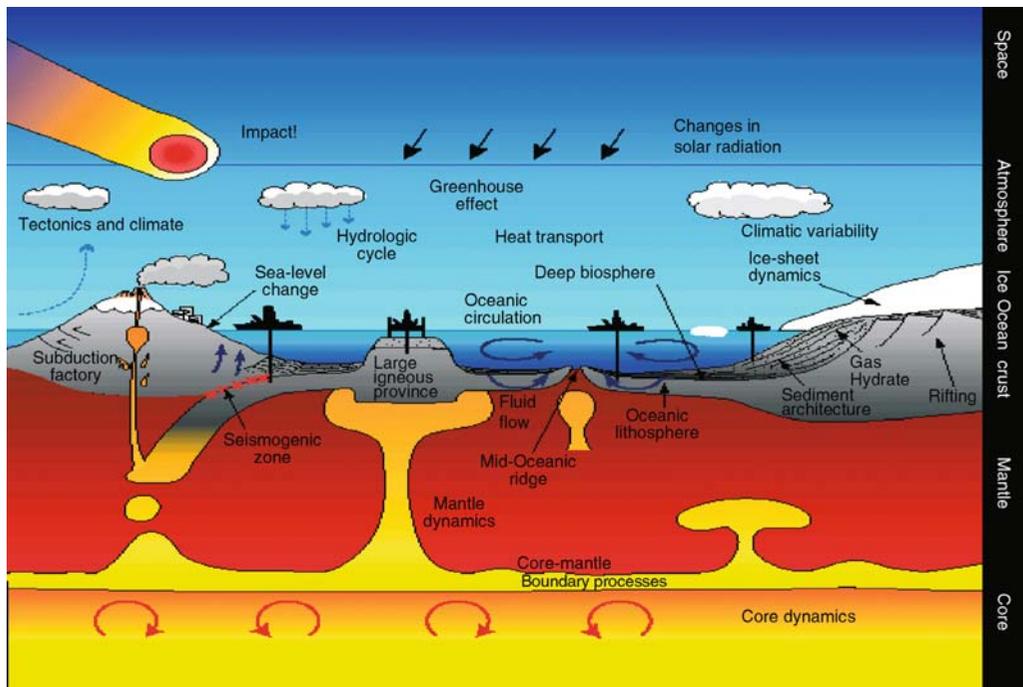

Figure O4 Earth system components, processes, and phenomena (courtesy of Asahiko Taira, Japan Marine Science and Technology Center).

ing of the global climate and even widespread extinctions of biological species. Such an event is thought to have occurred about 65 million years ago. A large extraterrestrial object, probably a meteor, apparently slammed into Earth at what is now Mexico's Yucatan Peninsula. In 1997, ODP drilled into sites 300 miles off northeastern Florida, extracting cores containing sedimentary layers that reveal in beautiful detail a cataclysmic story of destruction and biotic upheaval. The cores exhibit sedimentary layers of debris from the impact consisting of a layer of green, glassy globules and mineral grains, a succeeding layer showing remains of the meteorite but devoid of almost all life, and succeeding layers showing the return of microorganisms. The cores that document what is now known at the Cretaceous-Tertiary (K/T) boundary enable scientists to conduct geochemical and paleontological studies of the post-apocalyptic repopulation of the ocean (Norris, 1997).

Architecture of planet Earth

By convention, our planet is described as being made up of three major sections, an inner molten core, the mantle, which is composed mostly of solid igneous rock, and the crust, consisting of regions of consolidated rock, layers of sediment, and pockets of gases and fluids inhabited by microorganisms. In fact, these components of the planet are in motion and interacting with each other all the time. We see the effects of crustal and upper mantle motion in the form of volcanoes, earthquakes, faults, geysers, and other natural phenomena. The Ocean Drilling Program has focused a great deal of attention on describing the movement of rock, sediments, gases, and fluids in the oceanic crust and mantle. Core samples from the far reaches of the global ocean have confirmed the theory of plate tectonics by comparing sedimentary deposits, magnetic signatures, and crustal rocks from geographically disparate sites. Over the past two decades, ODP research has improved our understanding of Earth's deep mantle using numerical simulations, images derived from global seismic tomography, and experimental studies of materials at simulated mantle conditions. These studies suggest mantle architecture and dynamics that are considerably more complex than simple layering.

A dramatic example of plate tectonics, or continental drift, is apparent in the Atlantic Ocean. Until about 140 millions years ago, a narrow, shallow seaway lay between Europe and North America. The European and North American plates began to shift, resulting in a spreading of the seafloor and the formation of the Atlantic Ocean. A combination of geophysical measurements and studies of drill cores obtained by ODP off the coast of Portugal documents this gradual phenomenon by measuring the thickness of the crust and determining that the continental crust became shallower as it spread. It broke up when it had thinned to about 7 km, resulting in a crust-free zone of exposed mantle at the seafloor. Many of the rock cores have now been dated using radioactive isotopes to demonstrate that the focus of stretching of the crust and mantle migrated from the continent towards the ocean (Whitmarsh et al., 2001).

Another major focus of ODP technological and research effort has been the placement of long-term observatories in the ocean floor. Dubbed CORKs, these observatories are designed to document the flow of heat and chemicals within the interior of the crust by measuring temperatures, pressures, and compositions of fluids (Figure O5). CORKs have been placed on the axis and flank of the Juan de Fuca Ridge in the northern Pacific, and the flank of the Costa Rica Rift and the Nankai and Mariana subduction zones. Data from CORKs show that changes in mechanical and fluid-flow properties of rock formations result from plate strain,

notably at sites where earthquakes occur. Thus, research from CORKs is helping to explain the relationship between episodic plate motion, deformation, and earthquake energy release (Davis and Becker, 1998).

Observatories can also be used to measure seismic activity in crustal deformations offshore, too far for land-based measuring instruments to reach. ODP emplaced such an observatory offshore of northeast Japan, more than 1,000 m below the sea floor in water depths of 2,000 m. This observatory is designed to sense movement at plate boundaries, called subduction zones. Interpretations of measurements allow geophysicists to determine whether plate movement is creating plate boundary strain that could eventually erupt in a violent earthquake. Earth-

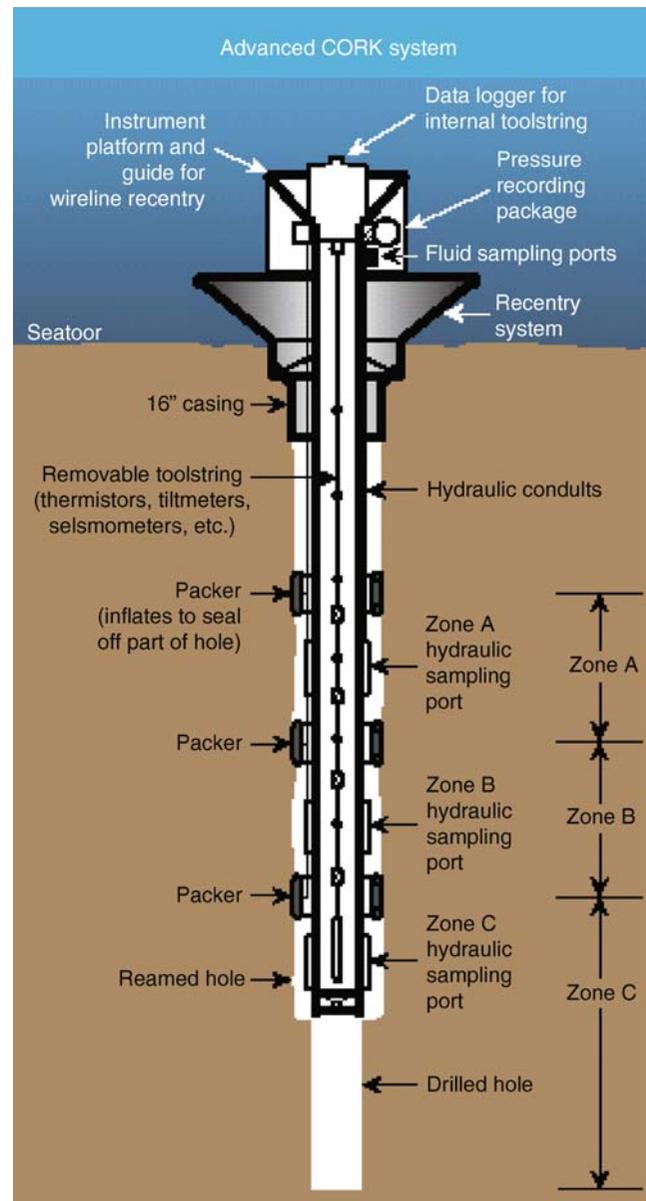

Figure O5 Advanced Cork System (courtesy of Earl Davis, Geological Survey of Canada and Keir Becker, University of Miami).

quakes are devastating manifestations of plate movement, but only represent a portion of the total energy storage and release being created at subduction zones. ODP observatories help us see the whole picture, allowing better prediction of natural hazards (Suyehiro, 2002).

Drilling through the entire thickness of Earth's crust has been a challenge since the very beginning of scientific ocean drilling. Scientists define the architecture of oceanic crust by comparing the seismic signature of the crust in the oceans to the various pieces of oceanic crust found on continents. ODP recently drilled one hole in the Pacific to a depth of 2,111 m below the sea floor – the deepest scientific hole drilled in the ocean. Another expedition extracted 1.5 km of rock core from below the seafloor at the Mid Atlantic Ridge. Core samples from the deep crust provide valuable information on deformation structures and rock composition from which interpretations of tectonic activity can be derived (Dick et al., 2000).

Deep biosphere

Living microorganisms have found a comfortable home in the various ecological niches of Earth's crust, from shallow sedimentary layers to deep regions of basalt rock. Until recently, it was assumed that the deep crust was a sterile, lifeless place, undisturbed by the messiness of organic metabolic processes. In the past two decades, ODP research has discovered a wide variety of microbial life forms deep within oceanic crust. Drilling has unearthed bacteria living as deep as 800 m below the seafloor, much deeper than was previously thought possible given the extreme temperatures and pressures in the deep crustal environment. Estimating the size and ecological impact of this so-called deep biosphere is a major scientific goal of ODP. While the concentration of living organisms in Earth's crust is small, the global volume of crust is enormous, indicating that crustal organisms may represent a significant fraction of the Earth's biomass (Parkes et al., 1994).

Recent research indicates that the ability of bacteria to cycle between active and dormant states in response to nutrient levels may answer one of the mysteries of how they survive in such inhospitable environments. Indeed, microbial activity has even been found in reservoirs of volcanic glass, suggesting that the microbes are metabolizing minerals as an energy source. Microbes in volcanic crust may be important catalysts of chemical change, and may help to regulate the cycling of elements between seawater and oceanic crust. The existence of such life forms that derive their energy from inorganic chemical reactions suggests that life may thrive in previously unsuspected places, such as on Mars and Europa (Fisk, 1997).

Bacteria isolated from continental hydrothermal environments have already made a major impact on biotechnology in areas like bioremediation, waste treatment, microbial enhanced oil recovery, and biominerals. Some bacterial populations appear to have survived for millions of years, suggesting they have some remarkable enzymes and metabolic processes. The seafloor may turn out to be an especially suitable setting for sampling the deep biosphere and measuring microbiological processes and fluid flow in support of biological communities. Subseafloor environments are often more stable and structurally less complicated than terrestrial environments. Drilling and core collection strategies are being developed to assure samples relatively uncontaminated by human activity.

Microbiology has become an integral part of ODP explorations. The drillship has a well-equipped microbiology laboratory that allows seagoing scientists to collect samples from

cores for experiments and analysis both immediately onboard and preserved for shore-based study. The results of these studies will contribute to our understanding of how the Earth and its inhabitants have co-evolved (Smith, 2002).

ODP technology

The ODP collects samples from the Earth's crust in locations that are not only great distances from shore-based laboratories but incredibly difficult to reach. ODP drilling sites may be thousands of miles from shore and more than 8 km below the ocean surface. ODP adapts technology developed by oil exploration companies, as well as engineering specialized drilling tools as required by scientists' research goals. The centerpiece of the ODP is the 143 m long drillship *JOIDES Resolution* (Figure O6). For more than two decades, this ship has made at least six expeditions a year to drill cores and take measurements inside the boreholes in all but very shallow, very deep, or ice-covered oceans. The ship is equipped with over a thousand square feet of state-of-the-art geophysical, geochemical, and microbiological laboratories, and accommodates 50 scientists and technicians and an equivalent complement of crew members.

ODP cores and downhole measurements are the priceless data that are used by both seagoing and shore-based scientists to conduct analyses, test hypotheses, and develop theories of how all the elements of the Earth system function. Cores are obtained by lowering a string of drill pipe through an opening in the ship's hull, called the moon pool, down to the seafloor. Core barrels, containers for the core, are lowered within the pipe. They collect core samples as the drill bit chews through the seafloor. Once the core arrives on deck, all scientists and technicians are busy taking measurements of its geophysical and geochemical properties, such as density, porosity, and magnetism. The core is then halved, with the working half being prepared for sampling and the archive half kept in pristine condition and saved for future research. Scientists spend much of their time on board measuring and analyzing core samples for composition, grain size, age, and color. At the end of the cruise, all cores are sent to one of four onshore repositories where they are stored in a temperature-controlled environment for future research.

The borehole left behind is also a source of valuable data that is collected and stored with care equal to the cores them-

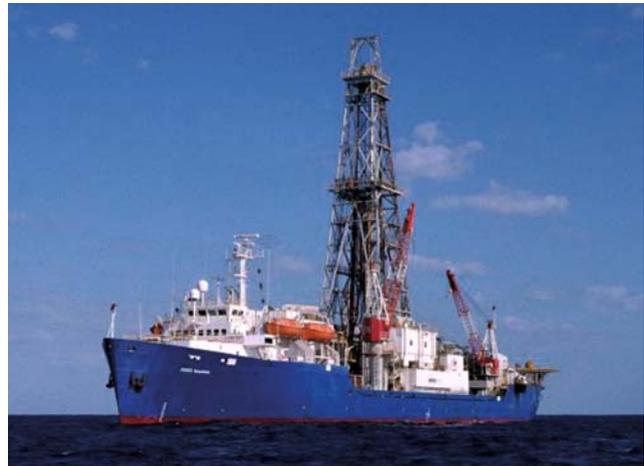

Figure O6 ODP drillship *JOIDES Resolution*.

selves. Downhole measuring tools are placed in the hole on wirelines both during and after extracting the core. Instruments attached to the wireline continuously measure geophysical conditions such as temperature, pressure, fluid flow, and magnetism, all of which are critical to understanding the dynamic processes in the environment from which the cores were extracted. These logging tools also include imaging tools that create a detailed “picture” of the inside of the borehole. These data help scientists to develop models and theories of sediment and rock structure, conditions and movements at plate boundaries, and shifts in crustal composition such as magma flows and intrusions (Goldberg, 1997).

ODP organization and funding

The ODP is an international partnership of scientists and research institutions organized to explore the evolution and structure of the Earth. Its composition and membership has grown throughout its thirty-year history to include the United States, Germany, Japan, the United Kingdom, the Australia/Canada/Chinese Taipei/Korea Consortium for Ocean Drilling, the European Science Foundation Consortium for Ocean Drilling (Belgium, Denmark, Finland, Iceland, Ireland, Italy, The Netherlands, Norway, Portugal, Spain, Sweden, and Switzerland), the People’s Republic of China, and France.

Member countries pool financial resources to fund ODP research. Program resources are managed by a non-profit corporation that subcontracts with various institutions to provide ship and logging operations, shore-based laboratories and core curation, and dissemination of samples, data, and research results.

ODPs research agenda has always been proposed and evaluated by participating ODP scientists. Individual scientists or groups of scientists propose research projects to ODP. Proposals are reviewed and evaluated by multidisciplinary panels representing scientists from all ODP member countries and institutions. The consortium of Joint Oceanographic Institutions for Deep Earth Sampling (JOIDES) constitutes a series of science advice panels and committees, which are charged with evaluating not only the scientific merit of proposals, but also considerations such as safety, likelihood of success, pollution prevention, and technological requirements.

This unique format brings together researchers and students from universities, industry, and government laboratories in member nations to work in modern, fully equipped shipboard laboratories on focused scientific projects. The results of research based on ODP cores, samples, and data are published openly in leading scientific journals and in ODP publications.

OCEAN PALEOCIRCULATION

Introduction

Because of its impact on global climate, one of the most important aspects of ocean circulation is the rate of meridional overturning (also called “Conveyor Belt” or thermohaline circulation) (Figure O7; see *Thermohaline circulation*). In the Atlantic Ocean, the meridional overturning circulation (MOC) brings heat from the tropics to high northern latitudes, which ameliorates the climate of the northern continents (Broecker, 1997). Changes in the rate of the Atlantic MOC and in the associated production of the North Atlantic Deep Water (NADW) may thus have been directly implicated in the large climatic cycles and abrupt climate changes that characterize the Quaternary period and may have contributed to the waxing and waning of the large continental ice sheets that covered North America and Northern Europe during glacial times (see *Quaternary climate transitions and cycles*). Changes in the global ocean circulation could have also played an indirect role in altering the Earth’s climate by influencing atmospheric CO₂ and greenhouse warming (see *Ice cores, Antarctica and Greenland*). Lower rates of deep-water ventilation would engender greater sequestration of carbon in the deep sea, resulting in lower atmospheric CO₂ and cooler temperatures (Toggweiler, 1999). Reconstructing past changes in ocean circulation (i.e., ocean paleocirculation) is thus an integral part of understanding the evolution of climate and has been subject to intensive scientific scrutiny for several decades.

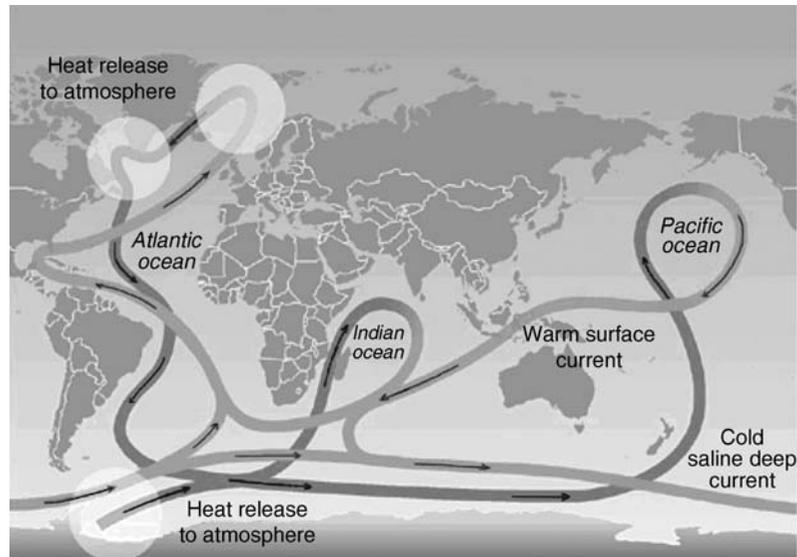

Figure O7 The thermohaline circulation of the ocean. Warm, shallow water is transported from the tropics to the high North Atlantic, where it comes in contact with cold air, cools down and eventually becomes dense enough to sink to the bottom. The newly-formed deep water flows to the south, goes around Antarctica and fills up the two other major ocean basins where it gradually mixes upward to return as a warmer shallower water mass to the North Atlantic (Intergovernmental Panel on Climate Change, 2001).

Reconstructing paleocirculation

The chemical and isotopic composition of marine sediments and skeletal remains of organisms that grow on the seafloor is one of our main sources of information for evaluating past changes in ocean circulation in relation to climatic variability. Changes in ocean circulation impart distinct chemical and isotopic signatures to seawater that are recorded in the carbonate shells of benthic foraminifera (i.e., protozoans living on the seafloor), in the carbonate skeletons of deep-sea corals and in the sediment accumulating on the seafloor. Results obtained from these geochemical tracers (or proxies) clearly reveal that significant changes both in the distribution of water masses and in the rate of deep-water circulation took place in the past, in concert with important climatic events. Reconciling the detailed interpretation of these different and sometimes conflicting proxies is yielding an increasingly clear depiction of how deepwater circulation contributed to or responded to past global climate changes.

Geochemical tracers of deep-water circulation can be broadly divided into two categories: (a) water mass tracers and (b) kinematic tracers of ocean circulation. Both types of tracers are complementary and necessary to fully document past changes in deep water circulation. The water mass tracers are better suited for reconstructing past expansions or contractions of the different water masses that fill the deep ocean basins, while kinematic tracers are necessary to constrain past changes in the rate at which volumes of deep water were produced (expressed in Sverdrups = $10^6 \text{ m}^3 \text{ s}^{-1}$).

Underlying principles

Proxies for water mass identification

In the deep Atlantic Ocean, two antagonistic water masses, the North Atlantic Deep Water (NADW) and the Antarctic Bottom Water (AABW), vie for spatial dominance. The NADW, which

initiates the global conveyor belt circulation (Figure O7), originates from the North Atlantic and flows southward towards the Southern Ocean, while the AABW originates from the Southern Ocean and flows northward. The latter water mass is denser, and wedges underneath the NADW.

In the modern ocean, these two deepwater masses can be clearly distinguished by their chemical and isotopic composition. Deep waters of southern origin have significantly higher dissolved nutrient concentrations (Figure O8). Nutrients consist of dissolved salts (nitrate, phosphate, silicate) that are taken up in surface waters to sustain the growth of phytoplankton and regenerated at depth from the decay of sinking organic matter. This biological cycling results in lower nutrient concentrations in surface waters and higher concentrations in deeper waters. Nutrient concentrations in deep waters have two components. When surface waters sink to produce deep waters, they already contain nutrients due to incomplete biological utilization and entrainment of nutrient-enriched water from intermediate depths. As newly formed deep waters age in deep ocean basins, they accumulate an increasing load of dissolved nutrients from the decay of organic matter exported from the surface. The former contribution to the total nutrient load of deep waters is the “preformed nutrient” concentration and the latter contribution is the “regenerated nutrient” concentration. Deep waters of southern origin have higher preformed nutrient concentrations because nutrient utilization in the surface waters around Antarctica is limited by the harsh environmental conditions that prevail in this region. This is the main reason why AABW has noticeably higher nutrient concentrations than NADW, which clearly identify its presence and its northward propagation above the seafloor (Figure O8). Assuming no changes in the preformed nutrient concentration of the two deep-water masses, further northward penetration of AABW would result in higher nutrient concentrations in the deep water of the Atlantic. Therefore, if we were able to estimate past

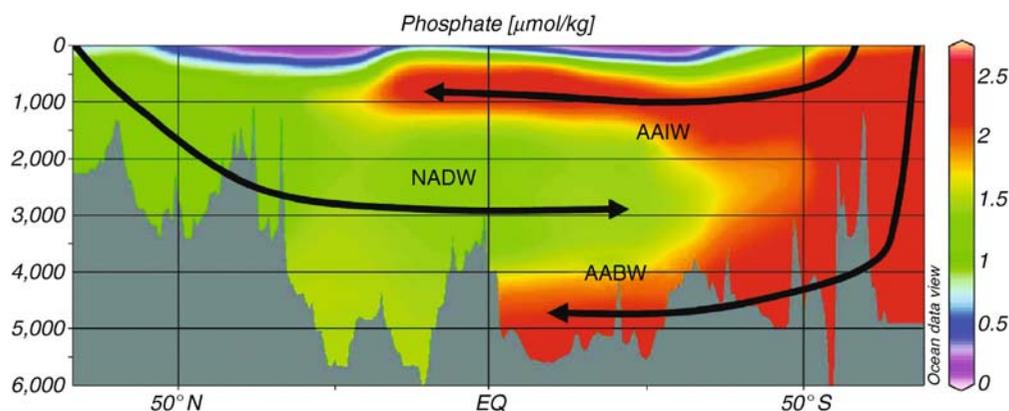

Figure O8 Latitudinal cross section of phosphate concentration in the Atlantic Ocean. The high phosphate concentrations in the two water masses of southern origin, the Antarctic Intermediate Water (AAIW) and the Antarctic Bottom Water (AABW), stand out in sharp contrast to the lower phosphate concentrations in the North Atlantic Deep Water (NADW).

changes in deep water nutrient concentrations, we could deduce the relative importance of these two water masses in the past. However, past changes in deepwater nutrient concentrations are not directly recorded in marine sediments. Instead, one has to find chemical and isotopic signatures (i.e., nutrient concentration proxies) that correlate closely with dissolved nutrient concentrations and become incorporated in marine archives (i.e., benthic foraminifera, deep-sea corals, or sediments). The most often used water mass proxies are the carbon isotopic composition ($\delta^{13}\text{C}$) of dissolved inorganic carbon and the dissolved concentration of several biologically recycled trace metals (Cd, Zn, Ba), which are recorded in the isotopic and chemical composition of benthic foraminifera and deep-sea corals that grow in contact with bottom water. Neodymium isotope ratio (ϵ_{Nd}) has also been used. Unlike the previous tracers, ϵ_{Nd} is recorded in the oxide coatings of settling particles that accumulate on the seafloor and is not directly affected by biological cycling.

$\delta^{13}\text{C}$ in benthic foraminifera

Carbon has two stable isotopes: ^{13}C ($\sim 1.1\%$) and ^{12}C ($\sim 98.9\%$). Isotopic compositions are reported in the “delta” notation, i.e., $^{13}\text{C}/^{12}\text{C}$ ratio expressed in permil deviation from a standard taken as reference:

$$\delta^{13}\text{C}_{\text{Sample}} = \left[\frac{\left(\frac{^{13}\text{C}}{^{12}\text{C}} \right)_{\text{Sample}}}{\left(\frac{^{13}\text{C}}{^{12}\text{C}} \right)_{\text{Standard}}} - 1 \right] 1,000$$

During photosynthesis, dissolved inorganic carbon, nitrate and phosphate are taken up by phytoplankton to produce organic matter in surface waters. Because ^{12}C is taken up preferentially to ^{13}C , the organic matter produced has a $\delta^{13}\text{C}$ value lower than the $\delta^{13}\text{C}$ of inorganic carbon dissolved in surface waters. Upon degradation and oxidation of organic matter in deep waters, the dissolved inorganic carbon produced has a similarly “light” isotopic composition (i.e., low $\delta^{13}\text{C}$). This isotopically light inorganic carbon is regenerated concurrently with nitrate and phosphate, resulting in a negative linear correlation between the nitrate or phosphate concentration and the $\delta^{13}\text{C}$ of dissolved

inorganic carbon in deep waters (Kroopnick, 1985; Figure O9a). The $\delta^{13}\text{C}$ of inorganic carbon dissolved in bottom waters is recorded by the carbon isotopic composition of the calcium carbonate produced by benthic foraminifera living on the seafloor, which thus indirectly record nutrient concentrations in bottom waters. By measuring the $\delta^{13}\text{C}$ of benthic foraminifera that lived in the past at different water depths, it is thus possible to reconstruct past changes in the $\delta^{13}\text{C}$ of seawater and deduce past changes in the concentration and vertical distribution of nutrients in deep waters (Samthein et al., 2001).

Cd/Ca, Ba/Ca and Zn/Ca ratios in benthic foraminifera or deep-sea corals

A similar principle can be applied to certain trace metals. Cadmium (Cd) is biologically recycled with phosphorus, resulting in a tight positive correlation between phosphate and dissolved Cd concentration in seawater (Figure O9b). As Cd becomes incorporated in biogenic carbonate minerals in proportion to its concentration in ambient seawater, the Cd/Ca ratio in fossil benthic foraminifera (Boyle, 1988) and deep-sea corals (Adkins et al., 1998) provides an independent means of reconstructing past changes in bottom water nutrient concentration. As for $\delta^{13}\text{C}$, this information can be used to contrast the relative contribution of NADW and AABW in the deep Atlantic Ocean, if we assume (i) no changes in the preformed nutrient concentrations in the water masses involved, and (ii) no changes in the rate of organic matter remineralization in deep waters.

Barium (Ba) and zinc (Zn) are also biologically recycled, but their regeneration from settling particles occurs at greater depth than for Cd. Instead of tightly correlating with phosphate, their seawater profiles mimic those of alkalinity or dissolved silicate (Figures O9c and O9d), which are controlled by the dissolution of carbonate and biogenic silica occurring in deeper water. As for Cd, the concentration of dissolved Ba and Zn in bottom water is recorded in the Ba/Ca and Zn/Ca ratios in the shells of benthic foraminifera (Lea and Boyle, 1989; Marchitto et al., 2000). Because of its deeper regeneration, the contrast in Zn concentration between NADW and AABW is more pronounced than for Cd. As a result, paired Zn and Cd measurement in the same foraminifera shells provides

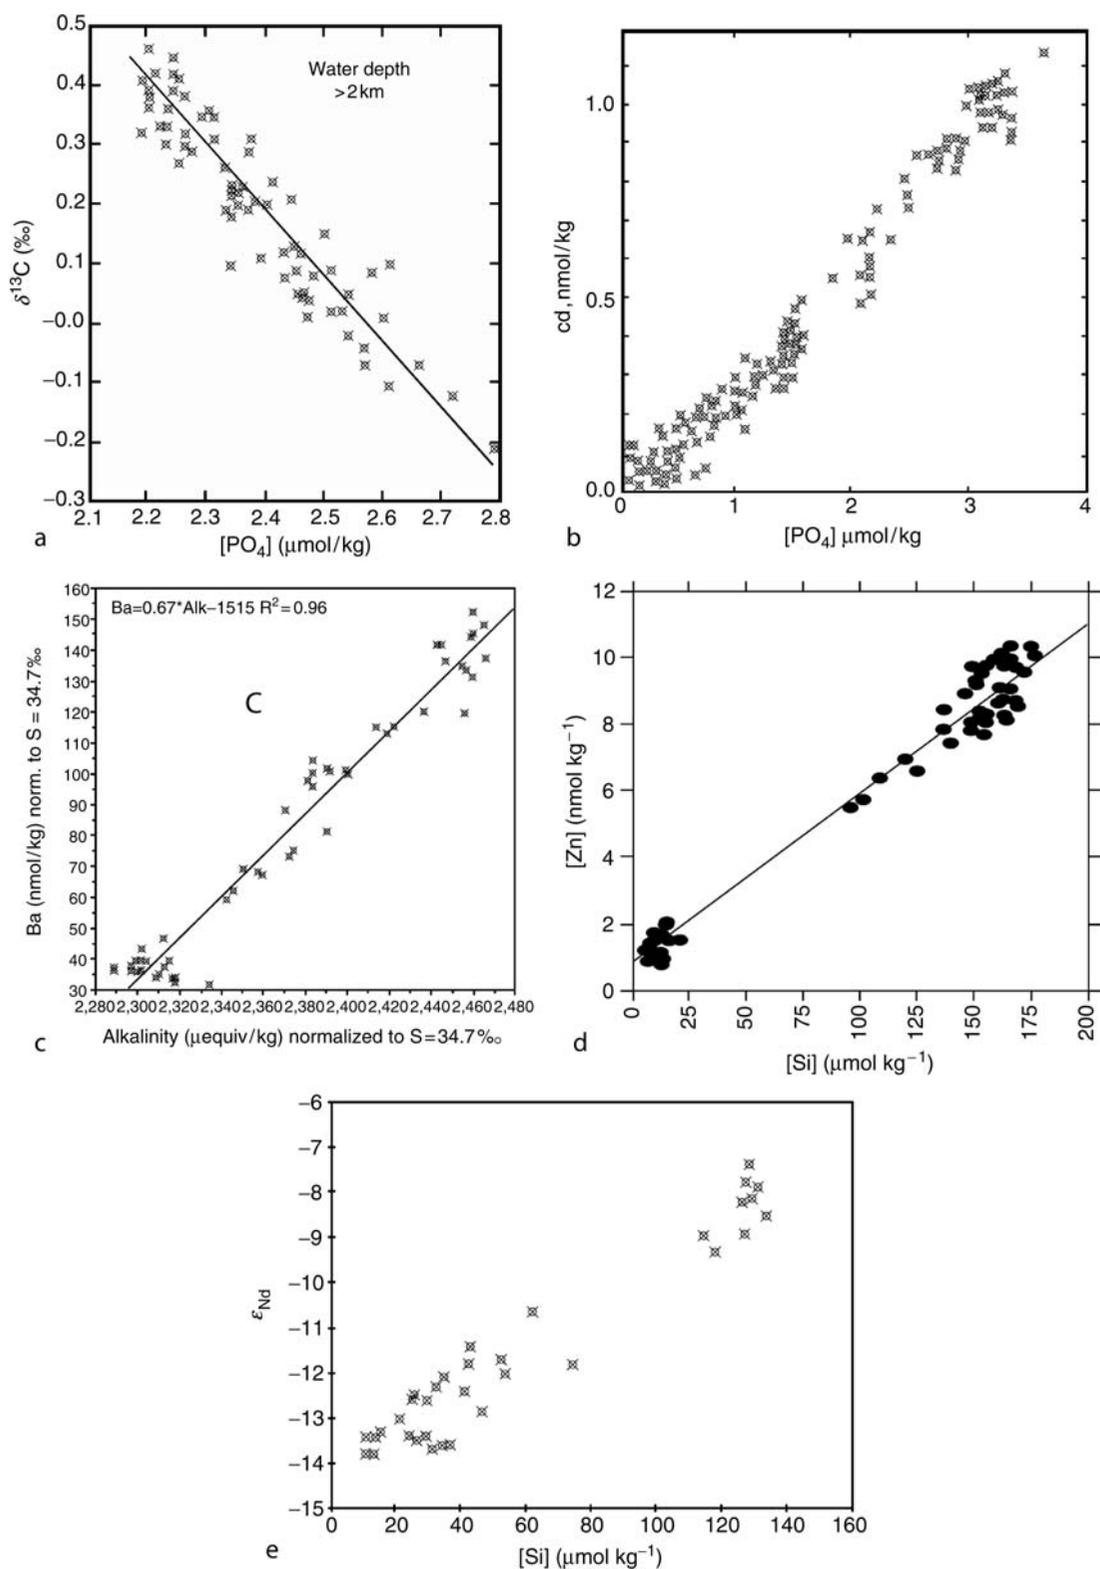

Figure O9 Correlations between seawater properties (nutrient concentration and alkalinity) and proxies used for their paleoceanographic reconstruction. (a) $\delta^{13}\text{C}$ of dissolved inorganic carbon vs phosphate concentration in deep water (adapted from Broecker and Maier-Reimer, 1992). (b) Dissolved cadmium vs. phosphate concentration in subsurface waters (adapted from Boyle, 1986). (c) Dissolved barium vs. alkalinity in surface and deep waters (adapted from Lea, 1993). (d) Dissolved zinc vs. dissolved silicate concentration in seawater deeper than 1,000 m (adapted from Marchitto et al., 2000). (e) ϵ_{Nd} vs. dissolved silicate concentration in the deep Atlantic Ocean (adapted from Rutberg et al., 2000).

a means of distinguishing between changes in AABW penetration and changes in preformed nutrient concentration (Marchitto et al., 2002).

Neodymium isotopic ratio (ϵ_{Nd}) in sedimentary oxides

Neodymium isotopic composition is reported as:

$$(\epsilon_{\text{Nd}})_{\text{Sample}} = \left[\frac{(^{143}\text{Nd}/^{144}\text{Nd})_{\text{Sample}}}{(^{143}\text{Nd}/^{144}\text{Nd})_{\text{Standard}}} - 1 \right] 10^4$$

Seawater ϵ_{Nd} reflects Nd input from nearby continental masses (von Blanckenburg, 1999). Deep waters formed in the North Atlantic acquire a Nd isotopic composition ($\epsilon_{\text{Nd}} = -13.5$) clearly distinct from that of the deep waters originating from the Southern Ocean ($\epsilon_{\text{Nd}} = -7$). There is a positive linear correlation between ϵ_{Nd} and silicate concentration (Figure O9e) in the deep Atlantic, reflecting a two end-member mixing between NADW (low silicate concentration and low ϵ_{Nd}) and AABW (high silicate, high ϵ_{Nd}). Dissolved Nd is removed from seawater by adsorption on iron and manganese oxides that precipitate in seawater and coat settling particles. The Nd isotopic composition associated with oxides, which can be chemically leached from sediment, thus provides a complementary means of estimating the northward penetration of deep waters of southern origin, which is independent of the biological recycling of nutrients (Rutberg et al., 2000). This is important, because changes in the concentration of the nutrient-related tracers described above could be affected by biological recycling, independently of circulation.

Kinematic proxies for estimating rates of circulation

Several proxies that provide information on changes in circulation rates have also been developed. They include (a) reconstruction of the $^{14}\text{C}/^{12}\text{C}$ ratio in the atmosphere, (b) paired planktonic-benthic ^{14}C age differences, (c) ^{14}C ages of ^{230}Th -dated deep-sea corals, (d) geostrophic flow reconstructions from benthic foraminifera $\delta^{18}\text{O}$, and (e) $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments.

$^{14}\text{C}/^{12}\text{C}$ ratio in the atmosphere

^{14}C is a radioactive isotope of carbon that is continuously produced in the atmosphere by cosmic rays (cosmic rays are protons that shatter nuclei of atoms in the atmosphere, producing neutrons that become incorporated into the nuclei of nitrogen atoms while ejecting a proton; as a result ^{14}N becomes ^{14}C). After formation, ^{14}C enters the global carbon cycle and decays with a half-life of 5,730 years, thereby providing a clock to date carbon-containing samples during the last $\sim 50,000$ years. However, accurate dating must take into account past variations in the $^{14}\text{C}/^{12}\text{C}$ ratio of the atmosphere (expressed as $\Delta^{14}\text{C}_{\text{atm}}$; see *Radiocarbon dating*). To that end, $\Delta^{14}\text{C}_{\text{atm}}$ has been reconstructed for the past 50,000 years (Hughen et al., 2004) by measuring the $^{14}\text{C}/^{12}\text{C}$ ratio of samples that could be independently dated (tree rings, ^{230}Th -dated corals, annually-layered sediments, marine sediments correlated to the precise timescale of Greenland ice cores). An important fraction of $\Delta^{14}\text{C}_{\text{atm}}$ variability results from variations in the intensity of the Earth's magnetic field; these affect the influx of cosmic rays and hence the production rate of cosmogenic nuclides like ^{14}C . This variability can be estimated from paleomagnetic data (e.g., Laj et al., 2002). Additional $\Delta^{14}\text{C}_{\text{atm}}$ variability can also result from changes in the rate of deepwater formation, which

affect the residence time of ^{14}C in the atmosphere. Thus, the residual between the reconstructed history of $\Delta^{14}\text{C}_{\text{atm}}$ and the $\Delta^{14}\text{C}_{\text{atm}}$ predicted from the changes in the intensity of the geomagnetic field can be attributed to changes in the rate at which ^{14}C is transferred from the atmosphere to the deep sea as a result of deep water formation (Hughen et al., 2004). $\Delta^{14}\text{C}_{\text{atm}}$ higher than predicted from paleomagnetic data indicates slower rates of transfer of ^{14}C from the atmosphere to the deep sea, reflecting lower rates of deep-water formation. However, changes in the air-sea exchange rate of ^{14}C , in the solar component of ^{14}C production modulation, and in the terrestrial carbon reservoir, together with the effect of the biological export of ^{14}C to the deep sea, must also be considered.

Paired planktonic-benthic ^{14}C age differences

^{14}C age differences between the fossil shells of planktonic (i.e., living in surface waters) and benthic (i.e., living on the seafloor) foraminifera recovered from the same sediment horizon and presumed to be contemporaneous can potentially provide quantitative information on past changes in deepwater renewal rates. Larger differences in age have been taken to indicate older deep waters and slower renewal rates (Keigwin and Schlegel, 2002).

There are two potential complications, however, with that approach. One stems from the variability in $\Delta^{14}\text{C}_{\text{atm}}$ with time. Although the planktonic and benthic foraminifera are contemporaneous, the benthic species are growing in water that was in contact with the atmosphere at an earlier time when $\Delta^{14}\text{C}_{\text{atm}}$ may have been different. The $^{14}\text{C}/^{12}\text{C}$ ratio of the benthic and planktonic foraminifera cannot thus be compared directly but one must take into account this difference in initial conditions (Adkins and Boyle, 1997). The second complication may be even more problematic to resolve. It arises from the fact that foraminifera do not acquire their carbon directly from the atmosphere. Instead, their carbon source is inorganic carbon dissolved in ambient seawater. The $^{14}\text{C}/^{12}\text{C}$ ratio of surface waters, where planktonic foraminifera grow, is controlled by exchange of CO_2 with the atmosphere and mixing with older dissolved inorganic carbon from below. As a result, the $^{14}\text{C}/^{12}\text{C}$ ratio of oceanic surface waters and planktonic foraminifera is lower than that of the contemporaneous atmosphere. In the modern ocean, at low to mid latitudes, surface waters have a $^{14}\text{C}/^{12}\text{C}$ ratio that corresponds to an age of ~ 400 years. This so-called "reservoir age," however, can be significantly larger at high latitudes (up to 1,300 years), particularly in the Southern Ocean, where upwelling rates of older deeper waters are higher and CO_2 exchange with the atmosphere is limited by extensive sea ice cover (Bard, 1988). Because deep water is formed at high latitudes, benthic foraminifera growing on the seafloor at low to mid latitude record a $^{14}\text{C}/^{12}\text{C}$ ratio that has been affected by a significantly older "reservoir age" than their contemporaneous planktonic counterparts living in surface water. This difference must also be considered when calculating the ventilation age of deep water.

^{14}C ages of ^{230}Th -dated deep-sea corals

Some species of corals live at great depths, sometimes as deep as 4,000 m. They can be dated by measuring the growth of ^{230}Th from the decay of ^{234}U included in the coral's carbonate lattice. Decay-correcting $^{14}\text{C}/^{12}\text{C}$ measured in the same coral samples and comparing it to the corresponding $^{14}\text{C}/^{12}\text{C}$ ratio of the atmosphere thus provides a means of estimating the

age of deep water (Adkins et al., 1998). These estimates must also take into account possible changes in “reservoir age” and the variability in $\Delta^{14}\text{C}_{\text{atm}}$. However, unlike the sedimentary archives, which provide continuous but relatively low resolution records (millennial to centennial timescales, depending on the sedimentation rates), deep-sea corals provide narrow (~ 150 years dictated by the life span of coral specimens) but high-resolution (decadal-centennial timescales) windows on past changes in deep water ages.

Geostrophic flow reconstructions from benthic foraminifera $\delta^{18}\text{O}$

Most of the warm water flowing to the far North Atlantic for NADW formation is supplied by the Gulf Stream (Figure O10a). The Gulf Stream enters the North Atlantic through the Florida Strait at a flow rate of about 30 Sverdrups. As it moves to the north, it is continually accrued by entrainment of water coming from the North Atlantic Subtropical gyre, and its flow rate increases gradually, reaching 150 Sverdrups as it turns eastward. In the Florida Straits, the Gulf Stream is nearly in geostrophic balance, i.e., the Coriolis acceleration associated with the flow of water (C) is balanced by the lateral pressure gradient across the Strait (P; Figure O10b). This pressure gradient is associated with a lateral seawater density gradient and results in sloping surfaces of constant seawater density, called “isopycnals.” If the flow rate of the Gulf Stream were to accelerate, the Coriolis force would intensify. To maintain geostrophic balance, the lateral pressure gradient would have to increase, which would be reflected by steeper isopycnals. The slope of the isopycnals across the Florida Straits can be estimated from the oxygen isotopic composition ($\delta^{18}\text{O}$) of benthic foraminifera living on the seafloor on each side of the Straits, thereby providing a means of estimating the flow rate of water through the Strait in the geological past. To the extent that the contribution from the subtropical recirculation gyre (Figure O10a) remained con-

stant, changes in flow rate in the Florida Strait could be used to infer changes in the rate of NADW formation (Lynch-Stieglitz et al., 1999). The main difficulties with this approach are (a) ascertaining the contribution from the subtropical gyre, and (b) the requirement that current velocity must be known at one level taken as reference, which is very difficult to constrain for past circulation (Wunsch, 2003).

$^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments

^{231}Pa and ^{230}Th are two natural radionuclides produced at constant rates in seawater from the decay of dissolved uranium. Both are rapidly adsorbed on settling particles and removed to the underlying sediment (Figure O11). As ^{231}Pa has a lower affinity for most marine particles than ^{230}Th , it has a residence time in deep water approximately five times longer and equivalent to the mean residence time of deep water in the modern Atlantic (ca. 200 years). As a result, nearly 50% of the ^{231}Pa produced in the NADW as it transits through the Atlantic is exported to the Southern Ocean, while most of the ^{230}Th is removed in the Atlantic sediment (Yu et al., 1996). Reflecting this differential export, the mean $^{231}\text{Pa}/^{230}\text{Th}$ of Atlantic sediments (activity ratio ~ 0.05) is only slightly above half the ratio of the rate of production of the two nuclides in the water column (0.093). $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments can thus record the rate at which NADW is produced and exported to the Southern Ocean. As the rate of NADW formation and export decreases, the extent of ^{231}Pa export to the Southern Ocean also diminishes, resulting in higher $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments (Marchal et al., 2000). The interpretation of this proxy is complicated, however, by the fact that the removal rate of ^{231}Pa from seawater depends on particle flux and composition. Lower $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments could also be due to higher particle flux or higher concentration of opal, a biogenic mineral produced by some plankton species. Past changes in particle flux and composition in the Atlantic Ocean must therefore be taken into account when

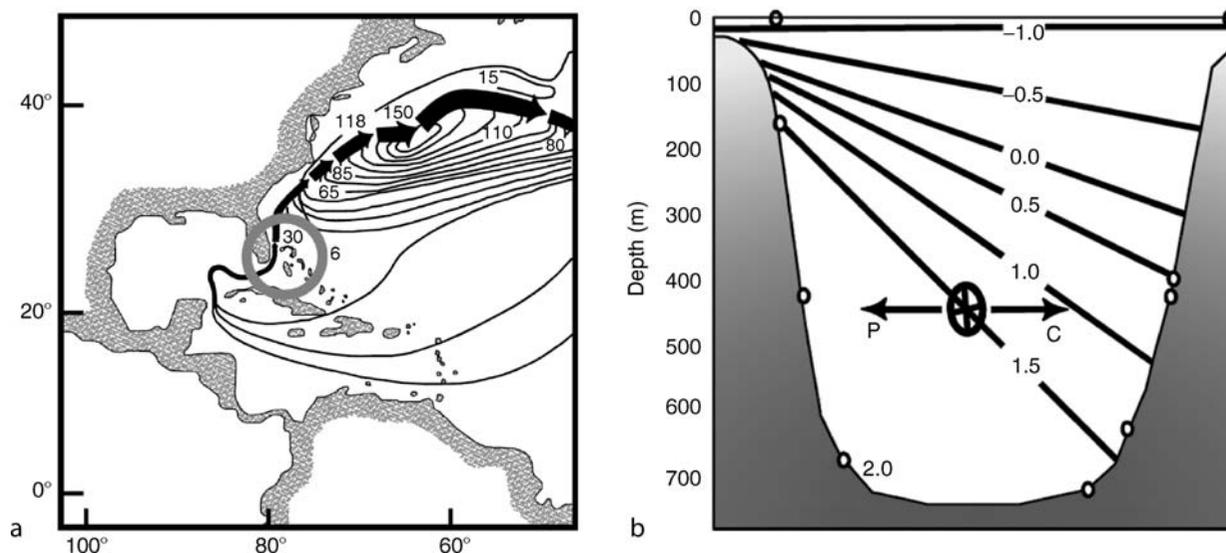

Figure O10 (a) Gulf Stream and recirculation in the North Atlantic subtropical gyre with total transport streamlines in Sverdrups, adapted from Worthington (1976). Red circle highlights the Florida Straits. (b) Cross-section in the Florida Straits showing sloping horizons of constant seawater density obtained from the $\delta^{18}\text{O}$ of modern benthic foraminifera (sampling depths are marked by open circles). The geostrophic flow that prevails in this region results from the balance between the Coriolis force due to the Earth's rotation (C) and the lateral pressure gradient created by the lateral density gradient (P). The cross indicates that the water flows away from the reader (adapted from Lynch-Stieglitz et al, 1999).

interpreting sediment $^{231}\text{Pa}/^{230}\text{Th}$ as a kinematic indicator of deepwater formation.

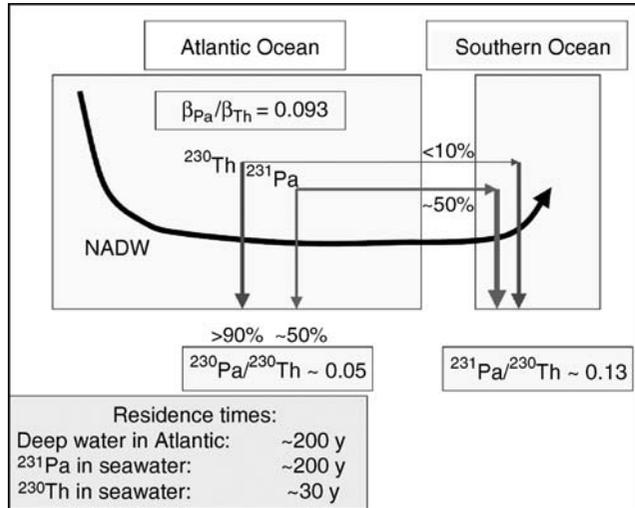

Figure O11 Schematic representation of the principle for estimating the rate of NADW formation from $^{231}\text{Pa}/^{230}\text{Th}$ in marine sediments. ^{231}Pa and ^{230}Th are produced uniformly in seawater from the decay of dissolved uranium ($\beta_{\text{Pa}}/\beta_{\text{Th}}$ = production rate ratio). Because of its shorter residence time in the water column, nearly all the ^{230}Th produced in the NADW during transit through the Atlantic is removed in the underlying sediment. On the other hand, since the residence time of ^{231}Pa in seawater is similar to the residence time of deep water in the Atlantic, approximately half of the ^{231}Pa produced in the Atlantic is exported into the Southern Ocean with NADW. The resulting deficit of ^{231}Pa in Atlantic sediment increases with the rate of NADW formation and export to the Southern Ocean.

Reconstruction of past changes in ocean circulation during the last glacial-interglacial cycle

Because of its half-life, information from ^{14}C can only be considered for the last 50,000 years and we can best constrain past changes in deep water circulation during that time span. This is a climatically important and interesting period, as it nearly encompasses the full range of Quaternary climatic variability. High-resolution climatic fluctuations over that time period are documented by the oxygen isotopic composition of the ice that has accumulated on Greenland (Figure O12), reflecting air temperature (see *Ice cores, Antarctica and Greenland*). The last ~10,000 years (i.e., the Holocene period) were characterized by relatively warm (i.e., higher $\delta^{18}\text{O}$ in ice) and stable conditions. In contrast, the preceding glacial period, when large ice sheets covered the North American and European continents, was characterized by large climatic fluctuations. These fluctuations are called Dansgaard-Oeschger cycles and consist of abrupt warmings followed by more gradual coolings. The transition to the Holocene, which coincided with the melting of most of the large northern continental ice sheets, was also punctuated by an abrupt warming ~15,000 years ago (Bølling), followed by a brief cold reversal (Younger Dryas) at ~12,800 yrBP, and a rapid final warming at 11,600 yrBP.

Changes in the distribution of deep-water masses

One of the most robust deductions derived from the water mass proxies is that climatic variability was associated with vertical redistribution of nutrient concentrations in the water column of the Atlantic. Nutrient concentrations at intermediate depths (above ~2,500 m) were lower during the last glacial period compared to today, while they were higher in deeper waters (below ~2,500 m). This has been corroborated by the $\delta^{13}\text{C}$, Cd/Ca and Zn/Ca ratios of benthic foraminifera (Figure O13). Lower nutrient concentrations in glacial intermediate waters have been taken as reflecting the formation of a shallower water mass in the North Atlantic (the Glacial North Atlantic Intermediate Water, GNAIW) in lieu of today's NADW, while higher nutrient concentrations in deep water have been taken

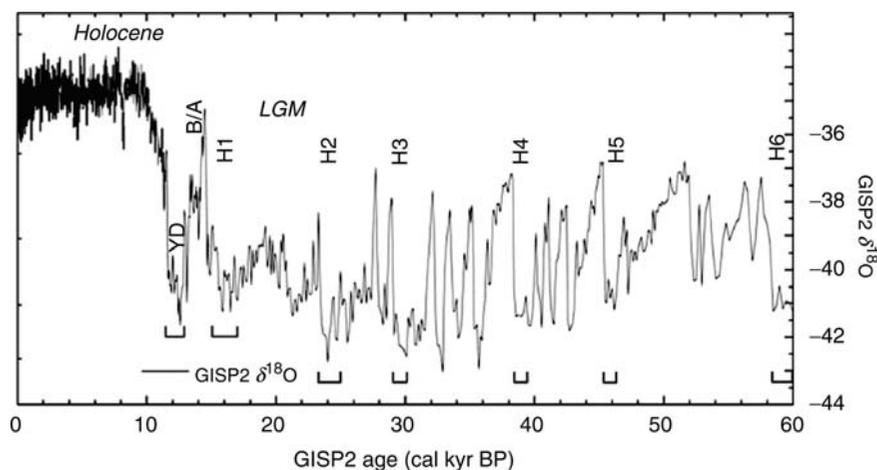

Figure O12 Oxygen isotopic composition ($\delta^{18}\text{O}$) of the ice that accumulated on Greenland during the last 60,000 years (Grootes et al., 1993). Higher $\delta^{18}\text{O}$ indicates higher temperature. LGM: Last Glacial Maximum (the time of maximum continental ice buildup). YD: Younger Dryas cold period. B/A: Bølling-Allerød warm period. H1 to H6 mark the timing of 6 massive iceberg discharge events recorded as high accumulation of ice-rafted debris in the North Atlantic, coinciding with the coldest periods (lowest $\delta^{18}\text{O}$) recorded in the ice core.

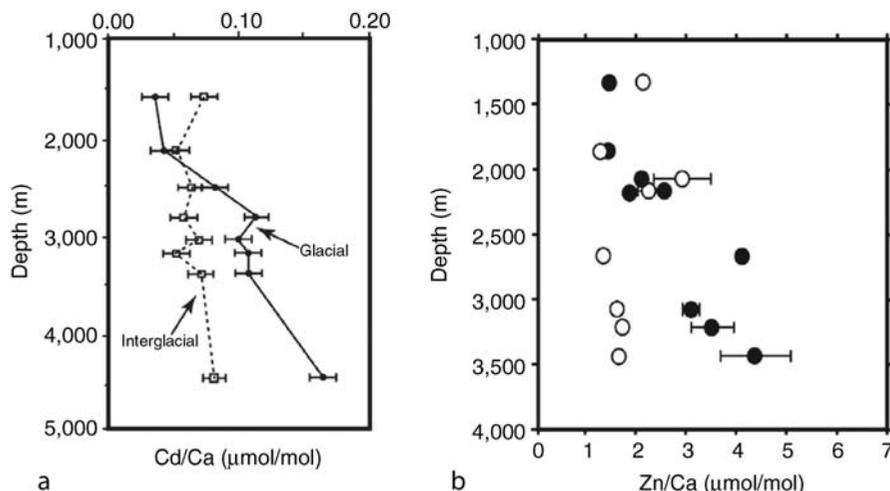

Figure O13 Vertical redistribution of nutrients in the Atlantic Ocean during the last glacial period recorded by (a) Cd/Ca (adapted from Boyle, 1988), (b) Zn/Ca (adapted from Marchitto et al., 2002) in benthic foraminifera. *Open symbols*: Holocene profile; *closed symbols*: glacial profile.

as indicating increased penetration of deep water of southern origin into the North Atlantic. Higher nutrient concentrations in the deep Atlantic could also reflect higher preformed nutrient concentration in North Atlantic surface waters or higher remineralization of organic matter in deep waters. However, the similarity between the benthic foraminifera record of Zn/Ca and Cd/Ca in the North Atlantic argues against dramatic changes in preformed nutrient concentrations (Marchitto et al., 2002). Increased penetration of southern water during the last glacial period has also been confirmed by ϵ_{Nd} , which is independent of nutrient recycling (Rutberg et al., 2000). The more extensive $\delta^{13}C$ database (Sarnthein et al., 2001) clearly shows increased northward penetration of southern water and replacement of the modern NADW by the shallower GNAIW during the last glacial maximum (Figure O14a,b). Combining $\delta^{13}C$ and Cd/Ca, Lynch-Stieglitz et al. (1996) provided evidence that the shallower GNAIW propagated to the Pacific Ocean, in a similar manner as today's NADW (Figure O7).

A third mode of deepwater mass distribution has also been identified from the distribution of benthic foraminifera $\delta^{13}C$, in which deepwater formation from the north was essentially eliminated and the entire water column of the Atlantic Ocean below the main thermocline was filled with water of southern origin (Figure O14c). This situation seems to arise during the coldest intervals of the glacial periods, which are associated with catastrophic iceberg discharges, called Heinrich Events (Figure O12). These events are recorded in the sediments of the North Atlantic as discrete layers of coarse-grained ice-rafted debris that are deposited as the icebergs melt. The shutdown of deep-water formation in the North Atlantic during these events has been attributed to melting of icebergs and lowering of the density of surface waters in areas of deepwater formation.

Changes in the rate of formation of deepwater masses

As pointed out by Legrand and Wunsch (1995), water mass tracers alone cannot uniquely constrain rates of deep-water formation. Doing so requires kinematic tracers. The initial study using $^{231}Pa/^{230}Th$ in Atlantic sediments (Yu et al., 1996) reached the surprising conclusion that the rate of deep water

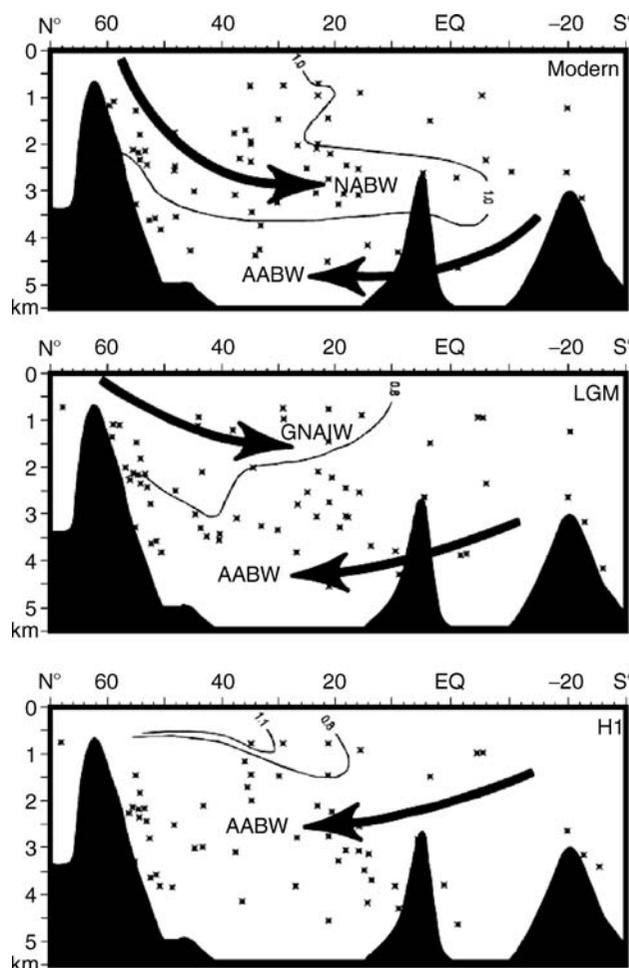

Figure O14 Vertical transects of benthic foraminifera $\delta^{13}C$ in the Atlantic Ocean (a) Modern (b) Last glacial maximum (c) Heinrich event H1 (adapted from Sarnthein et al., 2001).

formation in the North Atlantic during the last glacial maximum (GNAIW) and its export to the southern ocean was little different from today's rate of formation and export of NADW. The uncertainties on this estimate were quite large however, and the subsequent use of a zonally integrated general circulation model indicated that the existing data were not inconsistent with a possible 30% glacial reduction (Marchal et al., 2000). Reconstruction of the slope of the isopycnals in Florida Straits also suggested a 30% reduction in the rate of GNAIW formation (Lynch-Stieglitz et al., 1999), although this estimate also has very large uncertainties (Wunsch, 2003).

A high-resolution $^{231}\text{Pa}/^{230}\text{Th}$ profile obtained by analyzing a core retrieved from a drift deposit in the central North Atlantic provides important additional insights into the relationship between the rate of northern source deepwater formation and climatic variability (Figure O15). This record confirms the steady formation of NADW over the entire Holocene period at a rate similar to present (i.e., $^{231}\text{Pa}/^{230}\text{Th} \sim 0.055$). It also suggests a slight reduction of the rate of GNAIW formation during the last glacial maximum (i.e., $^{231}\text{Pa}/^{230}\text{Th} \sim 0.068$ between 17,500 and 20,000 yrBP), although this higher $^{231}\text{Pa}/^{230}\text{Th}$ may be partly due to the higher particle fluxes at that time. The most prominent feature of this new record, however, is the rapid increase in $^{231}\text{Pa}/^{230}\text{Th}$ to values similar to the rate of production (0.093) between 17,500 and 15,000 yrBP. This indicates that the formation of northern source deep water had totally ceased for a period of $\sim 2,500$ years (particle fluxes decreased during that time interval and cannot account for the observation), and coincided with the more recent Heinrich Event (H1; Figure O12). Deepwater formation in the North Atlantic re-started abruptly at 15,000 yrBP, coinciding with a rapid climate warming (Bølling) and a rapid rise in sea level. The latter must have been the result of accelerated melting of continental ice. A significant but lesser decrease in the rate of deepwater formation also occurred during the cold Younger Dryas period, followed by a gradual acceleration into the Holocene.

There is a good general agreement between this interpretation of $^{231}\text{Pa}/^{230}\text{Th}$ in North Atlantic sediment (McManus et al., 2004) and the reconstruction of atmospheric $\Delta^{14}\text{C}$ (Hughen et al., 1998, 2004). Comparing the latter with $\Delta^{14}\text{C}_{\text{atm}}$ predicted from the changes in the intensity of the geomagnetic field reveals deviations that are consistent with slower rates of transfer of ^{14}C from the atmosphere to the deep sea (i.e., lower rates

of deepwater formation) during the Younger Dryas cold period and Heinrich Event H1.

^{14}C ages of ^{230}Th -dated deep-sea corals suggest that changes in the rates of deepwater circulation may have been very abrupt. Adkins et al. (1998) have shown that within a period of 130 years, the ^{14}C age of bottom water at 40°N in the Western Atlantic at 1,800 m depth decreased by 670 years, suggesting an abrupt slowdown of deepwater formation rate at a time (15,400 yrBP) that preceded the Bølling warming. This observation indicates that deepwater formation rates could have fluctuated on centennial timescales, i.e., a "flickering" rate too rapid to be recorded in the $^{231}\text{Pa}/^{230}\text{Th}$ record. However, a detailed reconstruction of deep water circulation on this timescale, using the narrow windows of information both in time and space provided by deep-sea corals, requires the further analysis of a large number of widely-distributed coral specimens.

Conclusion

Much remains to be done to obtain a detailed and accurate reconstruction of past changes in deep water circulation, even during the relatively recent past of the late Quaternary. It is evident that none of the proxies used for water mass identification and circulation rates provides a simple, straightforward answer. Each proxy is affected by factors other than deepwater circulation and the circulation signal must be retrieved from a tangle of other influences. It is therefore important not to rely on a single tracer, but to use the full range of circulation proxies that is at our disposal. Apparent disagreements point to problems with the interpretation of at least some of the proxies and through an iterative process of proxy validations in the modern ocean, paleoceanographic reconstructions, and cross examinations, we gradually converge towards a better understanding of past ocean circulation. This endeavor is crucial not only to understand past climatic variations but also to improve our ability at predicting future climate changes that could potentially be triggered by human activity.

The picture that is slowly emerging suggests that during the last glacial period, GNAIW was generally produced at a rate that was not dramatically different from the modern rate of NADW formation. It also seems that, as is the case for the modern NADW (Figure O7), the GNAIW was part of a global "conveyor belt" circulation. However, this only ventilated the

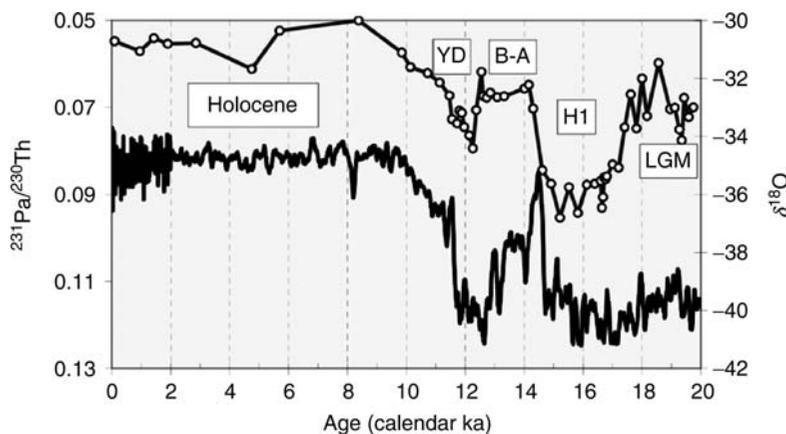

Figure O15 $^{231}\text{Pa}/^{230}\text{Th}$ in a high sedimentation rate core from the North Atlantic (adapted from McManus et al., 2004) compared to the $\delta^{18}\text{O}$ in Greenland ice. Low $^{231}\text{Pa}/^{230}\text{Th}$ = high NADW formation rate (note the reverse scale); higher $\delta^{18}\text{O}$ = warmer temperature.

upper 2,500 m of the ocean. Below that depth, deep waters presumably originating from the southern ocean were present. In contrast to this apparent lack of correlation between rates of deepwater formation and climate on these longer time scales, there seems to be a much closer relationship on shorter time-scales. During short periods of massive iceberg discharge (Heinrich Events) that punctuated the glacial period, deepwater formation in the North Atlantic may have totally ceased. The rapid warmings that followed these events seem to be the results of a rapid reinvigoration of the Atlantic MOC. Such a sequence of events has now been well documented for the last of the Heinrich Events (H1), which occurred during the early stages of the deglacial transition into the Holocene. Water mass proxies suggest similar sequences during the other Heinrich events, but confirmation with kinematic tracers is still required. The possibility that some of the abrupt climate changes in the past were associated with rapid changes in the rate of thermohaline circulation raises concerns that such events could happen in the near future.

Introduction

Ocean productivity – the uptake of dissolved inorganic carbon and its sequestration into organic compounds by marine primary producers – plays a major role in controlling the partitioning of carbon between the ocean and atmosphere. Productivity fluctuations can therefore influence climate by altering the atmospheric concentrations of the greenhouse gas carbon dioxide (Berger et al., 1989). In addition, changes in marine productivity have some bearing on the biogeochemistry of many trace elements (P, N, Si, Ba) and gases (dimethyl sulfide). The record of significant fluctuations in atmospheric carbon dioxide in air trapped within polar ice along with the increasing concern of potential climate warming induced by industrial carbon dioxide emissions has emphasized the need to understand the interrelationship between productivity, ocean chemistry, atmospheric carbon dioxide, and climate. Ocean paleoproductivity studies document past changes in the biological production of organic matter and skeletal material. These studies provide insight into the causes of such fluctuations, the consequences for biogeochemical cycles within the ocean, and their correspondence to Earth's climate.

There are two components of oceanic productivity that are of interest: (a) net primary production in the surface ocean; and (b) export production, which is the fraction of net primary production that leaves the surface ocean and sinks to the deep ocean. While the former is of interest for learning about oceanic ecosystems, and carbon and nutrient cycling within the ocean, the latter is more relevant for carbon sequestration and climate change. The unit for measuring productivity is flux of carbon ($\text{grams C m}^{-2} \text{ yr}^{-1}$) and typical values for open ocean net primary productivity today are 25–250 $\text{g C m}^{-2} \text{ yr}^{-1}$. Export production typically ranges from less than 10% and up to 50% of the net primary production.

The concept of changing oceanic productivity and the relation of such changes to climate stand at the beginning of paleoceanographic research. Arrhenius (1952) suggested such changes to explain the sedimentary record and in particular calcite accumulation and size distribution of a diatom (*Coscinodiscus nodulifer*) over time in the eastern Equatorial Pacific. Since direct measurements of carbon uptake or flux to the deep ocean cannot be done for past times, paleoproductivity reconstruction has been based on records obtained from marine sediments. Over the past 50 years, a large variety of methods has been applied to reconstruct productivity, attesting to the importance of this field. Some of these methods result only in qualitative estimates while others are more quantitative. Each of these methods (or proxy variables for productivity) has associated assumptions and limitations and therefore should be used with caution. Ideally, several proxies should be applied simultaneously at any given site or time interval to evaluate changes in marine productivity.

Reconstruction of productivity from organic matter or phosphorus in sediments

As a dominant biological component, measurements of organic carbon (C) content of sediments seem a logical choice for reconstructing biological C production. In areas removed from downslope transport of fine-grained material, it has been assumed that the flux of organic C reaching the sediment is proportional to its net export from the surface ocean (Figure O16). Indeed, sediment trap studies indicate that a general relation between the flux of organic matter to the deep sea and productivity exists. However, there is a strong depth dependence of the relation because of

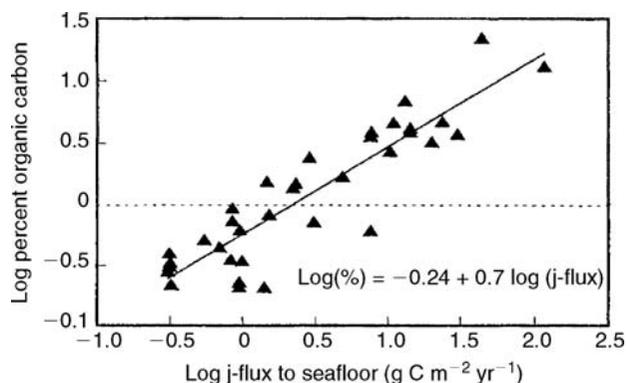

Figure O16 Correlation of organic carbon content in marine sediments with organic matter flux to the seafloor (after Berger and Herguera, 1992).

organic C degradation in the water column. Only a small fraction of the organic matter that arrives to the sediment is ultimately buried. However, at least at some oceanic locations, a relation between the abundance of organic matter in sediments and primary production has been observed. Empirical equations that quantitatively relate the accumulation rate of organic carbon in sediments to overlying productivity (Muller and Suess, 1979) or to the carbon flux to the seafloor (Sarnthein et al., 1988) have been suggested using data from the present ocean. The relation between organic matter content and productivity has been applied to reconstruct past oceanic productivity in various oceanic basins and for various time scales (Muller and Suess, 1979; Pedersen, 1983; Finney et al., 1988).

The interpretations of the fluctuations of organic carbon content in terms of paleoproductivity are complicated by processes affecting organic matter preservation such as sediment accumulation rates, deep water oxygen content, exposure time, and mineral surface area (Emerson, 1985; Keil et al., 1994). In addition, supply of organic C from terrestrial origin may result in overestimation of the oceanic productivity in coastal environments (Goni et al., 1998).

One of the elements directly related to organic matter is phosphorus (P). Phosphorus is an important nutrient to all living organisms. In general, marine phytoplankton incorporate P at a relatively constant ratio to their C content (the Redfield molar ratio of 106 C to 1 P). Accordingly, mapping past P accumulation may provide an indirect estimate of C flux and thus productivity (Delaney, 1998). Indeed, this proxy has been used to reconstruct past ocean productivity, typically over long geological time frames where organic C data is more likely to be compromised (Filippelli, 2002).

It must be kept in mind, however, that only a small fraction of P is preserved in the sediment (like C) and that, within the sediment after burial, P is transformed from the organic forms to authigenic minerals (Ruttenberg and Berner, 1993). To account for this complication, the “reactive P” fraction, which is the P that presumably was associated with organic matter, is used for paleoproductivity reconstruction (Delaney, 1998). In addition, post burial redox diagenesis may alter the P association and preservation in the sediment and therefore care must be taken to avoid samples that have been compromised by such processes (Delaney, 1998).

Reconstruction of productivity from carbonate or opal

Geologists have long recognized that variations in sediment composition parallel surface primary production. Indeed calcium carbonate and biogenic opal in marine sediments are predominantly composed of the hard parts of marine organisms (coccolithophores and diatoms). Sediment traps show a good correlation between the organic C flux and carbonate flux under certain conditions in the open ocean above the lysocline (Deuser et al., 1981; Ruhlemann et al., 1996) (Figure O17a). Similarly biogenic opal flux in sediment traps and on the seafloor generally correlates with the organic C flux (Calvert, 1966) (Figure O17b). These empirical relations based on traps and core top sediments can be used as a basis for reconstructing changes in location and intensity of export production. Indeed, Lyle et al. (1988) demonstrate linkage between mass accumulation rates of organic C, calcite, and biogenic opal and tie these to biological productivity.

Both these proxies, however, represent only changes in the export production of the specific organisms precipitating these minerals. One must therefore assume a predictable relation between total export production and the production of specific groups of organisms that are responsible for the precipitation of these minerals. Moreover, opal fluxes to the sediment may be dominated by event production such as during diatom blooms. In addition, both proxies are affected by a variety of physical and chemical oceanographic processes and not only by productivity. In particular, because the ocean is undersaturated everywhere with respect to opal, there is a major problem in quantitatively relating the amount of opal preserved in sediments to its production in the water column. Opal preservation rates depend on several factors including the global silica budget, pore water dissolved silica concentration, the thermal history of the sediment column, and the degree of silicification of the frustules (DeMaster, 1981; Treuger et al., 1995; Hutchins and Bruland, 1998). As a result, areas with high opal accumulation do not always correspond with areas of high productivity such as in the present-day Southern Ocean. Nevertheless, there do appear to be major trends in the history of opaline sedimentation over time and this proxy has been used to suggest qualitative changes in export production. Similarly, calcium carbonate accumulation in marine sediments may also suffer severe diagenetic modification of the original productivity-driven signal due to dissolution. This process, however, will occur predominantly in the deeper parts of the ocean where

seawater is undersaturated with respect to calcite. With proper site selection, or after accounting for dissolution (Mekik et al., 2002), it is possible to obtain representative patterns of carbonate production in most areas of the world's ocean.

Reconstruction of productivity from barite and Ba accumulation

Marine barite (BaSO_4), the major carrier of particulate Ba in the water column, is related to the marine carbon export flux (Bishop, 1988; Dymond et al., 1992). Barite precipitation in the water column is associated with decaying organic matter (Ganeshram et al., 2003). This results in a positive correlation between barite and excess-Ba (the Ba fraction not carried by terrigenous material – $\text{Ba}_{\text{excess}}$) and organic carbon fluxes in sediment traps and filtered particulate matter (Dehairs et al., 1980; Dymond et al., 1992). Based on this relationship in sediment traps, Dymond et al. (1992) predicted a positive correlation between the accumulation of $\text{Ba}_{\text{excess}}$ in marine sediments and carbon export (Figure O18a).

$\text{Ba}_{\text{excess}}$ has been used in many studies, to infer paleoproductivity (Nürnberg et al., 1997; Bonn et al., 1998; Bains et al., 2000). $\text{Ba}_{\text{excess}}$ is determined from the total Ba concentration in the sediment after subtracting the Ba associated with terrigenous material, which is calculated from total Al or Ti, and normalization to a constant detrital Ba/Al or Ba/Ti ratio. This calculation assumes that (a) all sedimentary particulate Ba besides the fraction associated with terrigenous aluminosilicates is predictably related to carbon export, (b) all of the Al (or Ti) is associated with terrigenous material, and (c) the Ba/Al (Ba/Ti) ratio used for normalization is in fact representative of each sample's terrigenous component and is constant in space and time. If the above assumptions are correct then $\text{Ba}_{\text{excess}}$ accumulation in sediments could be used to estimate carbon export.

Paytan et al. (1996) and Eagle et al. (2003) proposed an algorithm for paleoproductivity reconstruction based directly on barite accumulation in core top sediments (Figure O18b). In these studies, as in Dymond et al. (1992), the applicability of the proxy relies on the observation that barite forms and accumulates in proportion to biological productivity and the organic matter flux in the water column. In addition, barite shows promise as a paleoproductivity proxy because it is a highly refractory mineral with preservation as high as 30% in oxic sediments (Dymond et al., 1992). The barite accumulation

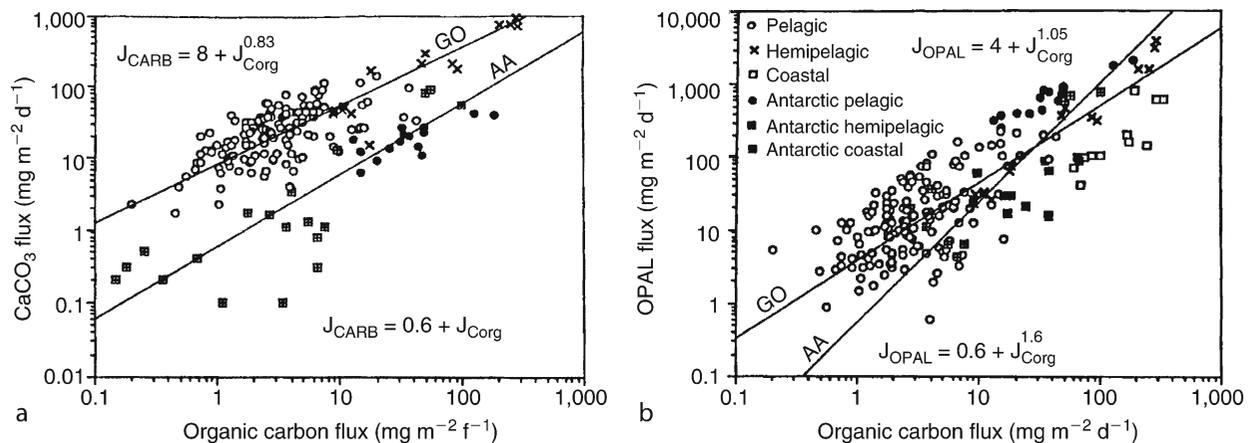

Figure O17 Relationship between (a) carbonate and (b) opal flux and organic carbon flux in sediment traps from various regions in the ocean. GO: global ocean; AA: Southern Ocean (after Berger and Herguera, 1992).

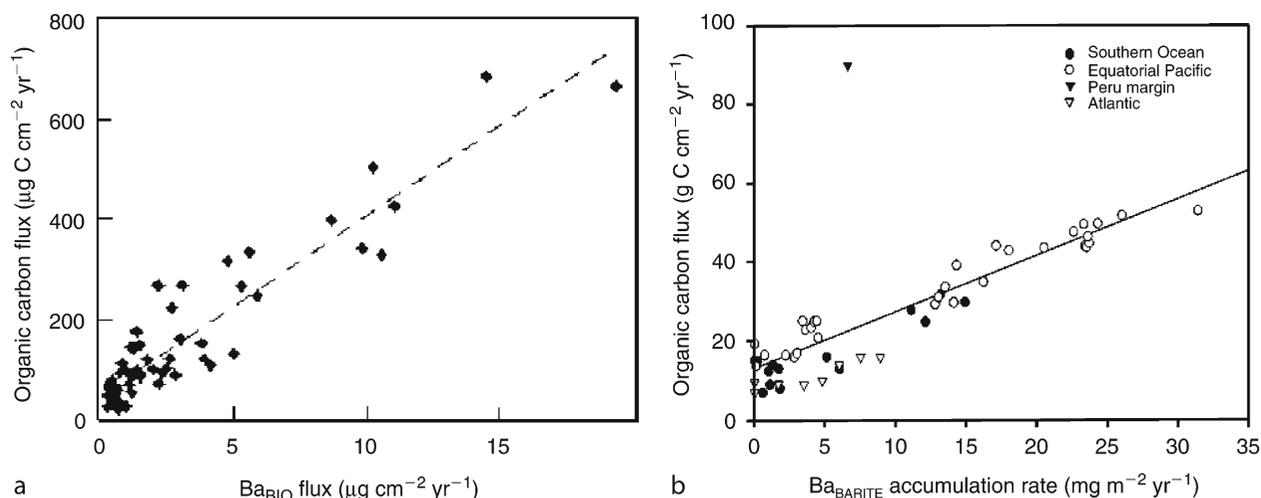

Figure O18 (a) Relation between excess Ba and organic C export in sediment traps (modified from Dymond et al., 1992). (b) Relation between barite accumulation rate in core top sediments and carbon export in the overlying water column (modified from Eagle et al., 2003).

rate in oxic sediments could therefore serve as a proxy for estimating paleocarbon export if the processes controlling barite formation and preservation are known and operate globally in the ocean.

Barium, however, is contained in other phases, some of which are biogenically-related (e.g., organic matter, biogenic silica, and biogenic carbonate), and others that are not directly related to carbon export (e.g., terrigenous silicates, Fe-Mn oxides, and hydroxides). The non-barite phases that are included in Ba_{excess} would not necessarily yield a predictable global $C_{\text{org}}/Ba_{\text{excess}}$ relationship as found by Dymond et al. (1992). This is because the ratio of organic carbon to these other biologically-related Ba phases varies spatially in the ocean, and because factors controlling Ba incorporation into Fe-Mn oxides and hydroxides are not directly biologically mediated. Although barite accumulation is not affected by the above factors, its preservation is affected by the dissolved Ba concentration in seawater; thus, some estimate of past oceanic Ba concentrations is needed for quantitative use of this proxy. In addition, barite in marine sediments is remobilized under sulfate-reducing conditions, so this proxy can only be applied when pore waters have remained saturated with respect to barite throughout the sedimentary record.

Reconstruction of productivity from microfossil assemblages

The use of species distribution has been widely applied for reconstructing productivity. Plankton assemblages in the surface ocean respond to nutrient concentrations, thus productivity. A number of foraminifera species have been identified as indicative of high productivity (*Globigerina bulloides*, *Neogloboquadrina dutertrei* and *Globorotalia tumida* at low latitudes, *Globigerina quinqueloba* in temperate latitudes and *Neogloboquadrina pachyderma* in cold upwelling waters). Single species abundances, however, may be more indicative of upwelling or other hydrographic physical processes rather than biological productivity. Multi-species based indexes using all of the foraminifera species in sediment cores to construct a quantitative estimate of productivity using standard transfer function

techniques are more robust (Imbrie and Kipp, 1971). The transfer functions (modern analogs) are constructed using modern primary production rates and a global coverage of core top foraminifera abundance data (Mix, 1989). The high abundance and diversity of foraminifera allows statistical analyses of small sediment samples (Figure O19a).

Similarly, the benthos biomass and the structure of the benthic community (species composition and size) reflect the supply of organic matter to the seabed, thus export production (Rowe, 1983). In particular, benthic foraminifera, which constitute a major portion of the benthic biomass, respond to changes in supply of organic carbon to the seafloor. Accordingly, changes in benthos abundance (population size) and benthic population composition (assemblage) have been used to qualitatively indicate changes in export production (Figure O19b). The biomass of total benthic foraminifera is positively correlated with the estimated local annual flux of organic C into the deep sea (Herguera, 2000). Specific species such as *Uvigerina peregrina* and *Globobulimina* sp. are characteristic of high nutrient fluxes, whereas *Cibicides wuellerstorfi* and *Cibicides kullenbergi* biofacies dominate areas of low productivity (Altenbach and Sarnthein, 1989). Transfer functions based on benthic communities and diatom assemblages have also been developed and applied to reconstruct past oceanic productivity (Loubere, 1999).

Many uncertainties remain, however, because our knowledge of the biology of the common fossil groups is limited. It is not clear to what extent the plankton assemblage reflects primary production, export production, or food availability. In addition, assemblages respond to a complex suite of environmental parameters that are not easily separated, thus are affected by other environmental variables (temperature, salinity, oxygen, etc.). Problems may arise from non-analog situations where the calibration using present-day core top samples does not represent past conditions. In addition, for all the species indices, there may be preservation effects and post-deposition changes in assemblages due to preferential dissolution, which will limit our ability to see true biological relationships. For longer time frames, evolution of species will also limit the utility of this type of index.

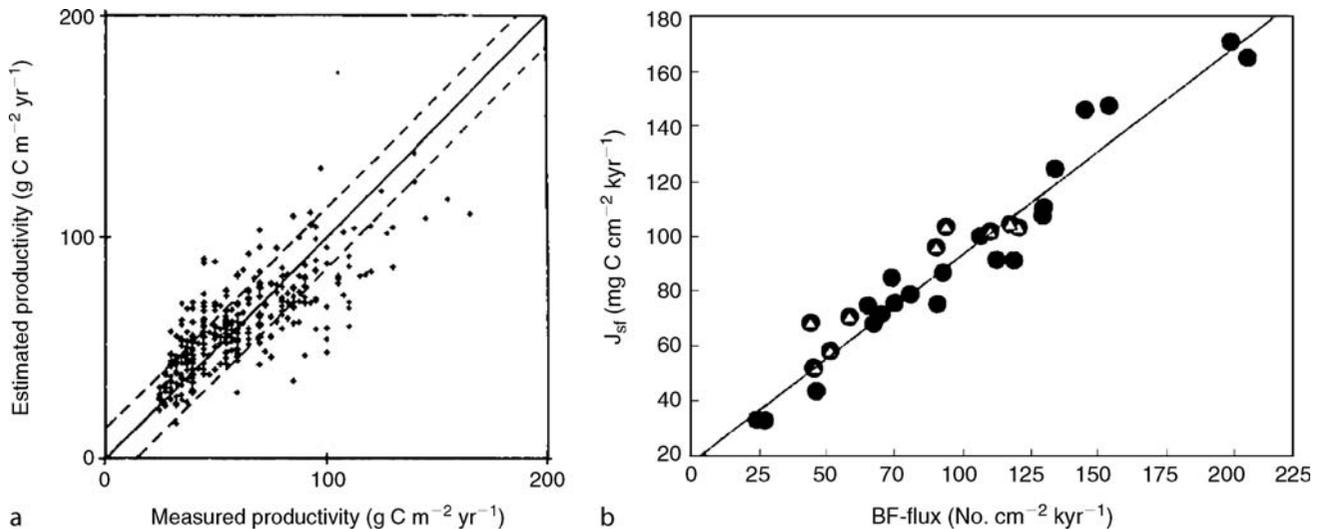

Figure O19 (a) Estimated versus measured values for productivity as generated from foraminiferal transfer functions. (b) Accumulation rate of benthic foraminifera (*BF-flux*) as a function of calculated flux of organic matter to the seafloor (*J_{sf}*) (after Berger and Herguera, 1992).

Reconstruction of productivity from carbon isotope records

A link between ocean productivity and carbon isotopes was first postulated by Tappan (1968), who suggested that change in $\delta^{13}\text{C}$ of carbonates towards heavier values is indicative of increased deposition of organic carbon, thus export production. The principle underlying this relation is carbon mass balance. During photosynthesis, since isotopically light carbon (^{12}C) is preferentially incorporated into the produced organic matter, the residual inorganic pool will become enriched in ^{13}C . This signature will be recorded in carbonate shells and therefore higher $\delta^{13}\text{C}$ of carbonates indicates increased burial of organic matter (with low $\delta^{13}\text{C}$ values) and hence higher productivity.

The difference between planktonic and benthic $\delta^{13}\text{C}$ compositions is a refinement of the above proxy (Figure O20). This difference is controlled by both the photosynthesis of organic matter in the surface ocean, which depletes the inorganic pool of ^{12}C , and the regeneration of this organic matter at depth, returning the ^{12}C to the deep-water inorganic pool. Thus, the larger the difference between the benthic and planktonic $\delta^{13}\text{C}$ (typically referred to as $\Delta^{13}\text{C}$), the higher the productivity (Shackleton et al., 1983; Curry and Crowley, 1987; Schneider et al., 1994).

It must be kept in mind that changes in oceanic circulation may modify the deepwater $\delta^{13}\text{C}$ independently of productivity. Moreover, when benthic foraminifera species are used for $\delta^{13}\text{C}$ analyses, it is important to choose species that indeed record the isotope ratio of dissolved inorganic carbon in seawater and not that of water within the sediment; thus only epifaunal species (organisms living on top and not within the sediments) should be used. In addition, because the isotopic fractionation during photosynthesis and shell production may vary between species and within each species depending on environmental parameters ($p\text{CO}_2$, carbonate ion concentrations, nutrient availability, etc.) a record obtained from a single species is preferable (Duplessy et al., 1984). Reconstruction of paleoproductivity via carbon isotopes becomes less reliable the farther back in time we go in the geological record. With now-extinct

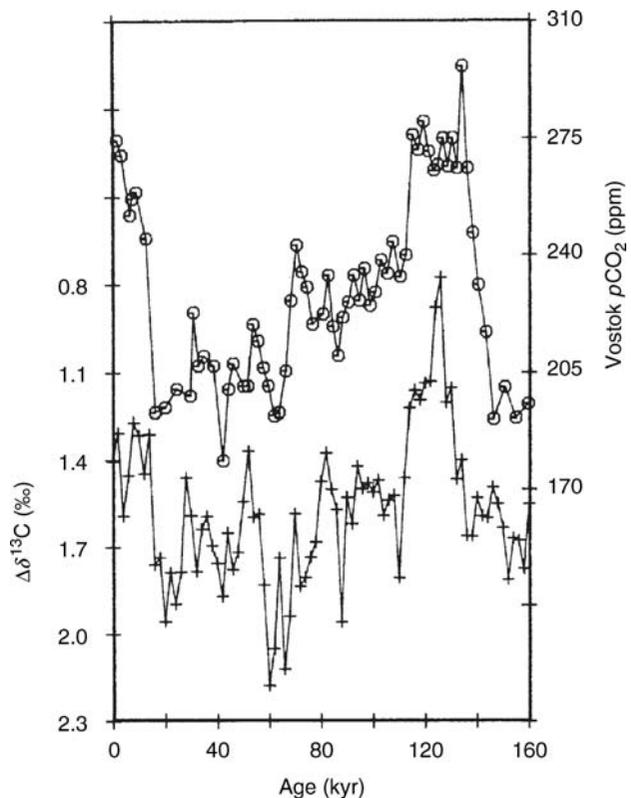

Figure O20 $\delta^{13}\text{C}$ difference ($\Delta\delta^{13}\text{C}$) between the benthic foraminifera *Uvigerina* sp. and the planktonic foraminifera *Neogloboquadrina dutertrei* in core V19-30 in the eastern Equatorial Pacific (+ symbols) (data from Shackleton and Pisias, 1985). Also plotted is the VOSTOCK ice core $p\text{CO}_2$ data from Barnola et al., (1987) (o symbols). The similarity between the records confirms the importance of export productivity variations (the biological pump) to atmospheric CO_2 (figure modified from Mix, 1985).

species, we can only indirectly verify the faithfulness of the C signal in their skeletons to the ambient water $\delta^{13}\text{C}$. In addition, the extent of diagenetic modification of carbonate $\delta^{13}\text{C}$ increases with time after burial and may be significant in areas where pore fluids contain “light” methanogenically-derived C.

Reconstruction of productivity from geochemical indicators

Several geochemical indicators that record particle flux in the water column have also been used as proxies for productivity (Al/Ti, Ba/Ti, $^{231}\text{Pa}/^{230}\text{Th}$, $^{10}\text{Be}/^{230}\text{Th}$). In vast areas of the open ocean, most of the particulate matter sinking in the water is of biogenic origin and thus is related to productivity.

Application of bulk Al/Ti and Ba/Ti ratios assumes that changes in the delivery of Al and Ba in non-lithogenic material are proportional to particle flux, which may then be related/converted to productivity. These proxy applications assume that in specific open-ocean locations (with low terrigenous input), total particle flux is proportional to C_{export} (Murray et al., 2000). Since Al is particle reactive, the adsorbed fraction of Al should increase with increasing particle flux; therefore, the excess Al content of deep-sea sediments (i.e., the fraction of Al not associated with aluminosilicate material) will increase with increasing particle flux (Murray and Leinen, 1996). Similarly, Ba/Ti should co-vary with bulk particle flux, and thus C_{export} (Figure O21; Murray et al., 2000). Bulk ratio proxies apply so long as Ti is exclusively of terrigenous origin, the fraction of Al or Ba associated with lithogenic Ti does not change significantly through time, and the excess Al or Ba is related to C_{export} in a predictable and consistent manner. The benefit of a normalizing ratio is that it does not require conversion of concentrations to accumulation rates, thus avoiding errors associated with such conversions.

In open ocean areas, a relationship exists between the mass flux of particulate matter and the unsupported $^{231}\text{Pa}/^{230}\text{Th}$ and $^{10}\text{Be}/^{230}\text{Th}$ activity ratios of recent sediments (Anderson et al., 1983; Rutsch et al., 1995). These ratios have been used as tracers to assess changes in productivity. The production rate of ^{231}Pa and ^{230}Th from dissolved U in seawater and the input of ^{10}Be to the ocean are known; however, the removal of these elements is not homogenous because they have variable residence times in

the ocean. Because ^{230}Th is more effectively scavenged, its flux to the seafloor is nearly equal to its rate of production; in contrast ^{231}Pa and ^{10}Be have longer residence times, which allows transport and preferential removal in high particle flux regions (Anderson et al., 1983). Therefore, high $^{231}\text{Pa}/^{230}\text{Th}$ and $^{10}\text{Be}/^{230}\text{Th}$ ratios indicate regions of extensive particle flux. The major advantage of the radionuclide ratios is that they are less sensitive to post-depositional diagenetic alteration. However, changes in ocean ventilation rate and dependence of scavenging efficiency in particle composition may influence the reliability of these proxies (Walter et al., 1999).

Accumulation of redox-sensitive metals in marine sediments is indirectly related to productivity, or more accurately, to the flux of C to the sediment. The higher the export production and organic C accumulation the more oxygen is consumed in the water column and sediment. As pore waters become sufficiently reducing, some metals precipitate and accumulate in the sediments. An example of an element that has been linked to organic C flux is uranium, which forms authigenic minerals in the sediment under reducing conditions (Kumar et al., 1995). Laminated sediments have also been linked to very high organic C fluxes. When the organic matter flux to the bottom waters is high, all of the dissolved oxygen is consumed, resulting in anoxic waters and low abundance of benthic organisms. This in turn reduces the degree of bioturbation and preserves the lamination in sediments. The above proxies, however, will also respond to changes in bottom water oxygen over time that are related to circulation and ventilation of the ocean and not to productivity, thus they are hard to interpret directly as reflecting changes in biological productivity.

It has recently been suggested that another geochemical proxy, the Sr/Ca ratio in coccolithophores, changes in proportion to calcification rates, which are higher when coccolith productivity is high (Stoll and Schrag, 2000). This proxy has been used for qualitative reconstruction of paleoproductivity; however, such reconstruction will only represent changes in coccolith productivity, which may be decoupled from total production. In addition, species-dependent Sr uptake rates and diagenetic alteration of original Sr/Ca ratios have not been completely ruled out and may complicate interpretation.

Reconstruction of productivity from nutrient content

Nutrient (N, P, Fe, Si) availability in many places controls the productivity in the surface ocean. Therefore, it has been suggested that knowledge of nutrient concentrations or their degree of utilization can be examined in the sedimentary record and may provide indirect information about past productivity. Such proxies include the nitrogen isotopic composition of organic matter (Altabet and Francois, 1994; Farrell et al., 1995), silicon isotopic composition of diatom frustules (De La Rocha et al., 1998), and the Cd/Ca ratio of planktonic foraminifera (Cd serves as an analog for P; Elderfield and Rickaby, 2000). The basic concept behind these proxies is that in areas where the nutrient pool (N, Si, P) in the surface ocean is not fully utilized, progressive assimilation of nutrients from surface seawater, accompanied by fractionation, produces strong gradients in the isotopic or elemental composition within the euphotic nutrient pool, which is then recorded by the plankton. This in turn leads to corresponding changes in the composition of particles that sink in the water column and accumulate in the sediment. For example, at high nutrient content relative to uptake (low utilization rates), ^{14}N is preferentially taken up by the phytoplankton and the organic matter, which under such conditions will have low $\delta^{15}\text{N}$ values. As nutrients are more efficiently utilized, less isotopic discrimination occurs and the $\delta^{15}\text{N}$ of organic matter shifts towards heavier

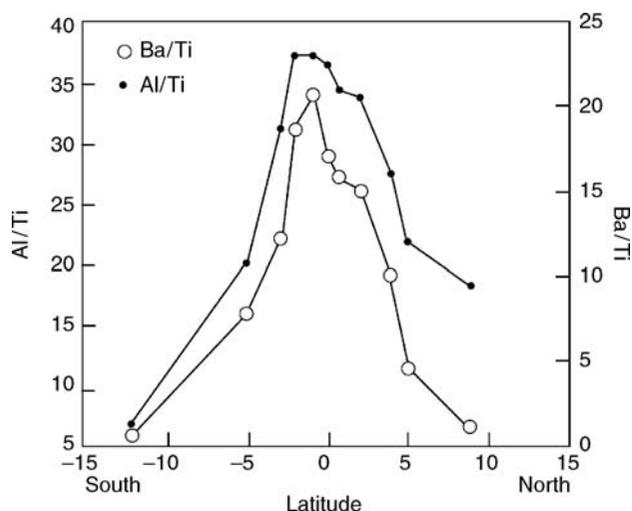

Figure O21 Profiles of Al/Ti and Ba/Ti trace productivity across a meridional transect at 140° W in the central equatorial Pacific Ocean (modified from Murray et al., 2000 and references therein).

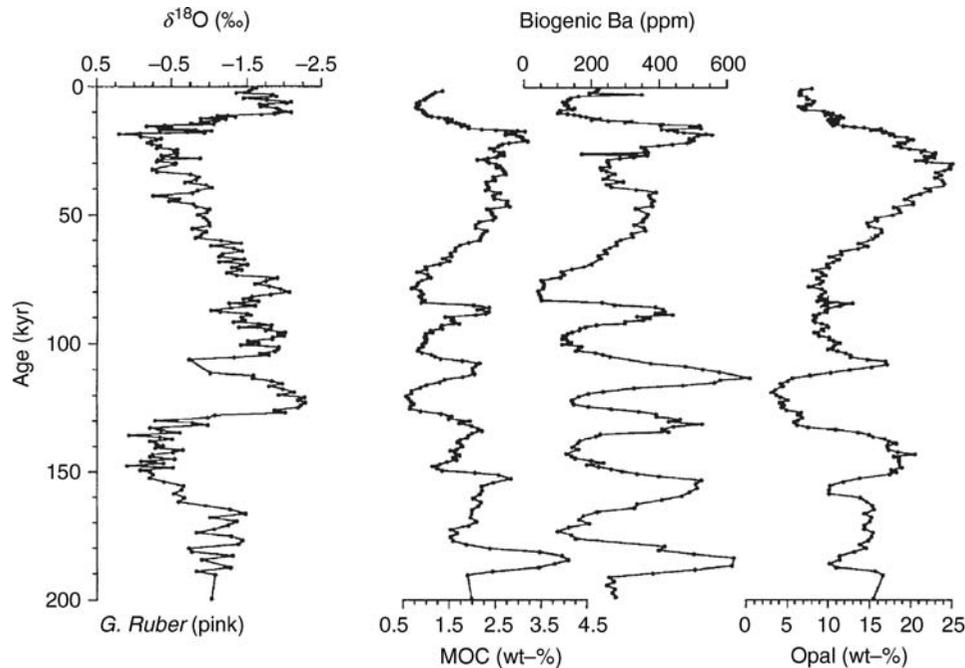

Figure O22 A multi-proxy approach for reconstructing marine productivity. Marine organic carbon (MOC), biogenic Ba, and opal co-vary down-core and show higher values during glacial periods (as indicated by the oxygen isotope record) in core GeoB 1008-3 from the South Atlantic (modified from Schneider et al., 1997).

values. Similar uptake effects result in changes in the $\delta^{32}\text{Si}$ of diatoms and the Cd/Ca ratio in planktonic foraminifera.

It must be kept in mind, however, that the relation between nutrient input and uptake (i.e., utilization) and biological productivity is not straightforward. In addition, changes in the isotope ratio or elemental composition of the bulk oceanic reservoir and post-depositional changes cannot be ruled out and may affect the sedimentary record (Montoya, 1994).

Reconstruction of productivity from organic biomarkers

Algal class structure is intimately related to overall water productivity and nutrients. Knowledge of the phytoplankton community can help distinguish high productivity from low productivity areas.

Marine phytoplankton, zooplankton and bacteria all synthesize a large number of organic compounds, many of which are taxon specific. The relation between the occurrence of certain compounds (biomarkers) and abundance of particular phytoplankton groups has been utilized to distinguish between marine and terrestrial organic matter and, in principle, could be used to reconstruct community structure.

Efforts to develop these proxies are underway; however, diagenesis is a major hurdle for quantitative reconstruction. In addition, the extraction of specific organic compounds from bulk sediment using solvents results in only partial recovery and the resulting extracted fraction may not be necessarily representative of the total organic matter.

Summary

Although ocean productivity is very important for understanding the operation of the global carbon cycle at present and in

the past, reconstruction of past ocean productivity patterns using empirical relations derived from present-day ocean characteristics is not a trivial undertaking. Each one of the proxies (methods) developed so far, although it contributes to our overall knowledge, has important limitations and therefore the best approach is to use multiple proxies (Figure O22). Critical evaluation of the validity of assumptions associated with each existing proxy and development of additional proxies will result in more robust reconstructions of paleoproductivity and understanding of the coupling and feedbacks between productivity, tectonics, and climate.

OCEAN PALEOTEMPERATURES

Ocean paleotemperatures are the principal characteristics of past ocean scenarios. Over geological time, ocean temperature patterns underwent large changes, responding on long timescales ($\times 10^6$ yr) to different plate tectonical configurations, favoring either circum-equatorial flow and promoting a generally warmer ocean, or circum-polar flow with steep low-to-high latitude temperature gradients. On shorter timescales ($\times 10^4$ – 10^5 yr), ocean temperatures respond to insolation changes controlled by Earth orbital parameters which determine the amount of radiation the Earth's surface receives. High-amplitude, short-term temperature fluctuations are superimposed on decadal-to-millennial time scales and match the short-term temperature fluctuations recorded in Greenland ice cores during glacial times. This is a recent discovery that has immediately focused interest in climate research because of the potential analogy to human-induced climate change.

Because ocean temperatures are a key component of the climate system, deciphering ocean paleotemperatures from “marine climate archives” reflecting the climatic state of the Earth continues to be a longstanding aim. Sea surface temperatures

(SSTs) exert an immediate impact on the atmosphere, driving atmospheric circulation in terms of heat and moisture transport, and oceanic-atmospheric gas exchange. Moreover, aside from salinity, temperature determines the density of surface water, which drives thermohaline deepwater circulation. Thus, paleo-SSTs allow conclusions to be drawn about oceanic and atmospheric circulation. Deepwater temperatures depend on the loci where they are formed by sinking of dense surface waters; paleo-deepwater temperatures reflect the state of thermohaline circulation.

Different concepts are used to reconstruct water temperatures of past times, including micropaleontological, stable isotope, biomarker, and geochemical approaches. Several micropaleontological and geochemical data sets have been calibrated with the aim of yielding quantitative paleotemperature proxies. A variety of studies of past ocean scenarios (e.g., of the Last Glacial Maximum, Cenozoic warm climates), based on paleotemperature proxies, has greatly improved our understanding of the climate system over the last few decades. In particular, ocean paleotemperatures may serve as boundary conditions to initiate and validate climate model calculations that aim to predict the magnitude of future global warming.

History

Geological and paleontological studies aiming to reconstruct Earth's climate are perhaps as old as these disciplines. The oldest paleoclimate records based on marine fossils from land outcrops date back to the late eighteenth and early nineteenth century, when Cretaceous boreal, tropical, and austral provinces were identified in mollusk, ammonite and other faunas and changes in biogeographical distribution patterns were interpreted in terms of climatic change (e.g., Hutton, 1795; Cuvier, 1817).

The earliest climate records aiming for quantitative temperature reconstructions from microfossils were based on the identification of key species in Pleistocene marine sediments; species that could be related to climate zones (e.g., Phleger et al., 1953). However, it was not until the second half of the twentieth Century that an array of studies on the biogeographical distribution of modern planktonic foraminifera in the world ocean and in marine sediments became available, the potential of this species group as a tool for climate studies was discovered (e.g., Bradshaw, 1959; Bé, 1977; and others), and a conceptual framework for quantitative faunal approaches was found (Imbrie and Kipp, 1971).

Stable isotopes began to flourish as a tool in paleoceanography in the mid-twentieth century. Urey (1947) first explored the potential of oxygen isotope fractionation in natural carbonates as a paleotemperature indicator. Epstein et al. (1953) established the first paleotemperature equation based on oxygen isotopes. They found a 0.2‰ decrease in oxygen isotopic composition (expressed as $\delta^{18}\text{O}$) per 1 °C temperature increase for mollusk calcite. Emiliani (1955) published the first “paleotemperature records” based on $\delta^{18}\text{O}$ variations of foraminifera in Caribbean sediment cores, which he interpreted purely in terms of temperature fluctuations of 6–8 °C. However, it was yet not fully recognized to what extent the oxygen isotopic composition of the ocean changes through time. Shackleton (1967) discovered $\delta^{18}\text{O}$ fluctuations of similar amplitude in benthic foraminifera of the deep Pacific where deepwater is continuously close to freezing temperature. Here it became evident that the major portion of the $\delta^{18}\text{O}$ fluctuations observed in deep sea sediments are a result of waxing and waning continental ice

volumes where the light ^{16}O isotope is alternately stored away and released into the ocean. This finding has converted $\delta^{18}\text{O}$ into a stratigraphical tool, and when combined with independent temperature proxies, into a salinity and ice volume proxy.

Since the mid-1980s, alkenones have become established as a sea surface temperature (SST) proxy. The use of this proxy is based on the finding that these lipids, which are produced by marine algae, show a characteristic unsaturation pattern that is linked to growth temperature (Marlowe et al., 1984; Brassell et al., 1986). Over the last 20 years, analytical methods have improved and data sets for calibration that cover wide ocean regions have been established for water column, laboratory cultures, and sediment surface samples. These eventually gave rise to a new proxy that is now widely applied in paleoceanography (Müller et al., 1998).

Knowledge that magnesium contents in carbonates vary with temperature dates back to the early part of the twentieth century (Clarke and Wheeler, 1922). Nevertheless, only the development of precise analytical methods in the last decade of the past century enabled utilization of this trace element in carbonate microfossils as a quantitative proxy for paleotemperature (Nürnberg et al., 1996).

Ongoing work concentrates on: (a) achieving a still more precise calibration of established paleotemperature proxies, in particular for deepwater temperature reconstructions and near the “cold end” of temperature transfer functions, (b) exploring the use of quantitative proxies further back in geological time, and (c) testing new approaches. Questions addressing future warming have focused interest on the temperature reconstruction of former warm periods; (d) Multi-proxy approaches enable comparison of different reconstructions and, moreover, help to identify the influence of different seasons and growth habitats on the SST signal. In this context, reef corals are particularly promising in providing SST records with annual, seasonal, and even monthly time resolution and thus have gained increasing importance in addressing questions of short-term climate change.

Concepts for paleotemperature reconstructions

Most concepts for reconstructing past water temperatures are based on microfossils because of their widespread occurrence in marine sediments. Sea surface waters are inhabited by planktonic microorganisms, some of them bearing shells. In general, marine phyto- and zooplankton occur everywhere in the open ocean. Temperatures range from less than -1.8°C in the polar ice-covered areas up to 30°C in the tropical belt.

As the shells settle to the sea floor and are fossilized in marine sediments they preserve information about the environment in which they once lived. Paleoceanographers take advantage of this ‘climate archive’ to decipher paleotemperatures from microfossils, either from their faunal (or floral) assemblages or by analyzing the stable isotope or trace element composition of the calcareous shells. Most commonly employed microfossil groups are planktonic foraminifera. In addition, coccoliths, dinoflagellate cysts, and siliceous microfossils (radiolaria and diatoms) are used, the latter in particular to reconstruct Southern Ocean environments, where carbonate preservation is poor.

In contrast, deep-water temperatures are far more uniform and are generally near the cold end of transfer functions, ranging from close to freezing temperature to approximately 3°C . This makes them more difficult to assess. Deep-sea benthic foraminifera and ostracoda (little crustaceans bearing a calcareous carapace) living at the seafloor similarly record

deepwater temperatures in the isotopic and geochemical composition of their shells. Benthic assemblage structures, however, are much more complex than those of planktonic foraminifera and are primarily controlled by variables different from temperature.

Transfer functions based on microfossil species assemblages

Planktonic species assemblages are primarily sensitive to temperature, most species showing preference for a certain temperature range to which their vital functions are optimally adjusted. Therefore, planktonic assemblages display an ocean-wide, bipolar, roughly latitudinal distribution pattern, reflecting the occurrence of tropical, subtropical, transitional, subpolar, and polar water masses (Figure O23). Plankton distribution patterns of former times may thus be used to determine SSTs by using so-called transfer functions if evolutionary changes did not affect these patterns – that is, approximately over the last 0.5 million years. Imbrie and Kipp (1971) were the first to apply multivariate statistical methods to census data of planktonic foraminifera in order to derive quantitative SST estimates. Their method commonly consists of subjecting relative species abundances counted in core tops from a specific ocean region to a principal component (Q mode) analysis in order to discriminate factors by correlation between single species. The factors represent statistical assemblages, characterized by an end member species, the distribution pattern of which is related to specific watermass qualities (Figure O23).

Usually 5–6 factors are sufficient to explain $> 90\%$ of total variance in the assemblages. The role of single species grouped in a factor is weighted by factor loadings. Regression analysis (linear or non-linear) of the factors with instrumental temperatures above each station provides a set of equations (transfer functions) which can be used to calculate paleotemperatures from fossil species abundances. The equations have the shape of Equation (1)

$$P_{\text{est}} = k_0 + k_1A + k_2B + k_3C + k_4D \quad (1)$$

Where P is an environmental parameter, k s are predictive coefficients, and A – D are variables. In example (2), by Imbrie and Kipp (1971), T_8 is the summer temperature estimate, and the letters A – D stand for the values of tropical (Figure O24), subtropical, subpolar, and gyre margin assemblages.

$$T_8 = 19.7A + 11.6B + 2.7C + 0.3D + 7.6 \quad (2)$$

The quality of the calculated temperatures may be assessed by the measure of communality. This statistical measure, which is defined as the squared sum of factor loadings calculated for the fossil assemblage, shows how well the fossil assemblage fits into the pattern of modern assemblages.

The most impressive example of temperature reconstructions based on this approach was, without doubt, a global reconstruction of sea surface temperatures for the Last Glacial Maximum (LGM), accomplished by the CLIMAP Project members (1981) in 1976–1981. They applied the “Imbrie and Kipp (I&K) method” to a worldwide set of 700 glacial sediment samples where they used planktonic foraminifera, radiolaria, and coccolith assemblages as a joint base to produce SST maps of the glacial ocean.

A more advanced approach to derive paleotemperatures from faunal assemblages is the Modern Analog Technique

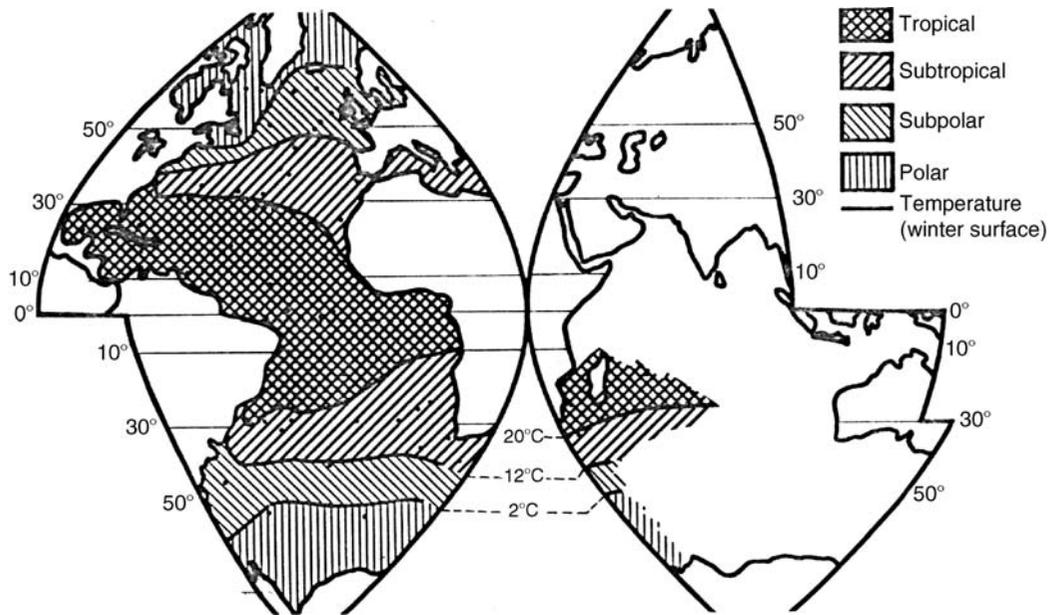

Figure O23 Distribution of core top samples dominated by statistical assemblages defined by Imbrie and Kipp (1971).

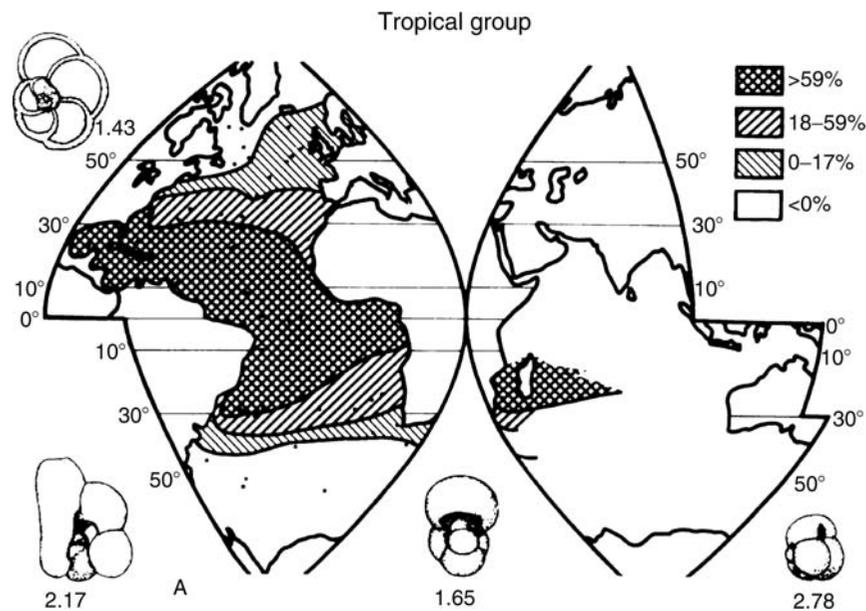

Figure O24 Geographical distribution of the tropical planktonic foraminifera group as defined by the multivariate statistical method. Four dominant species are shown with factor loadings ($\times 10$) (from Imbrie and Kipp, 1971).

(MAT) (Hutson, 1977), relying on the assumption that there is a direct relationship between the distribution of modern faunas and the physical properties of the environment. The method compares any fossil assemblage of planktonic foraminifera or other plankton with a set of census data from modern sediments in an ocean region (calibration data set) and transfers the measured temperatures above the most similar modern samples (= modern analogs) to the site of the fossil fauna. This approach employs a measure of faunal dissimilarity or similarity to identify the best modern analogs in the calibration data

set. The most commonly used dissimilarity coefficient is the squared chord distance (Equation (3)).

$$d_{ij} = \text{Sigma } k(p_{ik}^{1/2} - p_{jk}^{1/2})^2 \quad (3)$$

where d_{ij} is the squared chord distance between two multivariate samples i and j , and p_{ik} is the proportion of species k in a sample. Commonly, 10 modern analogs are selected. Measured sea surface temperatures at the various sample sites selected are averaged to give the paleotemperature. Further

refined variants of the MAT include SIMMAX (“similarity maximum”; Pflaumann et al., 1996, 2003), which weights the modern analog samples according to their geographical distance to the fossil sample, presuming that closer samples are more likely to record accurate temperatures. The Revised Analog Technique (RAM, Waelbroeck et al., 1998) pays tribute to the circumstance that core top samples as modern analogs are not evenly distributed across the ocean and therefore not all temperature settings are equally represented. Therefore, RAM does not use a pre-given number of analogs but defines for each sample the number to include, according to the dissimilarity. Moreover, artificial (interpolated) modern analogs are introduced into the database to strengthen the weight of poorly sampled temperature settings.

The use of Artificial Neural Networks (ANN; Malmgren et al., 2001) presents a more recent innovative approach to employ planktonic faunal data for SST reconstruction. The ANN technique is a computer-intensive method, which is based on an algorithm that has the ability to autonomously “learn” of a relationship between two groups of numbers (e.g., faunal and temperature data). The advantage of ANNs is that they have the ability to overcome problems of fuzzy and nonlinear relationships between sets of input and output variables. Each trained neural network serves as a unique transfer function, yet at the same time, this highly nonlinear and recurrent function is so complicated that it has the ability to simulate a decision algorithm.

To assess the differential quality of the outlined transfer functions, they have been applied to the same calibration data set of Atlantic core tops. Comparison of the resulting SST estimates to measured SST reveals that typical error ranges of transfer functions based on planktonic foraminifera range between $\pm 1^\circ\text{C}$ (SIMMAX; ANN; RAM) to $\pm 1.4^\circ\text{C}$ (I&K) (Malmgren et al., 2001).

The outlined transfer functions have the following general requirements in common: (a) The species composition in core top samples needs to be systematically linked to the environment of the ambient surface water mass; (b) the ecosystem has not undergone fundamental evolutionary changes, meaning that currently occurring species in an ocean basin are the same as those found in the sediments of the past period under investigation; (c) the ecological preferences of species have not changed over time; and (d) differential carbonate dissolution at the deep-sea floor has not significantly affected the species composition in the sediment.

Therefore, transfer functions *sensu strictu* are only valid for the period of time when all modern species have already existed. This applies to planktonic foraminifera of the last 0.5–0.7 million years. However, a number of authors have also tried to extend the use of transfer functions beyond that time limit. Aiming to reconstruct Miocene to Pliocene SSTs, Hooper and Funnell (1986) argued that it was legitimate to replace two species out of some 28, two species that only appeared in the Pleistocene, and the Miocene/Pliocene ancestor species that probably occupied similar ecological niches. Wang (1994) developed a transfer function for the reconstruction of Pliocene SST in the West Pacific. However, these attempts have not convinced the majority of investigators.

Oxygen isotopes

As with all stable isotopes, fractionation (= partitioning of isotopes between substances) of ^{16}O vs. ^{18}O in carbonates is temperature-dependent. The thermodynamic fractionation between

^{16}O and ^{18}O that occurs during carbonate precipitation offsets the $\delta^{18}\text{O}$ values of carbonate minerals relative to seawater by $\sim +30\text{‰}$. The $\delta^{18}\text{O}$ fractionation is a logarithmic function of temperature with a slope of -0.2‰ to -0.25‰ per degree Celsius, which means that a 1°C temperature increase results in an approximately 0.23‰ decrease in carbonate $\delta^{18}\text{O}$. Stable isotopes in carbonates are measured by mass spectrometry by determining the mass ratio in CO_2 gained from the reaction in which the carbonate sample is dissolved with phosphoric acid. Because ^{16}O is very abundant (99.76%) in nature and ^{18}O very rare (0.2%), the ratio between both isotopes is determined relative to a known standard (δ notation) (Equation (4)).

$$\delta^{18}\text{O}_{\text{Sample}} = ({}^{18}\text{O}_{\text{Sample}} / {}^{18}\text{O}_{\text{Standard}}) - 1,000 / {}^{18}\text{O}_{\text{Standard}} \quad (4)$$

In general, carbonate shells of foraminifera, both planktonic and benthic species, provide a fairly robust $\delta^{18}\text{O}$ record of predicted equilibrium. Thus, they allow for reconstructions of both sea surface and deepwater temperatures. However, the $\delta^{18}\text{O}$ signal of some species is offset from predicted equilibrium values by secondary effects related to cell biology, often referred to as vital effects. Several paleotemperature equations have been established for foraminiferal $\delta^{18}\text{O}$, based on calibrations from core-tops (Shackleton, 1974; Ganssen and Kroon, 2000) and laboratory cultures (Erez and Luz, 1983). They fit the polynomial form of equation (5)

$$T = a + b(\delta^{18}\text{O}_{\text{Calcite}} - \delta^{18}\text{O}_{\text{Water}}) + c(\delta^{18}\text{O}_{\text{Calcite}} - \delta^{18}\text{O}_{\text{Water}})^2 \quad (5)$$

Where T = temperature in $^\circ\text{C}$, a = temperature when $\delta^{18}\text{O}_{\text{calcite}} - \delta^{18}\text{O}_{\text{water}} = 0$, b is the slope, and c is the second order polynomial value. Shackleton’s equation (Equation (6)), for example, predicts a 0.23‰ decrease with reference to PDB (= Pee Dee Belemnite calcite) standard in $\delta^{18}\text{O}$ per 1°C increase.

$$T = 16.9 - 4.38(\delta^{18}\text{O}_{\text{Calcite}} - \delta^{18}\text{O}_{\text{Water}}) + 0.1(\delta^{18}\text{O}_{\text{Calcite}} - \delta^{18}\text{O}_{\text{Water}})^2 \quad (6)$$

Measurements of $\delta^{18}\text{O}$ by mass spectrometry are analytically highly precise, yielding an error smaller than 0.1‰ , which would translate into a temperature error as small as $< 0.4\text{--}0.5^\circ\text{C}$, if only temperature was involved. Because $\delta^{18}\text{O}$ in carbonates reflects both temperature fractionation and the $\delta^{18}\text{O}$ of ambient seawater where the carbonate has been precipitated, changes in seawater $\delta^{18}\text{O}$ over time also need to be considered. The global “ice volume effect” depends on the amount of ice accumulated on continents during the time under discussion. Where this ice volume effect is known, the portion of temperature-related fractionation in a $\delta^{18}\text{O}$ carbonate value can be identified.

In addition, $\delta^{18}\text{O}$ values in the ocean vary regionally with changes in the evaporation–precipitation balance, and locally with river and meltwater runoff. Since this “water mass effect” is difficult to assess in past ocean scenarios, it introduces a major portion of uncertainty into paleotemperature estimates from $\delta^{18}\text{O}$. Spatial and temporal variations of seawater $\delta^{18}\text{O}$ thus limit the use $\delta^{18}\text{O}$ in carbonates as a temperature proxy.

However, $\delta^{18}\text{O}$ is still widely used to estimate temperatures of warm climates in the absence of major ice sheets and low-to-high-latitude climatic gradients much smoother than in the Pleistocene; for example, for early Paleogene and Cretaceous times.

In these sediment records, the impact of diagenetic alteration on $\delta^{18}\text{O}$ may have been significant. Pearson et al. (2001) demonstrated from well-preserved planktonic foraminifera that low-latitude SSTs during the Late Cretaceous and Eocene epochs were as warm as 28–32 °C rather than 15–23 °C, as previously estimated. Their study also revealed a strong impact of diagenetic alteration on $\delta^{18}\text{O}$ of old fossil carbonates.

Since many sites in the Southern Ocean contain virtually no carbonate, the use of $\delta^{18}\text{O}$ from diatoms (marine algae bearing opal shells) has also been tested. Unfortunately, the systematics of oxygen isotopes in opal appears to be considerably more complex than for carbonates (Juillet-Leclerc and Labeyrie, 1986; Shemesh et al., 1992).

An innovative stable isotope approach currently under investigation is $\delta^{44}\text{Ca}$, based on the temperature-related fractionation between ^{44}Ca and ^{40}Ca isotopes. Note that the fractionation of Ca isotopes is inverse to that of oxygen isotopes. In culturing experiments with the planktonic foraminifer *Globigerinoides sacculifer*, a 1 °C increase in temperature resulted in a 0.24% increase of $\delta^{44}\text{Ca}$ (Näglér et al., 2000).

Magnesium-calcium ratio

In the ocean, magnesium may largely behave as a conservative tracer. This means that it occurs in a fixed ratio to calcium, displaying a long residence time. This concept, however, has been questioned by Martin et al. (2002), who suggested some glacial-to-interglacial changes in the oceanic Mg balance.

In calcite shells of planktonic foraminifera, this trace element occurs at very low concentrations (about 0.5–5 mmol mol⁻¹), being directly incorporated during calcite precipitation. Cronblad

and Malmgren (1981) published the first study on Quaternary climate cycles based on Mg in planktonic foraminifera. Newly developed high-precision analytical devices (Atomic Absorption Spectrophotometry (AAS); Inductively Coupled Plasma Spectrometry (ICP-MS; ICP-AS; ICP-AES)) facilitated high-precision Mg/Ca analyses of foraminiferal calcite and permitted its potential as a quantitative paleotemperature indicator to be explored. Precise measurements require a complex cleaning process of foraminifera shells, including physical and chemical steps where extraneous phases of Mg are removed, but the Mg content of the shells must not be affected.

The underlying concept for using Mg/Ca as a temperature proxy is based on the endothermic substitution of Mg in calcite, favoring the Mg substitution at higher temperatures. This relationship is not linear but underlies an exponential function. For inorganic calcite precipitates, the van't Hoff equation predicts an exponential Mg/Ca increase by 3% per degree Celsius. Foraminifera shells in general contain 5–10 times less Mg than inorganic calcite precipitates from seawater. The reason for this shift is still unknown. Possibly, lower Mg or higher Ca somehow is favorable for the internal-cell carbon cycle. On the other hand, foraminifera show a stronger response of shell Mg (on average, 9% increase in Mg per degree centigrade Celsius) to temperature than predicted by thermodynamics (Figure O25; Lea et al., 1999). This makes the Mg/Ca ratio of both planktonic and benthic foraminifera shells a very sensitive tool for reconstructing surface and deep-water temperatures.

The Mg substitution in calcite is different for the different foraminifera species, which necessitates a temperature calibration of each single species. Calibrations based on cultured

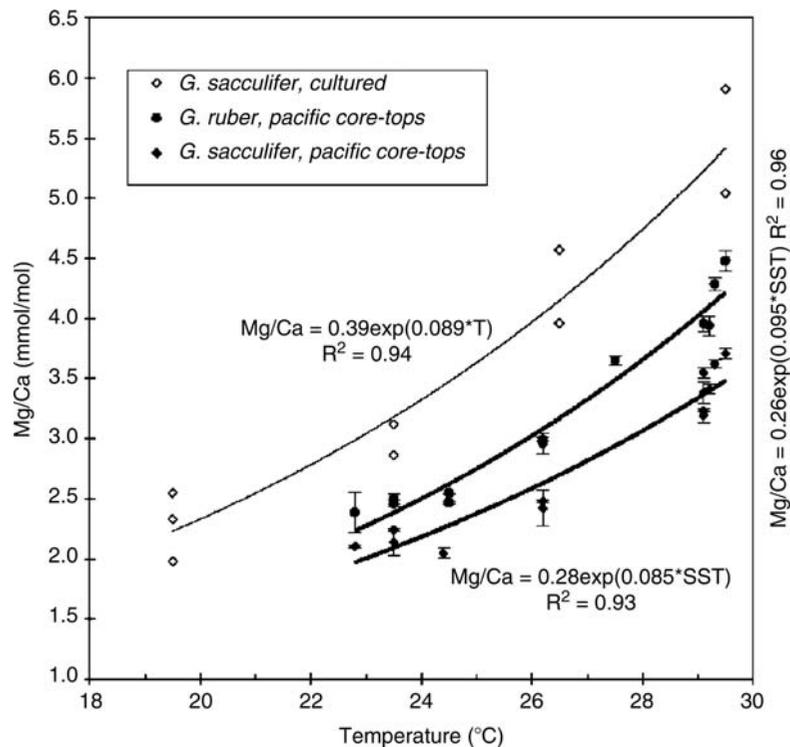

Figure O25 Comparison of exponential fits of Mg/Ca in planktonic foraminifera with temperature from cultured and core top planktonic foraminifera (from Lea et al., 1999).

planktonic foraminifera under controlled temperature conditions and from core tops fit equations of the form

$$\text{Mg/Ca}(\text{mmol mol}^{-1}) = b \cdot e^{mT} \quad (7)$$

where b is the pre-exponential constant (relevant for the absolute temperature, m the exponential constant (relevant for the temperature difference) and T is the temperature (Lea et al., 1999) (Equation (7)). Parallel Mg/Ca measurements on different planktonic foraminifera species that calcify their shells preferentially at different water depths may be used to reconstruct vertical temperature profiles of the water column according to calcification depth.

It is generally more difficult to assess the temperature of cold deep-water masses than warm temperature masses because temperature differences in deep-water masses are generally small. Moreover, the calibration of the slope between temperature and Mg/Ca is still quite uncertain near its “cold end.” To address questions on the evolution of deep-water temperatures, still more precise calibrations of benthic species are required (Martin et al., 2002). Nevertheless, the potential of Mg/Ca in benthic foraminifera has been demonstrated in a recent study of Lear et al. (2000). They suggested an ocean-wide gradual decrease in deep-water temperature of 12 °C over Cenozoic times on the basis of a mixed benthic Mg/Ca record (Figure O26).

Apart from foraminifera, ostracods have also proven useful indicators for bottom water temperatures (Dwyer et al., 1995; Cronin et al., 1996). As opposed to foraminifera, ostracod Mg/Ca ratios are fitted to temperatures through a linear relationship. Dwyer et al. (1995) revealed that a temperature drop of 3 °C in the deep North Atlantic Ocean occurred together with major Northern Hemisphere glaciation during the late Pliocene.

Differential dissolution results in an unwelcome secondary effect on Mg/Ca ratios in carbonate shells because Mg is preferentially removed from the shells, thus falsely suggesting cold paleotemperatures. A major complication arises from the fact that foraminifera shells are composed of carbonate layers containing different Mg concentrations, which are differentially susceptible to dissolution. Also salinity, pH, and, in the long term, changes in the marine Mg reservoir may affect Mg/Ca ratio.

Strontium represents a further trace element with potential for temperature reconstructions, yet has been little exploited

(especially in coral records). Its distribution in planktonic foraminifera is much more uniform (1.2–1.6 mmol mol⁻¹) than Mg, with a slope of approximately 5% per 1 °C.

Long-chain alkenones

Apart from shells, organic remains of marine plankton are also preserved in marine sediments. Proxies based on the composition of organic matter are particularly useful for sediments barren of carbonate, which occur below the carbonate compensation depth. Biomarkers are organic substances in the sediment that preserve sufficient structural characteristics to allow for conclusions on the original biogenic compound, even when modified. Lipids in the cell membranes of phytoplankton may vary in response to environmental stress in molecular chain length and unsaturation and thus record a paleotemperature signal. Notably, unsaturated long-chain ketones (= alkenones) shows a distinct dependency on growth temperature. Alkenones are produced by a few phytoplankton species belonging to the class of Prymnesiophyceae; in Late Quaternary sediments, they are mostly produced by the Coccolithophorid *Emiliana huxleyi*. Their physiological function in the living cells still is unknown, yet it is suspected that the increasing alkenone unsaturation with cooler temperatures compensates for increasing viscosity of the cell membrane (Prahl and Wakeham, 1987). With decreasing temperature, the concentration of 3-fold unsaturated (C37:3) and 4-fold unsaturated (C37:4) alkenones increases. Unsaturation of alkenones is measured by gas chromatography peak area integration. Unsaturation indices U_{37}^k and $U_{37}^{k'}$ (Equations (8) and (9)) express the ratio of (C37:4) (C37:3), and (C37:2) ketones or between 3- and 2-fold unsaturated (C:37) ketones.

$$U_{37}^k = [\text{C37:2}] - [\text{C37:4}] / [\text{C37:2} + \text{C37:3} + \text{C37:4}] \quad (8)$$

$$U_{37}^{k'} = [\text{C37:2}] / [\text{C37:2} + \text{C37:3}] \quad (9)$$

Indeed, the unsaturation indices adopt high values in low latitude warm waters and low values in high latitude cold waters. The role of 4-fold unsaturated alkenones, which only occur at high latitudes, is still debated. Some authors suspect that they are related to low salinity rather than to low SST. Calibrations of the U_{37}^k index versus growth temperature have been

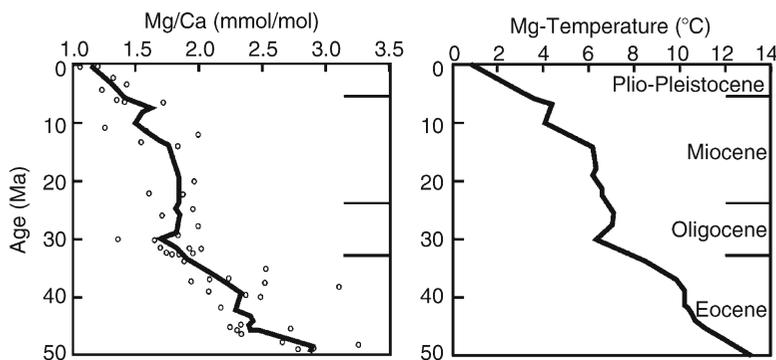

Figure O26 Gradual decrease of bottom water temperatures over Cenozoic times as deduced from Mg/Ca of mixed benthic foraminifera species (Lear et al., 2000).

established based on culturing experiments (Prahl and Wakeham, 1987; Prahl et al., 1988), particulate organic matter from sediment trap samples obtained in the water column (Herbert, 2001), and sediment surface samples (Müller et al., 1998). The calibrations generally fit linear regressions of U_{37}^k with temperature in the form of the example (Equation (10)) by Müller et al.

$$U_{37}^k = 0.033\text{SST} + 0.044 \quad (10)$$

The global calibration of core top samples by Müller et al. (1998) covers the ocean with 456 samples between 60° N and 60° S and a temperature range of 1–29 °C (Figure O27; Equation (10)). The regression does not significantly differ from that obtained by Prahl et al. (1988, 1993) based on culturing experiments. The best overall fit has been shown for average annual temperatures at 10 m water depth (Müller et al., 1998). However, growth depth may vary regionally, as shown for the subtropical gyres, where coccolithophorids tend to live in deeper layers (references in Herbert, 2001).

Strictly speaking, these calibrations are valid for the Late Pleistocene back to 250,000 yBP, when *Emiliana huxleyi* made its first appearance in marine sediments. However, alkenones produced earlier by other Prymnesiophyts may have preserved a comparable temperature signal. Herbert and Schuffert (1998) analyzed alkenones in Miocene to Pliocene samples from ODP site 958 and found a 5 °C temperature drop off Northwest Africa in the Late Pliocene. They argued that as long as alkenones performed a similar (though as yet unknown) biological function, calibrations established for the Late Pleistocene should similarly apply to older alkenone records. Recently, alkenones were also identified in Lower Cretaceous sediments, representing the oldest records of these compounds (Brassell and Dumitescu, 2003).

Summary

As a primary expression of the Earth is past climatic stages, paleotemperatures are a central issue in paleoceanography. Most concepts used to reconstruct ocean paleotemperatures rely on marine microfossils, either on plankton assemblages or on the isotopic or trace metal composition of carbonate shells. Table O1 summarizes the main approaches currently used in paleoceanography to reconstruct paleotemperatures.

Mara Weinelt

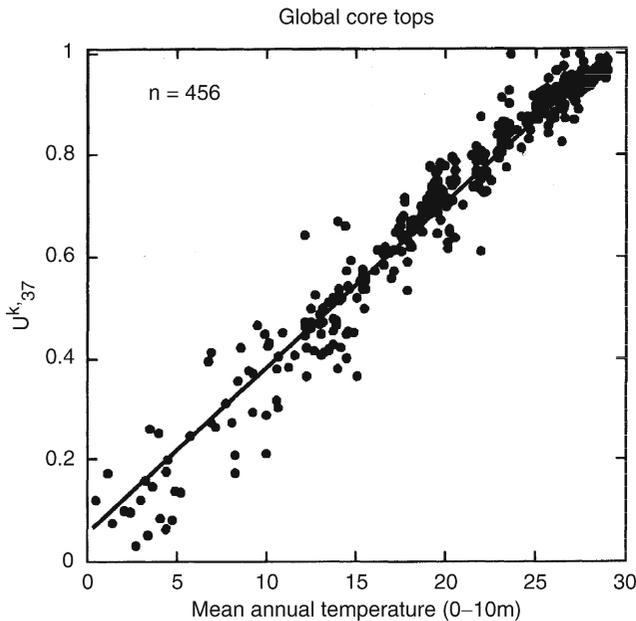

Figure O27 Global calibration of U_{37}^k index versus temperature by Müller et al. (1998).

Table O1 Summary of main approaches currently used to reconstruct ocean paleotemperatures and environment and time period where they are applicable

Approach/method	Reconstruction of	Applicable time
Transfer functions based on plankton assemblages		
I&K method	SST	500,000–700,000 yBP
MAT/SIMMAX/RAM	SST	500,000–700,000 yBP
ANN	SST	500,000–700,000 yBP
Long-chain alkenone Unsaturation indices $\delta^{18}\text{O}$	SST	250,000 yBP Neogene/Cretaceous?
Planktonic foraminifera	Temperature of upper water column (depending on calcification depth of single species)	Lower Cretaceous to present
Siliceous microfossils Benthic foraminifera	SST Deep-water temperature	Unlimited, where $\delta^{18}\text{O}$ of seawater can be assessed
Mg/Ca Planktonic foraminifera	Temperature of upper water column (depending on calcification depth of single species)	Lower Cretaceous to present
Benthic foraminifera Ostracods Reef corals	Deep-water temperature Deep-water temperature	In principle, unlimited In principle, unlimited
Sr/Ca $\delta^{18}\text{O}$	Tropical shallow water temperatures Tropical shallow water temperatures	Historical times, in particular Historical times, in particular

ORGANIC GEOCHEMICAL PROXIES

Introduction

Organic matter is produced principally by photosynthetic plants, bacteria, and archaea. The amounts and kinds of lipids, carbohydrates, proteins and other biochemical components have varied as the amounts and kinds of plants and microbes have changed over time. Incorporation of organic matter into the sediments of lakes and oceans, which are nature's archives, typically blends components from many sources. Biochemical components of biota are altered to become the geochemical constituents of sediments, first by metabolic utilization by microbes and other biota and later by oxidation-reduction processes. Despite these very early diagenetic changes, sedimentary organic matter retains important information about its origins, and it provides equally important information about how it was delivered and deposited.

Different environments support different biological communities, with the result that geochemical components indicative of changes in the communities exist in sediment horizons deposited at different times. These proxies of paleoclimatic, paleolimnologic, and paleoceanographic histories are provided by the elemental, isotopic, and molecular compositions of sedimentary organic matter.

Organic matter C/N ratios

The proportions of sedimentary organic matter that originate from aquatic as opposed to land sources can be distinguished from compositional differences between algae and vascular land plants. Fresh organic matter from aquatic algae is protein-rich and cellulose-poor and yields molar C/N values that are commonly between 4 and 9. Vascular land plants, which are protein-poor and cellulose-rich, create organic matter that usually has C/N ratios of 20 and greater.

Partial degradation of organic matter during early diagenesis sometimes modifies the initial elemental compositions and hence C/N ratios of organic matter in sediments. C/N ratios of fresh wood samples are generally higher than those of wood that has been buried in sediments (Meyers et al., 1995). This change reflects selective degradation of carbon-rich sugars and lipids in the buried wood. In contrast, the C/N ratio of algal organic matter can increase during sinking and early sedimentation as nitrogen-rich proteins are selectively degraded. When diagenetically

elevated C/N ratios of marine organic matter are found in sediment records, they imply periods of enhanced aquatic paleoproductivity, such as occur in oceanic upwelling systems (Twichell et al., 2002). In most depositional settings, changes in the elemental composition of sedimentary organic matter are minor and do not erase the distinctive C/N differences between the organic matter derived from aquatic algae and land plants.

Organic matter stable isotopic compositions

The carbon and nitrogen stable isotopic compositions of bulk sedimentary organic matter are widely used to reconstruct paleoenvironmental conditions by assessing sources of organic matter in sediment records and past changes in the availability of nutrients in the surface waters of lakes and oceans.

Organic $\delta^{13}\text{C}$ values

Carbon isotopic ratios are useful to distinguish between marine and continental plant sources of sedimentary organic matter and to identify organic matter from different types of land plants. The carbon isotopic compositions of organic matter reflect principally the dynamics of photosynthetic carbon assimilation and the $^{13}\text{C}/^{12}\text{C}$ ratio of the carbon source. Most plants assimilate carbon using the C_3 pathway, which discriminates against ^{13}C to produce a $\delta^{13}\text{C}$ shift of about -20‰ from the source isotopic composition. Some plants use the C_4 pathway, which creates an isotope shift of about -7‰ . All C_4 plants are specialized for warm, dry, land environments.

The distinctive $\delta^{13}\text{C}$ values of C_3 and C_4 plants can be combined with the characteristic C/N values of algal and land-plant tissues to identify the major sources of organic matter in sediments (Figure O28, top). Deviations from the generalized $\delta^{13}\text{C}$ and C/N values occur, which represent natural variations in biochemical compositions, diagenetic modifications of initial compositions, or valuable evidence of paleoenvironmental changes.

The amount of inorganic carbon that is available for assimilation can affect the $\delta^{13}\text{C}$ values of photosynthesized organic matter. Periods of increased primary productivity in lakes and oceans are commonly recorded as increases in the $\delta^{13}\text{C}$ values of the organic matter that becomes buried in the sediment record. Production of algal organic matter selectively removes ^{12}C from photic zone dissolved inorganic carbon reservoirs. As availability of the inorganic carbon becomes less, the $^{13}\text{C}/^{12}\text{C}$ ratio of the remaining inorganic carbon increases and leads to less negative $\delta^{13}\text{C}$ values of subsequently produced organic matter. However, if inorganic carbon concentrations are elevated, then algal photosynthesis selectively assimilates ^{12}C from the replete carbon reservoir to produce organic matter with more negative $\delta^{13}\text{C}$ values. Cretaceous black shales, which record elevated algal production under a CO_2 -rich atmosphere and have $\delta^{13}\text{C}$ values of about -28‰ (Rau et al., 1987), are a classic example of this kind of environment.

$\delta^{15}\text{N}$ values

Nitrogen is a biolimiting nutrient in aquatic systems, and it has multiple oxidation states that have different isotopic compositions. The $\delta^{15}\text{N}$ values of sediment organic matter consequently reflect the paleoenvironmental processes that affect nitrogen biogeochemical cycling. The $\delta^{15}\text{N}$ value of the dissolved NO_3^- that is commonly assimilated by algae is typically $5\text{--}10\text{‰}$, whereas the value of atmospheric N_2 made accessible to land plants by nitrogen-fixing soil bacteria is about 0‰ . This isotopic difference

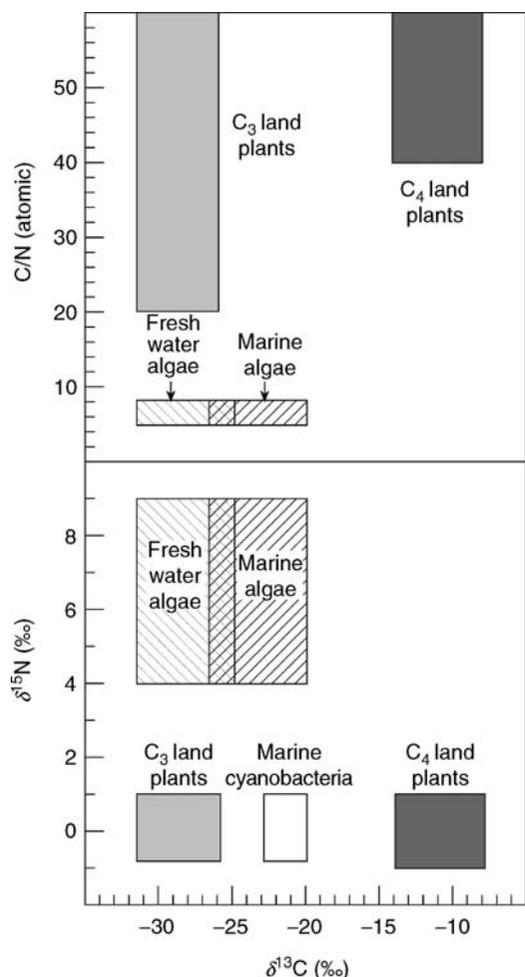

Figure O28 Generalized elemental and carbon isotopic (*top*) and nitrogen and carbon isotopic (*bottom*) compositions of organic matter from marine and freshwater algae, C₃ and C₄ land plants, and cyanobacteria.

is preserved in the $\delta^{15}\text{N}$ values of organic matter from algae and from land plants (Figure O28, *bottom*) because the limited availability of nitrogen discourages much isotopic discrimination.

Denitrification occurs during dysoxic conditions in lakes and oceans and strongly discriminates against ^{15}N to yield N_2 enriched in ^{14}N and residual nitrate enriched in ^{15}N . These conditions accompany the strong stratification that seasonally happens in many lakes and is a permanent feature of some oceanic areas. Subsequent uptake of the residual nitrate by algae leads to organic matter with high (12–14‰) $\delta^{15}\text{N}$ values in the sediment records of these settings. Conversely, good ventilation of the water column is recorded as relatively low (3–4‰) $\delta^{15}\text{N}$ values.

Nitrogen-fixing organisms such as cyanobacteria are autotrophs that convert dissolved N_2 to bioavailable NH_4^+ when anoxia exists within the photic zone of lakes and oceans. Their activity leads to lower $\delta^{15}\text{N}$ values in sedimented organic matter. Evidence of this special environmental condition exists in sediments deposited between 10 to 3.3 ka in Lake Bosumtwi, Ghana, where it records a period of strong stratification in this lake (Talbot and Johannessen, 1992). Suitable conditions for cyanobacterial activity also commonly occur in eutrophic lakes.

Sediments deposited in central Florida lakes display shifts to low (–1 to 3‰) $\delta^{15}\text{N}$ values as eutrophication of these lakes increased (Brenner et al., 1999). The remarkably low (–4 to 0‰) $\delta^{15}\text{N}$ values of Cretaceous black shales (Rau et al., 1987) and of Pliocene-Pleistocene sapropels in the Mediterranean Sea (Struck et al., 2001) imply strong salinity stratification of these marine settings and consequent enhancement of cyanobacterial primary production. As such, these sediment records indicate periods of wetter paleoclimatic conditions that were maintained for multi-thousand-year periods.

Sediment $\delta^{15}\text{N}$ values are also sometimes useful in reconstructing algal paleoproductivity histories, especially in lakes where phosphorus is often more biolimiting than nitrogen. In nitrogen-replete environments, biota discriminate in favor of ^{14}N , and sediment $\delta^{15}\text{N}$ values are relatively low. During times of amplified phosphorus delivery, either from human activities or from climate-enhanced weathering of regolith, increased algal utilization of bioavailable nitrogen and consequent decreased discrimination in favor of ^{14}N appear as shifts to larger $\delta^{15}\text{N}$ values in sediments (Meyers and Lallier-Vergès, 1999).

Biomarker molecules

Biomarker molecules are compounds that characterize biotic sources and that retain their source information after burial in sediments (Table O2). Biomarkers in sediments and rocks are usually diagenetically stabilized derivatives of specific precursor compounds, yet the carbon skeletons of the derived molecules preserve the source-distinctive structures of their precursor compounds. Although biomarkers typically constitute less than 1% of sediment organic matter, they yield important paleoenvironmental information that bulk organic geochemical proxies cannot provide.

Hydrocarbons

Because of their low susceptibility to microbial degradation relative to other types of organic matter, saturated hydrocarbons are generally robust recorders of the origins of organic matter in sediments. The hydrocarbon compositions of many aquatic algae and photosynthetic bacteria are dominated by the C₁₇ *n*-alkane (Cranwell et al., 1987). Vascular land plants contain large proportions of C₂₇, C₂₉, C₃₁, and C₃₃ *n*-alkanes in their waxy coatings, and the biomarker constitutions are indicative of different kinds of plants. The *n*-alkane distributions of grasses and herbs are dominated by C₃₁, birches by C₂₇, and most trees by C₂₉ (Schwark et al., 2002).

Fatty acids

Fatty acids in lake sediments typically originate from multiple sources. The *n*-C₁₆ and *n*-C₁₈ alkanolic and alkenolic acids are ubiquitous components of biota, whereas the even-chain C₂₄–C₃₀ *n*-alkanoic acids originate principally from the waxy coatings of land plants (Cranwell et al., 1987). The long-chain *n*-acid components of organic matter in sediments therefore represent transport of land-derived debris to the depositional setting. Unsaturated *n*-C₁₆ and *n*-C₁₈ acids are major constituents of the lipids of algae, yet they are rapidly degraded by microbes during and after sedimentation. The microbes contribute their own distinctive biomarker acids to the sediments. For example, *normal* and *anteiso* C₁₅ alkanolic acids have been used as indicators of microbial biomass in lake sediments (Goossens et al., 1989), and they represent *in situ* production of secondary lipids at the expense of primary organic matter.

Table O2 Examples of important biomarker molecules and their significance to organic geochemical reconstructions of paleoenvironmental and paleoclimatic histories

Biomarker molecules	Source/significance
Hydrocarbons	
C ₂₇ , C ₂₉ , C ₃₁ and C ₃₃ <i>n</i> -alkanes	Vascular land plant waxes; indicates land-plant organic matter contributions and community compositions
C ₁₅ and C ₁₇ <i>n</i> -alkanes	Aquatic algae; indicates aquatic organic matter
7- and 8-methyl-branched C ₁₇ alkanes	Cyanobacteria; indicates aquatic nitrogen fixation
Pristane	Phytol sidechain of chlorophyll; indicates zooplankton-based food chains
Phytane	Phytol sidechain of chlorophyll; methanogens; halophilic bacteria; indicates anoxic conditions
Botryococcane	Mat-forming freshwater alga <i>Botryococcus braunii</i>
Fichtelite	Conifer resins; indicates reducing depositional conditions
Retene	Conifer resins; indicates oxidizing depositional conditions
Fatty acids	
C ₂₄ , C ₂₆ , and C ₂₈ <i>n</i> -alkanoic acids	Vascular land plant waxes
Iso and anteiso branched acids	Bacteria; evidence of microbial organic matter
Fatty alcohols	
C ₂₄ , C ₂₆ , and C ₂₈ <i>n</i> -alkanols	Vascular land plant waxes
Alkenones	
C ₃₇ , C ₃₈ , and C ₃₉ alkenones	Marine haptophyte algae; proxies for sea surface paleotemperatures
Sterols and sterols	
Dinosterol and derivatives	Dinoflagellate-derived organic matter
4-methyl sterols	Dinoflagellate-derived organic matter
Brassicasterol	Diatom-derived organic matter
C ₂₉ sterols	Land-plant organic matter
C ₂₇ sterols	Marine or freshwater algal organic matter
Pigments	
Fucoxanthin, diadinoxanthin	Diatom-derived organic matter
Peridinin	Dinoflagellate-derived organic matter
Myxoxanthophyll, oscillaxanthin	Cyanobacteria; indicates aquatic nitrogen fixation
Isorenieratene derivatives	Green sulfur bacteria; anoxic conditions in photic zone
Lignin-derived phenols	
Cinnamyl/vanillyl ratio	Proportions of woody and non-woody land-plant tissues
Syringyl/vanillyl ratio	Proportions of gymnosperm and angiosperm land-plant organic matter

Unlike the shorter chain-length fatty acids, the longer chain-length ones survive in sediments and provide evidence of their plant origins.

Fatty alcohols

Fatty alcohols have source patterns roughly similar to those of fatty acids. Epicuticular waxes of land plants contain even-chain *n*-alkanols from C₂₂ to C₃₀ (Rieley et al., 1991). However, unlike fatty acids, *n*-alkanol distributions dominated by the C₁₆ to C₂₂ components generally indicate organic matter derived from aquatic algae and bacteria and not biota in general (Volkman et al., 1999). Individual species of plants can have distinctive chain-length patterns that deviate from these generalized distributions.

Alkenones

Long-chain (*n*-C₃₇, *n*-C₃₈, *n*-C₃₉) methyl and ethyl alkenones are distinctive biomarkers of marine coccolithophores. Their abundance in sedimentary records can be used as a paleoproductivity proxy for these algae, but their special usefulness is as paleotemperature proxies. Alkenone distributions usually consist of a series of homologs having a mixture of 1, 2, 3, and 4 double bonds that is temperature-sensitive. The algae produce proportionally more polyunsaturated homologs as water temperatures decrease in order to maintain cell-wall fluidity. Alkenones also appear in lake sediment records (Zink et al., 2001), but their utility as a paleoenvironmental proxy is not yet established because their origin is unknown.

Sterols and their derivatives

Sterol compositions distinguish aquatic contributions of organic matter in sediments from land-derived material. Cholesterol (C₂₇) is the dominant algal sterol, whereas β -sitosterol (C₂₉) is the major sterol in emergent water plants (Nishimura and Koyama, 1977). Land-plant leaf waxes contain C₂₈ and C₂₉ but not C₂₇ sterols (Rieley et al., 1991). Ternary plots of the C₂₇, C₂₈, and C₂₉ sterol compositions of algae, vascular plants, soils, and sediments identify ecological patterns (Huang and Meinschein, 1979) that can be applied to paleoenvironmental interpretations. Specific sterols are particularly useful to paleoenvironmental reconstructions. Stronger wind-induced upwelling is indicated from increased amounts of dinosterol and C₂₇ + C₂₈ 4-methylsterols, which are dinoflagellate biomarkers, in glacial-age sediments in the equatorial Pacific (Prah et al., 1989).

Pigments

Plants have evolved a variety of photosynthetic pigments that can serve as biomarkers. Chlorophyll *a*, the most common pigment, is non-specific, but aquatic plants and microbes produce distinctive secondary pigments (Table O2) that facilitate photosynthesis in water. Human-induced eutrophication of Esthwaite Water in the English Lake District is recorded as progressive increases in the concentrations of myxoxanthophyll and oscillaxanthin, two carotenoids indicative of cyanophytes and hence conditions of elevated lake productivity (Griffiths, 1978). Climate-induced strong surface stratification of the Mediterranean Sea during times of Pliocene sapropel formation is implied by

isorenieratene derivatives in the sapropel layers but not outside them (Passier et al., 1999). Isorenieratene is a carotenoid that is diagnostic for green sulfur bacteria, which are photosynthetic obligate anaerobes, and their presence means that a near-surface anoxic zone intruded into the photic zone.

Lignin derivatives

Lignins are phenolic polymers that are synthesized by higher plants to construct parts of their vascular and structural systems. Nearly all vascular plants grow on land, and therefore the lignin fraction of sediment organic matter largely records the contribution and preservation of land-plant materials. Gymnosperms and angiosperms synthesize distinctive types of lignin components. Past changes in continental vegetation can therefore be inferred from the kinds of lignin found in sediment records. Molecular analysis of lignin typically begins with an aggressive oxidation step to break down the biopolymer into various phenolic monomeric fragments. The oxidation fragments of lignin have been grouped by Hedges and Mann (1979) as a guide to identifying their plant sources (Table O2). A measure of the relative contributions of woody and non-woody land-plant tissues is given by the C/V (cinnamyl/vanillyl) ratio, which is the sum of *p*-coumaric acid plus ferulic acid concentrations divided by the sum of the three vanillyl phenols. Gymnosperm sources of land-plant residues are distinguished from angiosperm sources by the S/V (syringyl/vanillyl) ratio, which is the sum of the amounts of the three syringyl phenols divided by the sum of the vanillyl phenols.

Compound-specific isotopic compositions

Isotopic analysis of individual biomarker compounds provides a powerful source of paleoclimatic and paleoenvironmental information. Compound-specific stable isotope analysis improves identification of the biological origin of specific components within the complex mixture of materials that constitutes sediment organic matter.

Compound-specific $\delta^{13}\text{C}$ values

Studies of the $\delta^{13}\text{C}$ values of biomarkers have been especially important in tracing the evolution of C_4 plants. A shift to less negative $\delta^{13}\text{C}$ values of individual plant-wax C_{27} to C_{33} *n*-alkanes and C_{24} to C_{30} *n*-alkanols enabled Freeman and Colarusso (2001) to identify a dramatic expansion of C_4 vegetation on the Indian subcontinent between 8 and 6 Ma that has persisted to modern times. This paleoecological change reflects uplift of the Tibetan Plateau and associated growth of regional aridity.

The distinctive isotopic compositions of biomarkers from C_3 and C_4 plants also trace Holocene environmental changes. Sediments of Lake Baikal, Siberia, exhibit a 3‰ shift to more negative bulk organic matter $\delta^{13}\text{C}$ values that might record a shift from glacial-age C_4 to post-glacial C_3 plants. Brincat et al. (2000) show from $\delta^{13}\text{C}$ values of individual C_{27} to C_{31} *n*-alkanes in the sediment record that C_3 plants have remained the dominant vegetation throughout this period. Instead of recording a floral transition, the bulk organic carbon isotopic shift indicates increased fluvial delivery of isotopically light soil-derived carbon to the lake in response to a change to locally wetter post-glacial climate.

Applications of multiple biomarker compound-specific carbon isotopic measurements are especially fruitful for detailed paleoenvironmental reconstructions. Filley et al. (2001) utilize the $\delta^{13}\text{C}$ values of biomarkers from vascular plants (lignin

derivatives, C_{29} and C_{31} *n*-alkanes, C_{26} *n*-alkanol), cyanobacteria (7- and 8-methylheptadecanes), and phytoplankton (C_{17} *n*-alkane) to reconstruct the delivery of sedimentary organic matter in Mud Lake, Florida, over the past five millennia. Originally a land-plant dominated marsh, the lake evolved into a cyanobacteria-dominated system as the regional climate became more humid and the local water table rose.

Compound-specific δD values

Because the hydrogen in most organic matter originates from water, the D/H ratio in aquatic biomarker compounds is a sensitive paleohydrologic proxy. The δD of lake water can be reconstructed within 10‰ from the D/H ratios of sterols derived from phytoplankton (Sauer et al., 2001). The D/H ratios of the C_{23} *n*-alkane that is a biomarker for *Sphagnum* were used by Xie et al. (2000) to reconstruct a multi-century paleoclimatic record for Bolton Fell Moss, Cumbria, England. The δD values increase during times of warmer climate and decrease when climate was cooler as rates of evaporative distillation of bog waters increased or decreased. Similarly, Huang et al. (2002) employed δD variations in *n*-hexadecanoic acid, which is produced principally by lake algae, to reconstruct the post-glacial temperature record preserved in the sediments of Crooked Pond, Massachusetts.

Summary

Sediment organic matter provides a variety of elemental, isotopic, and molecular proxies to reconstruct past climates and ancient environments. C/N ratios identify the general origin of organic matter from aquatic or land plants. Bulk and compound-specific $\delta^{13}\text{C}$ values distinguish proportions of C_3 and C_4 plant organic matter and thereby identify periods of dry climate. Nitrogen cycling is sensitive to various environmental conditions that leave distinctive impacts on $\delta^{15}\text{N}$ values. Biomarker molecules identify organic matter contributions from specific sources, which record different environmental settings, and they provide information about depositional conditions from their alterations from precursor compounds.

OSTRACODES*

Introduction

Ostracodes (also ostracods, Ostracoda) are a class of bivalved, aquatic Crustacea that secrete a small (0.1 to > 2-mm long) calcitic shell (the carapace) that is commonly fossilized. Ostracodes are used widely in paleoclimatology and the reconstruction of marine and non-marine paleoenvironments because of their small size, ecological sensitivity, well-known biology and shell chemistry, long stratigraphic range (Ordovician-present), and occurrence in sediments from lakes, estuaries, bays, and oceans.

There are an estimated 33,000 described living and extinct ostracode species divided into two subclasses, the Myodocopa and Podocopa, and 10 orders distinguished from one another on the basis of appendages and carapace features such as size, shape, muscle scar pattern, pore patterns, and hinge structure. Many Myodocopids are pelagic in habitat; some are non-calcitic and are rarely fossilized. The Podocopa includes the order Podocopida, (Figures O29 and O30), which are the most commonly fossilized ostracode group and the most applicable to paleoclimatology.

Morphology and ecology

The carapace consists of two valves articulated along the dorsal margin, encompasses the living animal, and forms part of the organism's cuticle, which is secreted by the epidermis. Ostracodes grow by molting (ecdysis), during which podocopids produce 8–9 molts or instars. Both adult and juvenile carapaces and valves are commonly fossilized. Most ostracode genera and species can be identified on the basis of external and internal carapace features, although examination of soft parts is necessary to identify species in some groups and recent genetic studies have added considerably to understanding ostracode taxonomy.

Most species are free-living (either benthonic or pelagic), move by crawling or swimming, reproduce sexually (a few are parthenogenic), and disperse passively (there is no planktonic larval stage). They inhabit a full range of aquatic environments from small ephemeral pools of water, groundwater, to all types of lakes, estuaries, bays, rivers, and oceanic environments. Species are adapted to specific microhabitat conditions and physical and chemical factors controlling species distribution include temperature, salinity, light availability, solute chemistry, alkalinity, oxygen and carbon dioxide levels, and food resources.

Application to paleoclimatology and paleoenvironments

The ecological sensitivity of living species has made ostracodes useful for paleoenvironmental reconstruction since the nineteenth Century, especially in studies of Quaternary sediments where living species are often found as fossils. Quantitative analyses of faunal assemblages and indicator species have been used extensively to reconstruct water solute composition and regional atmospheric conditions in lakes, salinity and submerged aquatic vegetation in estuaries, ocean temperatures on continental shelves, dissolved oxygen on continental slopes, and deep water masses in abyssal environments.

During the past decade, the application of ostracode shell chemistry to contemporary issues surrounding climate variability has accelerated rapidly, especially in paleolimnology

because ostracodes are usually the only calcitic microfossil group. With greatly improved understanding of the factors that control the trace element (magnesium/calcium, strontium/calcium ratios) and stable isotopic (oxygen and carbon) composition of the carapace, ostracode researchers have been able to quantify temporal changes in lake and ocean temperature, atmospheric temperature and precipitation, estuarine and bay salinity, and other climate-related parameters (see review papers in Holmes and Chivas, 2002). For example, in semi-arid to subhumid, hydrologically-closed lakes, precipitation

influences the salinity, solute chemistry and $^{18}\text{O}/^{16}\text{O}$ ratios of the water. Chivas et al. (1993) applied these relationships to infer salinity and evaporation changes in Lake Keilambete, Australia during the late Quaternary using a $\delta^{18}\text{O}$ isotopic record and Sr/Ca ratios for several ostracode species. In deep lakes, ostracode shell chemistry can provide a record of atmospheric temperature. Von Grafenstein et al. (1999) reconstructed decadal scale changes in atmospheric temperature from the $\delta^{18}\text{O}$ record of *Candona* from the Ammersee, Germany for the important glacial, deglacial and Holocene

Figure O30 Scanning electron photo of deep sea ostracode *Bradleya*. Left valve, 1.0 mm long.

interval, and showed a remarkable correspondence to the paleotemperature record from Greenland ice cores. Wansard (1996) also reconstructed summer temperatures from Lake Banyoles, Spain for the interval 30,000–6,000 years ago using Mg/Ca ratios in *Cyprideis*.

Ostracode shell chemistry has also been applied to shallow water paleoclimate records. In the Gulf of Carpentaria, northern Australia, DeDecker et al. (1988) reconstructed the late Quaternary salinity changes caused by changing sea level from Mg/Ca, Sr/Ca and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of *Cyprideis*. Dwyer et al. (2001) showed that salinity influences Mg/Ca ratios in Florida Bay, which allowed them to reconstruct paleosalinity history controlled by climate processes such as the El Niño–Southern Oscillation. In Chesapeake Bay, eastern North America, water temperature controls the Mg/Ca ratios in *Loxoconcha* and Cronin et al. (2003) reconstructed a 2,200-year bay temperature record. In the deep sea, studies by Dwyer et al. (1995, 2000), Cronin et al. (2000), and Didié and Bauch (2002) provide evidence from ostracode shell chemistry for Pliocene and Quaternary variability in deep-sea temperatures, associating them with orbital and suborbital control of deep-water formation.

OUTWASH PLAINS

Outwash plains are extensive areas of glaciofluvial sediments deposited in the proglacial zone. They occur in topographically unconfined locations, such as the margins of ice sheets or piedmont glaciers, distinct from the valley trains or valley bottom deposits that occur in front of valley glaciers in confined settings. The Icelandic term “Sandur” (plural: Sandar) is often used.

Sediment is deposited primarily by braided meltwater streams that migrate across the surface of the outwash plain. The whole plain is rarely covered all at once except during extreme jökulhlaup floods. During floods, previously deposited sediments may be reworked and redeposited. Outwash deposits can retain sedimentological signatures of long periods of discharge from the glacier, making it possible to judge the relative significance of ablation dominated discharge and discharge related to extraordinary events such as subglacial volcanic eruptions as in Iceland. Outwash plains that are periodically inundated by floods exhibit distinctive sediment structures.

Outwash plains can aggrade to thicknesses of several hundred meters and bury the snout of the glacier from which the meltwater and sediment are derived. Melting of buried ice can then lead to the formation of kettles and pitted outwash surfaces, and rapid retreat of the ice margin can leave a distinctive ice-contact slope at the head of the outwash plain. Fluctuations in meltwater discharge or supply of sediment can cause changes in the rate of aggradation, and incision can occur creating terraces in the outwash surface.

Close to the glacier, sediments are often coarse grained and poorly sorted, with sub-angular clasts. Farther from the glacier sediments are characteristically finer grained and better sorted with more rounded clasts.

Sedimentary structures within the outwash can reveal details of flow regimes and sedimentary processes, can help to reconstruct paleodischarges, and can help to unravel the dynamic history of the glacier from which they are derived Benn and Erans (1998) provide a useful review of this topic.

OXYGEN ISOTOPES

Natural occurrence

Oxygen has three stable isotopes with atomic mass numbers of 16, 17, and 18 (^{16}O , ^{17}O and ^{18}O), which occur naturally in relative proportions of 99.76%, 0.04%, and 0.2%, respectively. Because ^{17}O and ^{18}O fractionate (to a first order) proportionally with respect to ^{16}O , and because of the very small abundance of ^{17}O , the isotopic ratio $^{18}\text{O}/^{16}\text{O}$ ($\sim 1/500$) is most commonly measured in water (e.g., groundwater, ice), carbonate sediments (CaCO_3), oxygen gas (O_2), carbon dioxide (CO_2), and organic matter, in which the $^{18}\text{O}/^{16}\text{O}$ ratio varies by more than 100%.

The $^{18}\text{O}/^{16}\text{O}$ ratio of a sample is measured by mass spectrometry on CO_2 or O_2 . The isotopic composition is usually expressed relative to a standard (which depends on the measured material) and expressed with the δ notation:

$$\delta^{18}\text{O} = \left[\frac{(^{18}\text{O}/^{16}\text{O})_{\text{Sample}}}{(^{18}\text{O}/^{16}\text{O})_{\text{Standard}}} - 1 \right] (\times 1,000, \text{ per mil}) \quad (1)$$

Atmospheric fractionation and local temperature control of the isotopic composition

Isotopic fractionation occurs during water evaporation and condensation (processes 1, 2 and 3 in Figure O31). At equilibrium, the $^{18}\text{O}/^{16}\text{O}$ ratio in the condensed phase (liquid or solid) is higher by approximately 10 per mil as compared to the vapor phase. In the hydrological cycle, water is mostly fractionated in the atmosphere during the net transport of vapor between low to high latitudes, ocean to continents, or low to high elevations, as a result of successive condensation–evaporation stages (Dansgaard, 1964). At each stage, the isotopic enrichment of the condensate depletes the remaining vapor in ^{18}O as compared to ^{16}O (Figure O32, and process 3 in Figure O31), and this results in more depleted precipitation at the next condensation stage. In this process of distillation, the isotopic depletion of the vapor is primarily related to its exhaustion (quantity of remaining vapor compared to the initial quantity). Multivariate analyses of the $^{18}\text{O}/^{16}\text{O}$ ratio in modern precipitation have shown that the main parameters controlling this depletion are the local temperature, the quantity of precipitation, the distance to the coast, and the elevation (Figure O33). The corresponding effects have been coined “temperature effect,” “amount effect,” “continental effect,” and “altitude

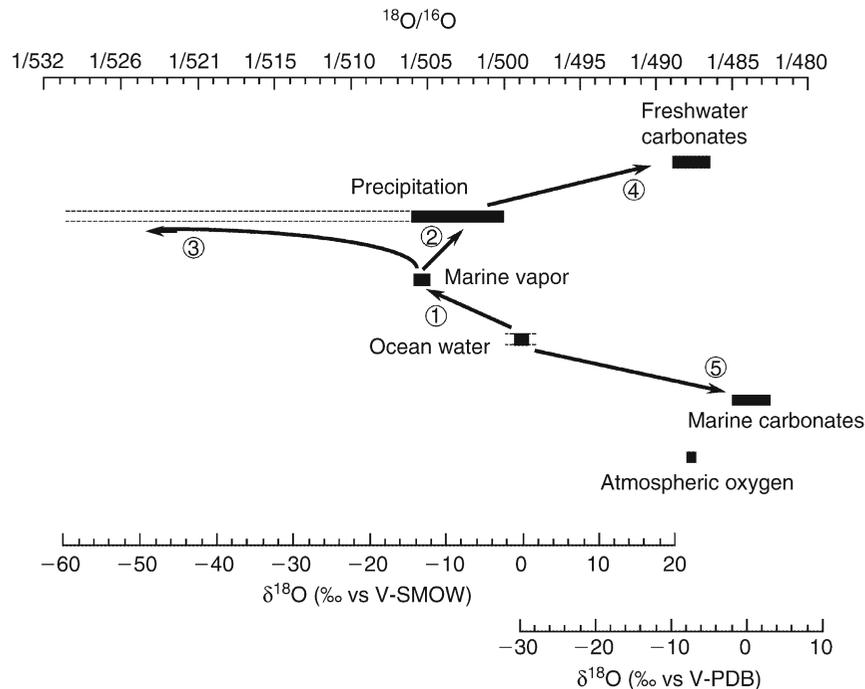

Figure O31 Range of the isotopic composition of oxygen at the surface, and relationships between the different compositions.

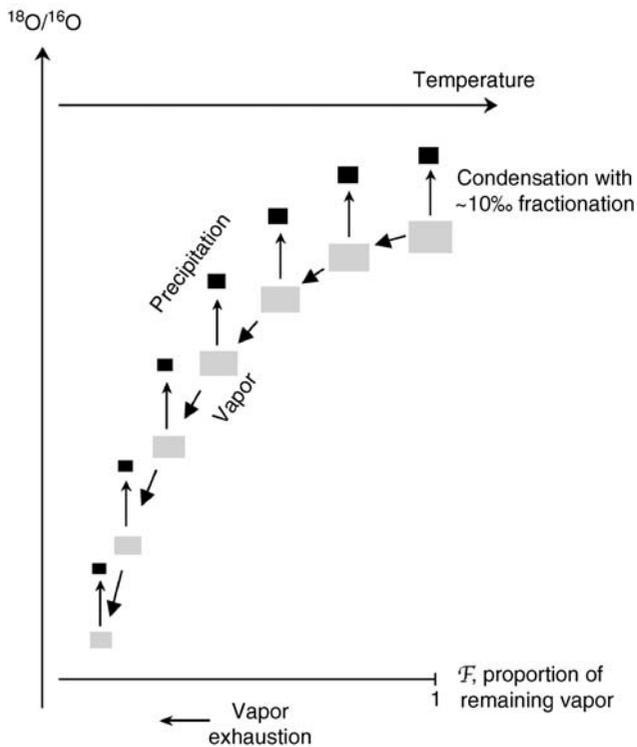

Figure O32 Isotopic evolution of a vapor mass, modeled as a Rayleigh-type distillation: an initial vapor mass is exhausted by successive condensation stages, for instance during an advection to higher latitude. At each stage, the $^{18}\text{O}/^{16}\text{O}$ ratio of the condensate is enriched by $\sim 10\text{‰}$ compared to the vapor ratio, which depletes the remaining vapor. F is the fraction of remaining vapor.

effect.” This isotopic depletion in the atmosphere determines the composition of the water reservoirs on the Earth, from the ocean to the cryosphere. See Mook (2001) for a thorough exposition of the environmental isotopes.

When minerals like carbonate, phosphate, and silica, which constitute sediments, form in water, their $^{18}\text{O}/^{16}\text{O}$ ratios are fractionated with respect to the water ratio, a fractionation mainly controlled by temperature (Epstein et al., 1953). Hence, fossil water, mainly ice and groundwater, as well as sediments, represent potential archives of information regarding past climates and environments.

Precipitation and the isotopic thermometer

The first primary standard for water was the Standard Mean Ocean Water (SMOW; Craig, 1961a,b). Because of problems with its definition, the International Atomic Energy Agency (IAEA) defined the Vienna Standard Mean Ocean Water (V-SMOW), with an isotopic composition very close to SMOW, and prepared in a large amount such that it is still distributed to laboratories today. Its absolute $^{18}\text{O}/^{16}\text{O}$ atomic ratio is $2,005.20 (\pm 0.45) \times 10^{-6}$ (Baertschi, 1976). This composition has been chosen to be very close to the oceanic composition. As such, most precipitation has a much lower $^{18}\text{O}/^{16}\text{O}$ ratio (Figure O31 and O33), and secondary, more depleted, standards are used for their measurements. IAEA now recommends that isotopic measurements on water be expressed with respect to V-SMOW, and normalized on a two-standard scale, V-SMOW and SLAP (Standard Light Antarctic Precipitation), assuming a value $\delta^{18}\text{O} = -55.5\text{‰}$ for SLAP (Coplen, 1995).

The usual measurement technique is to equilibrate a small amount of CO_2 gas with each water sample, and to determine the isotopic composition of this CO_2 by mass spectrometry. This technique requires only a few milliliters of water. The

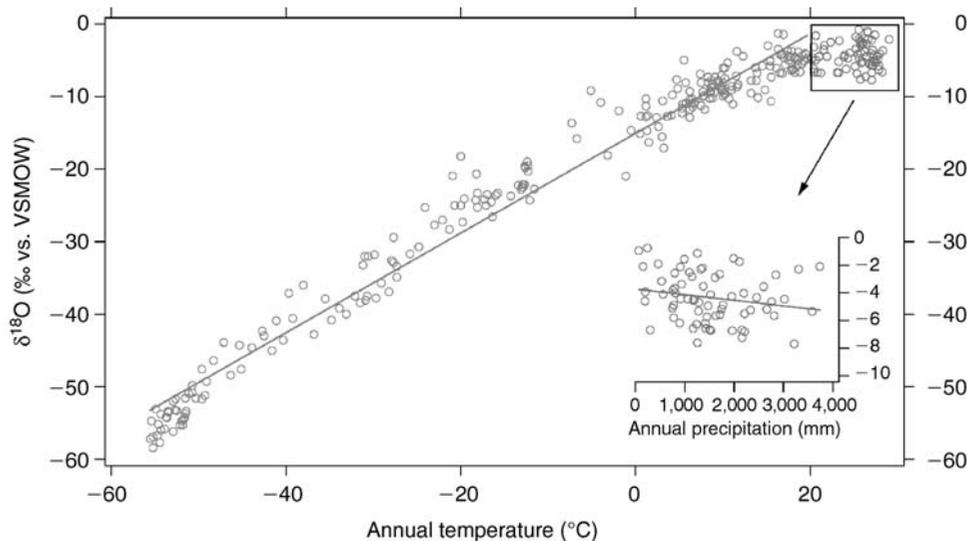

Figure O33 $\delta^{18}\text{O}$ – surface temperature relationship for modern precipitation (annual averages) (data from the GNIP network Rozanski et al., 1993), augmented by some polar data (cf. Figure O34). The linear correlation is calculated for points with an annual temperature $< 20^\circ\text{C}$ ($N = 243$ points, $r = 0.987$). The insert shows the annual $\delta^{18}\text{O}$ – precipitation relationship (“amount effect”) for stations with annual temperature $> 20^\circ\text{C}$.

sample composition is measured with respect to a reference sample, which has been previously calibrated against V-SMOW. Both samples are measured under the same conditions, so that a correction for the gas–water fractionation does not have to be applied. This technique usually achieves a precision better than 0.1‰, but with lower accuracy, as shown from interlaboratory comparisons organized by IAEA. Other techniques have been developed, like water hydrolysis and laser spectrometry.

The isotopic composition of precipitation is imprinted, more or less directly, in many continental records like glacier ice, snow, groundwaters, tree rings, freshwater carbonates, speleothems, etc. The discussion below focuses on ice, but may be extended in a similar way to the other archives (see below).

Isotopic measurements on precipitation have been shown to correlate strongly with surface temperature at mid-to-high latitudes, and with the amount of precipitation at low latitudes, the so-called “amount effect” (Figure O33; Dansgaard, 1964; Rozanski et al., 1993). The isotope–temperature relationship can be described with the vapor exhaustion, as shown by a simple distillation model (batch distillation, also called “Rayleigh distillation”: Figure O32; Dansgaard, 1964). The modeling of this relationship can be improved by considering other secondary parameters, like the proportion of different water phases in the clouds (vapor, liquid, and solid water), evaporation of the falling droplets (especially for the “amount effect”); and kinetic fractionation during the formation of snow (Jouzel and Merlivat, 1984).

The observed correlation between $\delta^{18}\text{O}$ and temperature (Figure O33) is strongest for annual means, and in polar regions (Figure O34). It is based on different stations, and thus a spatial gradient $\Delta\delta^{18}\text{O}/\Delta T$ is defined, where Δ is a variation over space. This gradient is traditionally used to interpret isotopic variations (e.g., in the ice) in terms of past temperature, and has been called the “isotopic paleothermometer” (Figure O34). Yet, a temporal gradient $\Delta\delta^{18}\text{O}/\Delta T$ must be used to interpret past isotopic variations, where Δ is a variation, at one location, over the timescale of the considered climatic variations. In recent years, estimates of temperature variations in Central Greenland

have been achieved independently of $\delta^{18}\text{O}$. They have shown that, over the last glacial period, the isotopic paleothermometer underestimates past temperature variations by a factor of two; that is, the temporal gradient is about half the spatial one (Cuffey et al., 1995; Jouzel, 1999). So far, there is no evidence for such a strong bias in East Antarctica records (Jouzel et al., 2003). The difficulty in interpreting past $\delta^{18}\text{O}$ variations thus consists in determining the relevant temporal $\delta^{18}\text{O}$ –temperature gradient, because a number of climatic parameters can cause this gradient to differ from the spatial gradient. Some of these parameters are briefly described below; a thorough review can be found in Jouzel et al. (1997).

The origin of the temperature–isotope relationship in precipitation has to be determined for each case. The $\delta^{18}\text{O}$ of the condensate is determined by both the vapor $\delta^{18}\text{O}$ and the local temperature at the condensation level, T_c . Over the year, temperatures at the surface (T_s) and at the condensation level (T_c) may well correlate during precipitation events, particularly in polar regions. For Antarctica, a linear relationship $T_c = 0.67 \times T_s - 1.2$ has been observed (Jouzel and Merlivat, 1984). This justifies the use of the surface temperature T_s , rather than T_c , in the paleothermometer, and alternatively may help explain some bias of this thermometer if the correlation between T_s and T_c has not held through climatic changes.

The $\delta^{18}\text{O}$ of the vapor, before condensation, mainly depends on the fraction of remaining vapor (f in Figure O32). To a first order approximation, as shown by simple modeling, this fraction is somehow determined by the difference between the temperature of the remote vapor source and the temperature at the location of precipitation. This is so because the temperature governs the quantity of vapor the air can hold (specific humidity). Thus, interpreting a $\delta^{18}\text{O}$ record in terms of local temperature changes only requires that the remote (source) temperature has remained constant in time. For instance, Aristarain et al. (1986) analyzed snow from the Antarctic Peninsula and showed that, given that the precipitation originates in the Southern Ocean, a covariation of the local and oceanic temperatures can explain a temporal gradient

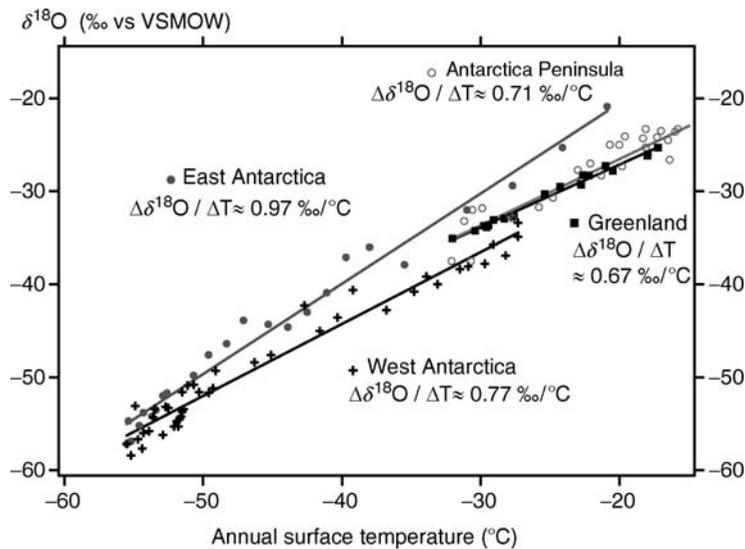

Figure O34 Isotopic paleothermometer for polar stations: data from Dahe et al. (1994) for Antarctica, and Johnsen et al. (1989) for Greenland.

$\Delta\delta^{18}\text{O}/\Delta T$ lower by a factor of two than that of the observed spatial slope. A way to check the temperature stability of the precipitation source is provided by the deuterium-excess, a second-order isotopic parameter measured in precipitation (Jouzel and Merlivat, 1984). To a first order, the isotopic composition of hydrogen in the water (δD , see *Deuterium, deuterium excess*) is linearly related to the composition of oxygen, $\delta^{18}\text{O}$, because both vary similarly with temperature; thus, combining $\delta^{18}\text{O}$ and δD gives access to other climatic parameters.

It is also important to consider that each isotopic measure from an archive results from the accumulation of many precipitation events, and is thus a weighted average, usually over several months or years. If the accumulation is not evenly distributed over the year, the temperature record may be biased towards one particular season. For Central Greenland, modeling studies have shown that the contribution of the warm season to the yearly accumulation may have been more important during glacial periods than today (Krinner et al., 1997). This would bias the glacial $\delta^{18}\text{O}$ signal towards warmer temperature, and may explain why the temporal gradient $\Delta\delta^{18}\text{O}/\Delta T$ is lower than the spatial gradient (cf. supra).

At low latitudes, the $\delta^{18}\text{O}$ depends less on temperature and more on the quantity of precipitation (Figure O33), which is called the “amount effect.” The isotopic signal may be interpreted in terms of hydrologic changes, especially in the monsoon area.

The isotopic record of carbonate sediments

Carbonate isotopic fractionation and the temperature scale

Carbonate is a widely distributed sediment, usually of biogenic origin, and for this reason it is also the most frequently used to retrieve a climatic signal routinely from the ^{18}O composition. The climatic interpretation of the carbonate $\delta^{18}\text{O}$ signal is based on the pioneering work done by Harold C. Urey, Samuel Epstein, Cesare Emiliani, and their colleagues at the University of Chicago. They developed the concept of paleothermometry, and defined the first isotopic reference, a belemnite from the Peedee formation in South Carolina, called PDB. The isotopic ratio is measured with a mass spectrometer directly on the CO_2 degassed by reaction with pure H_3PO_4 (McCrea, 1950). For PDB, this isotopic ratio is $2,067.2 \times 10^{-6}$ (Figure O31). From measurements of the isotopic fractionation between water and carbonate, they demonstrated the potential of fossil carbonate to record environmental parameters (Urey, 1947; McCrea, 1950), especially temperature: newly formed carbonate records the isotopic composition of the water, accounting for an isotopic fractionation that is temperature-dependent. Epstein et al. (1953) calibrated a temperature equation on living mollusks, based on the isotopic composition of the carbonate (δ_c) and of the water (δ_w):

$$t = 16.5 - 4.3 \times (\delta_c - \delta_w) + 0.14 \times (\delta_c - \delta_w)^2 \quad (2)$$

with t in $^\circ\text{C}$ and the δ in per mil with respect to VPDB. Applying this equation to a long marine record, Emiliani (1955) pioneered the use of $\delta^{18}\text{O}$ in paleoceanography. Due to a shortage in PDB, IAEA defined the Vienna Peedee Belemnite (V-PDB) reference with respect to the standard of the National Bureau of Standard NBS-19 as: $\delta^{18}\text{O}_{\text{NBS19}/\text{VPDB}} = -2.2\text{‰}$. The reference material currently distributed to laboratories is NBS-19.

Isotopic records and stratigraphy for the last million years

The paleotemperature equation (Equation 2) is applied to carbonate shells secreted by planktonic or benthic micro-organisms like foraminifera, coccolithophoridae, which are found in marine sediments retrieved by deep sea coring. It is also applied to other organic carbonate found in marine as well as freshwater environments, like corals, mollusks, etc. (Figure O31, processes 4 and 5), and to inorganic carbonates like speleothems. Comparison between inorganically and organically precipitated calcite has shown a fair agreement for the isotopic fractionation of oxygen, suggesting that, to a first order, organic carbonate precipitates close to equilibrium with the surrounding water. Yet, the temperature dependence of this fractionation (Equation 2) has been recalibrated several times on different species to account for small departures from equilibrium (Wefer and Berger, 1991; Bemis et al., 1998). This temperature dependence is approximately -0.25 per mil of δ_c per $^\circ\text{C}$, or -4 $^\circ\text{C}$ per mil of δ_c . Equation 2 also shows that, for a constant temperature, a 1 per mil variation of δ_w is equivalent to a 4 $^\circ\text{C}$ change. Over the last million years, which have been dominated by glacial cycles, both temperature and sea water composition have changed, with similar effects on the isotopic record. The marine glacial cooling of a few degrees has increased fractionation by around 1 per mil, while stocking up water in wide ice sheets has also enriched δ_w (and thus δ_c) by 1 per mil. This amplification of global climatic changes explains the similarity of isotopic records retrieved from different oceanic regions, which underlies the so-called oxygen isotope stratigraphy: periodic $\delta^{18}\text{O}$ up-and-downs are matched between records and numbered, with odd and even numbers corresponding to warm and cold periods, respectively (Figure O35). The SPECMAP group (Imbrie et al., 1984) compiled a global $\delta^{18}\text{O}$ signal by retaining the most significant excursions of different records. The final objective of SPECMAP was to produce a common temporal framework in order to date other records. The absolute dating of this framework has been a difficult task. Magnetic reversals detected in the sediments are widely used, the youngest one being the Brunhes-Matuyama about 780,000 years ago. Sea level markers like coral terraces are also used, since sea level variations are imprinted in the marine isotopic signal. Spectral analysis of the isotopic records have proved their origin in the variations of the Earth orbit (Hays et al., 1976), confirming the astronomical theory of glacial cycles. A dating technique derived from this confirmation, called “orbital tuning,” consists in tuning the age of a record to the orbital configurations, assuming some relationships between them.

The marine $\delta^{18}\text{O}$ signal: temperature and ice volume

The marine carbonates record both variations of water temperature and of water $\delta^{18}\text{O}$. The latter is conceptually divided into a global and a local component. The global component affects the quantity of ^{18}O of the ocean as a whole, on a timescale longer than the ocean mixing time so that it is expected to be homogeneous. This is due to fluctuations of the ice sheet volume, which extract or release isotopically depleted water from or to the oceans (Figure O31). On timescales longer than hundred million years, an imbalance in the ^{18}O oceanic budget is also possible (Lécuyer and Allemand, 1999). The local component affects the spatial distribution of ^{18}O . For the surface, this is mainly due to hydrological

conditions: precipitation-minus-evaporation budget, plus any continental contribution (runoff, iceberg discharge, etc.). Because salinity is also sensitive to this hydrological budget, a good correlation is observed between both tracers (Craig and Gordon, 1965; Figure O36). For this reason, the local component of $\delta^{18}\text{O}$ variation has been coined the “salinity effect,” in addition to the global “ice volume” effect. The $\delta^{18}\text{O}$ distribution is also modified by changes in the ocean circulation, by mixing the different water masses and altering their isotopic fingerprint. Table O3 sums up the different interpretations of a sediment $\delta^{18}\text{O}$ signal.

The “ice volume” effect is related to the decrease of the global oceanic mass M_0 during the growth of ice sheets with

a mean isotopic composition $\delta^{18}\text{O}_i$. At steady state, the conservation of the ^{18}O mass between the remaining oceanic mass M and the additional mass dM of the ice sheets reads:

$$M \times \delta^{18}\text{O}_s + dM \times \delta^{18}\text{O}_i = M_0 \times \delta^{18}\text{O}_{s0}, \quad (3)$$

where the subscripts s and i stand for sea and ice sheet, respectively, and 0 for the time before the growth of ice sheets. dM is expressed relative to ocean mass because it is then comparable to the eustatic sea level change. The global oceanic $\delta^{18}\text{O}$ variation (“ice volume effect”) is then:

$$\delta^{18}\text{O}_s - \delta^{18}\text{O}_{s0} = dM/M \times (\delta^{18}\text{O}_{s0} - \delta^{18}\text{O}_i). \quad (4)$$

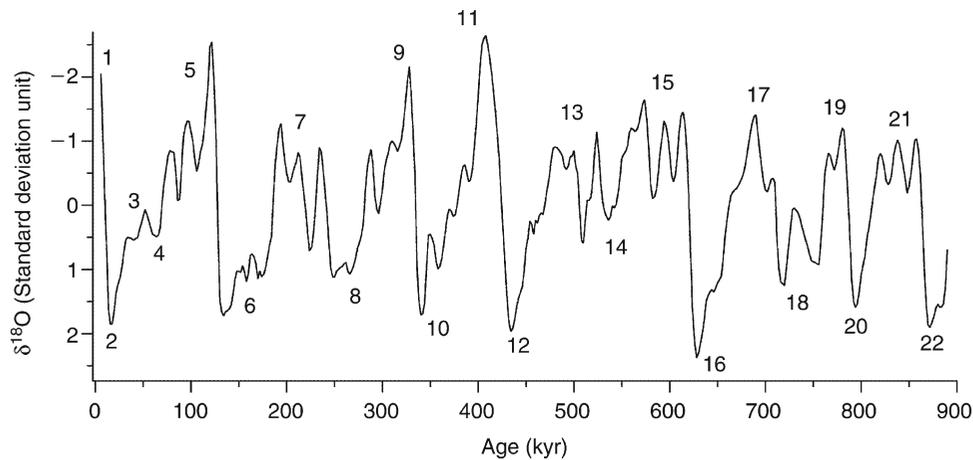

Figure O35 Isotopic stack over the past 900,000 years (after Bassinot et al., 1994), representative of the global ocean variations. Note the usual inverted y-axis, so that an upward excursion corresponds to a warming, and conversely. The $\delta^{18}\text{O}$ values have been scaled so that the record has an average of 0 (centered) and a standard deviation of 1. The marine isotopic stages (MIS) are numbered in *bold*: odd numbers for warm stages, even numbers for cold ones.

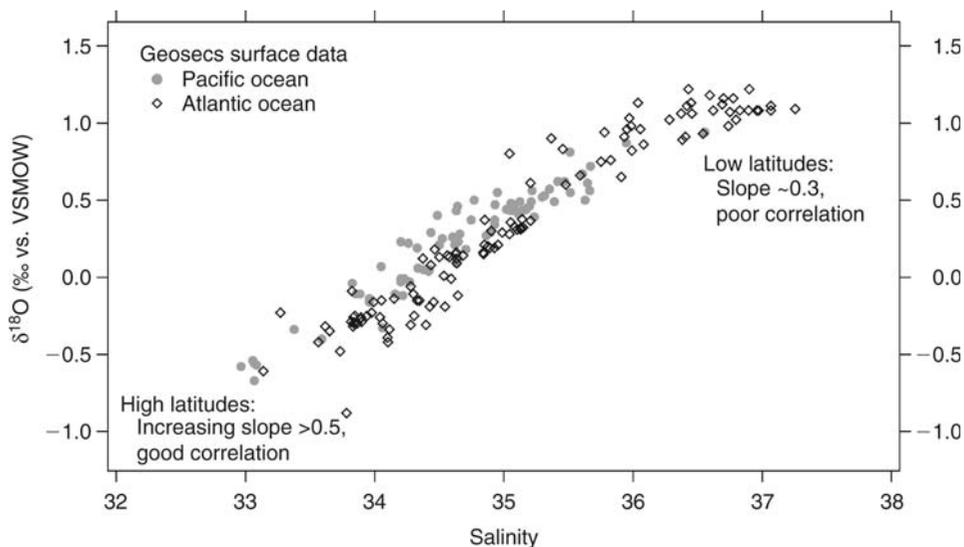

Figure O36 Relationships between surface salinity and water $\delta^{18}\text{O}$ for the Atlantic and Pacific Oceans, due to the common dependence on the hydrological cycle. Note also the highest values in the tropical Atlantic, due to a net transfer of vapor to the Pacific (GEOSECS data from Östlund et al., 1987).

For the Last Glacial Maximum, the variation $\delta^{18}\text{O}_s - \delta^{18}\text{O}_{s0}$ is estimated directly from benthic foraminifera records (Labeyrie et al., 1987) and pore water analyses (Schrag et al., 1996), with a current consensus value ranging between 1 and 1.3‰. Ice sheet growth dM is estimated from changes in coral terrace levels, and from modeling the ice sheet distribution and isostatic rebound. It is equivalent to approximately 120–140 m of sea level (thus, $dM/M \sim 130/4,000$). These values are consistent with a mean ice composition $\delta^{18}\text{O}_i$ between -30 and -50 ‰ (Mix et al., 2001). All these estimates are biased; for instance, the benthic foraminifera record approximates the $\delta^{18}\text{O}_s - \delta^{18}\text{O}_{s0}$ difference because the temperature of their deep environment has changed. Thus, only the combination of these different approaches is able to reduce the uncertainties in each term in Equation 4. Over the Cenozoic, the past 65 million years, the marine $\delta^{18}\text{O}$ record shows a consistent increase of about 5 per mil (Figure O37), an amplitude too large to be interpreted by the waning and waxing of ice sheets. This long positive trend is interpreted as a global ocean cooling by 7°C over the Eocene. Increasing steps around 33 Ma and 15 Ma

ago are interpreted as corresponding to the building up of the Antarctic ice sheet (for a total of about 1.2‰) and the Northern Hemisphere ice sheet around 3 Ma ago (Zachos et al., 2001).

On longer timescales, reliable marine oxygen records are difficult to produce because of the scarcity of sediments, and because the likelihood that the sediments have been altered and re-equilibrated under different environmental conditions increases dramatically. A case study is provided by reconstructions of climatic conditions during the Cretaceous and Early Cenozoic periods. Different proxies, including marine $\delta^{18}\text{O}$, point to a globally warmer climate, consistent with a higher atmospheric CO_2 level, except in the tropics where interpretation of marine $\delta^{18}\text{O}$ records points to temperatures as warm as today or even cooler. This contradiction seems to be due to an alteration of the isotopic signal during diagenesis (Pearson et al., 2001). Over the Paleozoic (timescale of hundreds of millions of years), isotopic data display an increasing isotopic trend of ~ 8 ‰, but its origin could be a long term cooling, a diagenetic alteration, or even an ^{18}O enrichment of the global ocean, among other possibilities (Veizer et al., 1999).

Table O3 Basic interpretation of $\delta^{18}\text{O}$ signal recorded in biogenic sediments

Interpretation	Main origin in variations of	How to isolate it	Original reference
Temperature	Water temperature (also: living depth, etc.)	Subtract the global ice signal, assuming no local seawater change	Shackleton, 1967
Water $\delta^{18}\text{O}$			
Global component	Ice sheet volume	Assume no temperature change (e.g., in benthic foraminifera)	Labeyrie et al., 1987
Local component	Local hydrological balance ("salinity effect") (also: water mass mixing)	Subtract the global ice signal plus an independent estimate of temperature change	Duplessy et al., 1991
Biological bias ("vital effect")	Non-equilibrium biogenic fractionation (also: growth rate, secondary calcification, diagenetic exchange, etc.)	Isotopic measurements on living organisms in known conditions (collection with tows; culture)	Epstein et al., 1953

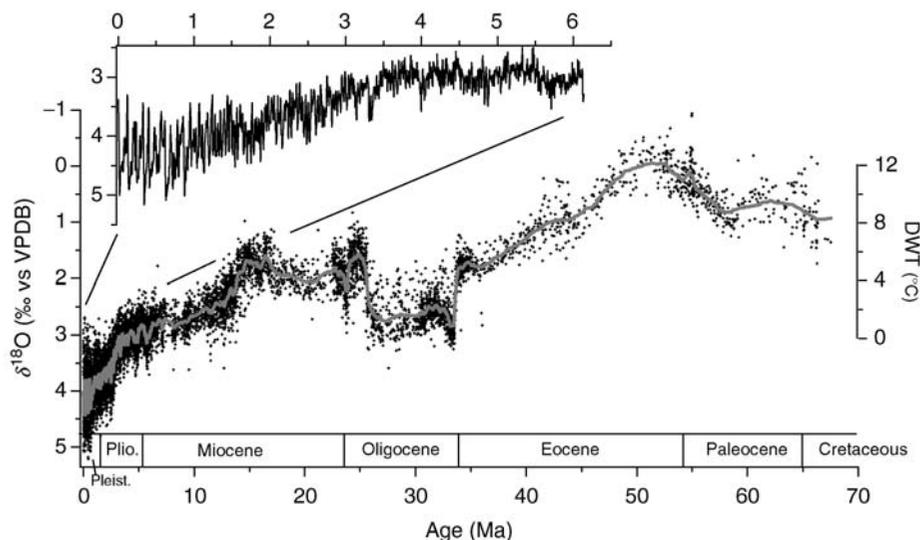

Figure O37 Trend of the deep ocean $\delta^{18}\text{O}$ over the Cenozoic (last 70 Myr), compiled from benthic records (Zachos et al., 2001). The close-up shows the last 6 Myr. The measured $\delta^{18}\text{O}$ values have been adjusted to approximate the water value. The Deep Water Temperature (DWT) scale (right side) has been calculated by considering a marine $\delta^{18}\text{O}$ of -1.2 before the appearance of ice sheets (before ~ 35 Ma).

Still, positive excursions lasting tens of million years have been contemporaneous with periods of cooling or large glaciations, and seem to be of climatic origin.

Bias on the sediment $\delta^{18}\text{O}$ record

Comparisons have been performed between known environmental conditions (temperature and water $\delta^{18}\text{O}$) and the $\delta^{18}\text{O}$ of living shells, from either tow fishing or aquarium cultures. First, some species appear to calcify out of isotopic equilibrium with water, possibly due to kinetic bias. Second, species live at different depths and thus record different environmental conditions. This is especially important for planktonic species living in the mixed layer because of the strong vertical gradient of temperature. In addition, organisms may migrate vertically over several hundreds of meters, on a seasonal or daily basis. Depending when the calcification happens, the exact depth recorded by the $\delta^{18}\text{O}$ may be different to that of the usual living habitat. Thus, interpreting a sediment $\delta^{18}\text{O}$ record requires a precise calibration on modern tests to know which conditions are represented in terms of depth and season. Isotopic corrections have been determined in order to estimate the correct environment; for instance, $\delta^{18}\text{O}$ measured from the foraminifera *C. wuellerstorffi* is usually corrected by 0.64 per mil to be closer to the value in equilibrium with deep water conditions. A good review of these biases is provided by Wefer and Berger (1991).

Diagenesis may also alter the original isotopic signal. This is especially true for aragonitic and high-magnesium calcitic shells, because these minerals are not stable and recrystallize. Low-magnesium calcitic shells, like those of foraminifera, are not free of diagenetic alteration, which must be discarded by a thorough examination and cleaning.

Other records: corals and speleothems

These carbonates, like sediments, record both the temperature and the water $\delta^{18}\text{O}$ composition, with some possible offset to the expected equilibrium value. In addition, they grow with fine laminations that may be annual bands, as for corals, allowing both a high-resolution sampling and a detailed chronology. They can be well dated by counting the annual bands and by ^{14}C and U/Th techniques. Subannual $\delta^{18}\text{O}$ measurements on corals showed that oxygen isotopes record the seasonal temperature, with some offset (Fairbanks and Dodge, 1979), although changes in the isotopic composition of surface water (linked to precipitation or river runoff) may explain part of the variations. In the tropics, reef building species have been shown to be especially useful for documenting ENSO (El Niño-Southern Oscillation) variability in areas where either temperature or precipitation change dominates the isotopic signal (Cole et al., 1993). Because most reef-building corals live in symbiosis with algae (zooxanthellae), they can only grow within a restricted depth range, which makes them reliable records of sea level variations. Speleothems grow from calcite precipitation when CO_2 -supersaturated water degasses. Since this water comes, more or less directly, from precipitation, the calcite $\delta^{18}\text{O}$ is strongly influenced by the factors affecting the $\delta^{18}\text{O}$ of precipitation (see above), including the local temperature. At mid-to-high latitudes, the positive correlation between the $\delta^{18}\text{O}$ of precipitation and temperature (Figure O33) is balanced by the negative effect of the temperature on the isotopic fractionation (Emiliani, 1971, note 23). At low latitudes, if the precipitation $\delta^{18}\text{O}$ is under greater control of the quantity of precipitation (Figure O33), the influence of temperature may be amplified (Neff et al., 2001). Changes in

the marine $\delta^{18}\text{O}$ add to this complexity, making a quantitative interpretation of a speleothem record not that straightforward. Several records, $\delta^{18}\text{O}$, $\delta^{13}\text{C}$, growth rate, trace elements, etc., are usually combined in order to decipher the origin of the signals. One of the longest $\delta^{18}\text{O}$ records, from Devils Hole, Nevada, covers more than half a million years (Winograd et al., 1992).

Global biogenic productivity estimated from oxygen isotopes

Measurements of the isotopic composition of atmospheric oxygen, O_2 , have shown an enrichment as compared to the ocean (Dole, 1935), by 23.5 per mil versus V-SMOW. This enrichment, called the “Dole effect” (see Dole effect), is mainly determined by gross biospheric fluxes, respiration and photosynthesis. Estimation of Dole effect variations from measurements in air bubbles trapped in glacial ice allows one to infer past changes in these fluxes. More recently, Luz et al. (1999) exploited a mass-independent fractionation of oxygen isotopes in the stratosphere to infer the global biospheric productivity (i.e., gross production of O_2 by photosynthesis). Most chemical processes fractionate oxygen isotopes according to their mass, in which case the fractionation of ^{17}O to ^{16}O is around half that of ^{18}O to ^{16}O (0.521, precisely). In contrast, in the stratosphere, a series of reactions involving O_2 , O_3 and CO_2 does not fractionate ^{18}O versus ^{17}O , and thus modifies their proportion in atmospheric CO_2 and O_2 . The extent of this atmospheric anomaly depends on the relative intensities of mass-dependent and mass-independent processes. It is expressed as the deviation towards the mass-dependent relationship between ^{18}O and ^{17}O :

$$\Delta^{17}\text{O} (\times 10^6 \text{ per meg}) \equiv (\delta^{17}\text{O} - 0.521 \times \delta^{18}\text{O}) \quad (5)$$

where $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ are isotopic compositions with respect to air.

Measurements of oxygen $\Delta^{17}\text{O}$ in air bubbles trapped in Greenland ice core allowed Luz et al. (1999) to infer that the global biospheric productivity did not differ significantly over the last 80,000 years, although it was slightly lower than at present.

PAGES

The PAGES mission

PAGES (Past Global Changes) is the IGBP (International Geosphere Biosphere Programme) project charged with providing a quantitative understanding of the Earth's past climate and environment. Reliable predictions of global climate change and its environmental impacts in the future require an understanding of processes operating on time scales longer than the short instrumental record. The study of natural archives of past climatic and environmental variability can provide this information.

Why PAGES?

PAGES operates on the principle of subsidiarity, a term borrowed from the European Union. This means that projects within the PAGES umbrella are those that clearly benefit from value added through participation in a coordinated, international, cooperative framework. Although research funding for paleoenvironmental science is almost entirely national, the global nature of the questions involved, the global distribution of proxy archives, and the fact that the community of paleoresearchers is global, requires a globally integrated research strategy. PAGES provides interdisciplinary and international linkages between nationally funded research projects in order to ensure that the combined effort adds to more than the sum of the parts. PAGES synergies lead to community building and the development of integrated research objectives. Tangible products include the website (www.pages-igbp.org), newsletter (*PAGES News*), and numerous books (Markgraf, 2001; Alverson et al., 2002), special issues (Alverson et al., 2000; Clark and Mix, 2002), synthesis papers (Alverson and Kull, 2002), outreach publications (Alverson et al., 2001a), and brochures (Alverson et al., 2001b).

Research program

The PAGES research program is structured to bring researchers from a variety of disciplines and countries together. Thus, no explicit disciplinary or national structures exist within the program. Rather, the program elements are designed to reduce

constraints imposed by geography and artificial disciplinary boundaries such as those that commonly separate physical oceanography from continental paleoecology from archaeology. Although the five foci that make up the core of the PAGES program have been created to group types of research together, they are by no means restrictive, and collaboration between foci is strongly encouraged. The activities of each focus are guided by a chair and a small steering group. PAGES activities are driven by rapidly evolving scientific understanding and are designed to shift focus accordingly. The most recent structure and activities are always readily available on the website; www.pages-issp.org.

Focus 1 – PANASH

The goal of the Paleoclimate and Environments of the Northern and Southern Hemispheres (PANASH) focus is to reconstruct paleoenvironments and paleoclimate along three Pole-Equator-Pole (PEP) terrestrial transects using a multiproxy data and modeling approach. One of the major roles of the PEP transects is to facilitate the development of north-south research partnerships and foster a unified sense of purpose within the diverse international and interdisciplinary community that addresses questions of past global change. The PEP transects have been extremely successful in achieving these goals, as evidenced by the strong community interest in PEP meetings, as well as the peer reviewed synthesis publications that have arisen from each transect (Dodson and Guo, 1998; Markgraf, 2001; Battarbee et al., 2004; Dodson et al., 2004).

In addition to supporting the PEP transects, PANASH as a whole stimulates global exchange of information among marine, atmospheric, and terrestrial scientists, historical ecologists, and environmental archaeologists. Its primary tasks are to:

- document the amplitude, phase, and geographic extent of past climate change in the two hemispheres,
- determine the history of potentially important forcing factors,
- identify the feedbacks that amplify or reduce the influence or the effect of these forcings,
- identify the mechanisms of climatic coupling between the two hemispheres.

The basis of all PANASH activities is a hypothesis-driven approach to understanding modes of climatic and environmental variability through the use of global, multi-proxy based climate and environmental reconstruction. As an example of the wealth of information that must be integrated within PANASH, Figure P1 shows a highly condensed impression of the variety of proxy records of environmental variability available over a range of timescales from around the world.

Focus 2 – The PAGES/CLIVAR intersection

The PAGES/CLIVAR Intersection focus aims to improve the understanding of decadal to century scale climate variability, especially when relevant to improving predictability, through the use of high resolution paleoclimatic data. The activities within this focus are overseen by a joint working group shared between PAGES and the World Climate Research Program (WCRP) Climate Variability and Predictability Program (CLIVAR). The four principal areas of focus, as outlined at the first international CLIVAR conference (Alverson et al., 1999), are:

1. extending the instrumental climate record back in time with quantitative proxy data that can be accurately calibrated against instrumental records,

2. documenting and understanding rapid climate change,
3. documenting and understanding natural climate variability during the Holocene and other interglacial periods with background climatic states similar to those of today,
4. testing the ability of climate models to capture known past climate variability.

Focus 3 – IMAGES

The International Marine Past Global Changes Study (IMAGES) is the marine program shared between PAGES and the Scientific Committee for Ocean Research (SCOR). The principal aim of this program is to understand the mechanisms and consequences of past climate changes involving ocean circulation, salinity, and ventilation as well as the past history of marine ecosystems and carbon cycle dynamics, using oceanic sedimentary records. IMAGES supports a number of working groups, some of which are oriented around cruise planning and others around more general research questions. One major task of IMAGES is to organize international pooling of financial resources and research expertise in order to enable cruises to be carried out throughout the world oceans. All IMAGES activities are carried out with strong input

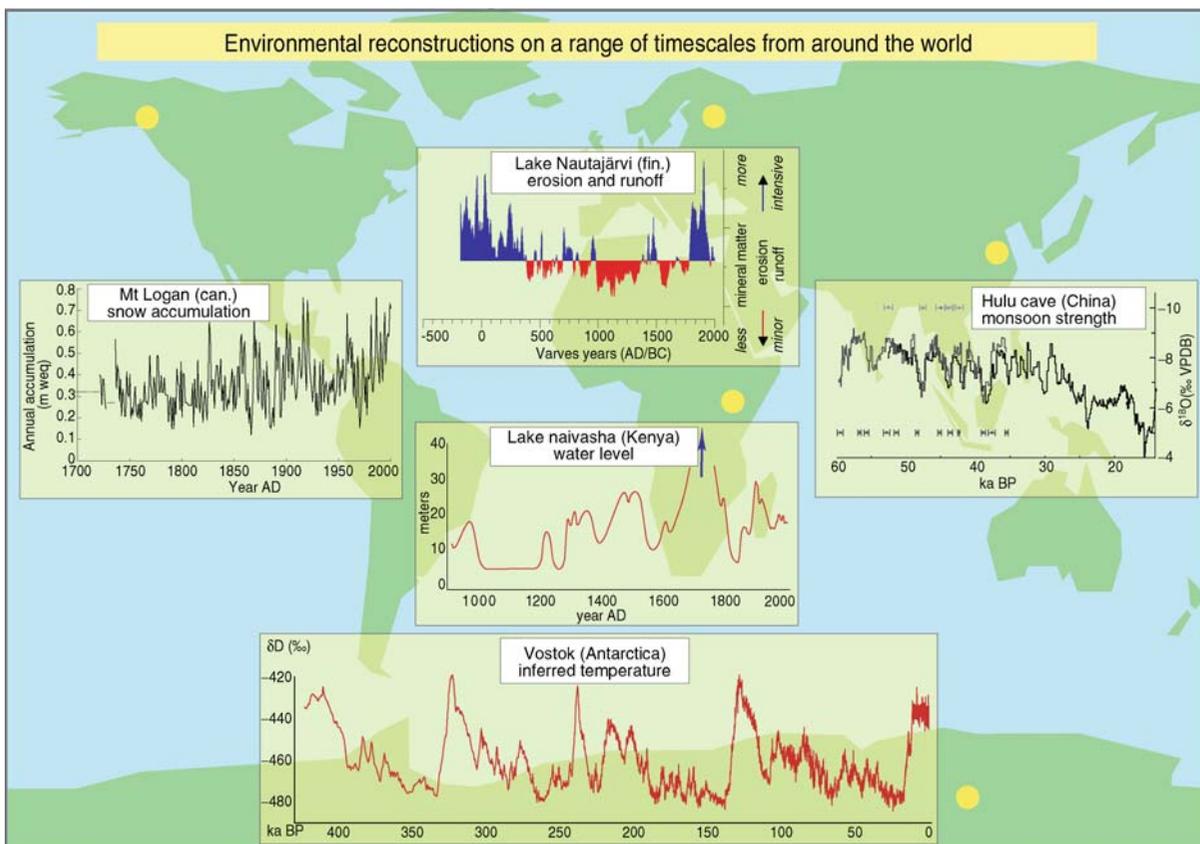

Figure P1 A highly condensed view of the variety of proxy records of Quaternary environmental variability available over a range of timescales from around the world. Yellow dots indicate the location of these records on the underlying global map. The records are: 1. A three hundred year record of snow accumulation, related to the Pacific Decadal Oscillation, from an ice core on Mt. Logan, Canada (Moore et al., 2002). 2. A two thousand year record of runoff intensity, related to the North Atlantic Oscillation, from a Finnish laminated lake sediment core (Ojala, 2001). 3. An oxygen isotope record, as indicator of moisture source and hence monsoon penetration, covering the last glacial period through the Holocene from a speleothem in Eastern China (Wang et al., 2001). 4. A lake level reconstruction from Naivasha, Kenya as an indicator of regional hydrological balance (Verschuren et al., 2000). 5. Isotopically inferred temperature changes over four glacial cycles from the Vostok ice core in Antarctica (Petit et al., 1999).

and interaction from climate modelers, continental scientists, and ice core researchers.

Focus 4 – Polar programs

The focus of the Polar programs is bi-polar. Examples of research within the scope of this focus include the European and US N GRIP ice core programs, EPICA, and the International Trans-Atlantic Scientific Expedition (ITASE), which seeks to map the spatial variability of Antarctic climate over the last millennium. This initiative is shared with the Scientific Committee on Antarctic Research (SCAR). In addition to ice core work, a wealth of other archives in polar regions are employed to provide a robust picture of high latitude environmental change. For example, the ESF-funded Quaternary Environment of the Eurasian North project (QUEEN) concentrates on mapping the extent of the last glaciation, and the CircumArctic Paleo-Environments program (CAPE) facilitates integration of paleoenvironmental research on terrestrial and adjacent margins covering the last few glacial cycles.

Focus 5 – Past ecosystem processes and human environment interactions

The Past Ecosystems and Human-Environment Interactions focus highlights PAGES concern with ecological responses to climate change and past human activities. The research within Focus 5 integrates past human-environment interactions at sub-continental scale with research and modeling based on present-day ecosystems and watersheds. The focus is divided into three main activities: Human Impacts on Terrestrial Ecosystems (HITE), Land Use and Climate Impacts on Fluvial Systems during the Period of Agriculture (LUCIFS), and Human Impact on Lake Ecosystems (LIMPACS). These activities are case-study based and focus on ecosystems made vulnerable to global change through any combination of natural and human-induced stresses. They also explore the basis for the durability of long-sustained ecosystems, and questions of sensitivity, thresholds, and non-linear responses.

Initiatives

In addition to its standing foci, PAGES supports initiatives driven by scientific questions arising within the community. The PAGES Steering committee serves to critically ascertain if proposed initiatives should qualify for PAGES endorsement and support. Successful initiatives develop a clear research and workshop agenda over a 3–5 year period leading to a tangible goal. PAGES support for these initiatives is flexible but can include enhancing the profile of the initiative, advertising it to the international community, and providing partial funding for workshops. One example of a successful initiative is the Environmental Processes of the Ice Age: Land, Oceans, Glaciers (EPILOG) program, which arose in 1999 as a multi-national working group of the PAGES marine program IMAGES. EPILOG received PAGES support, including co-funding for several workshops, and recently published an extensive special issue on ice sheets and sea level of the last glacial maximum (Clark and Mix, 2002). The required qualifications for a PAGES initiative are:

1. A question that seems likely, within a 3–5 year timeframe, to be tractable in the sense of leading to a peer-reviewed product that advances the field.
2. A clear reason why PAGES should be involved, for example to facilitate new international or interdisciplinary bridges and community building.

Program structure

PAGES activities are overseen by an international scientific steering committee (SSC) appointed by the Steering Committee of the IGBP. The sixteen members, who each serve for at most two consecutive three-year terms, are chosen to provide a balance of scientific expertise and national representation. This committee meets once a year to provide guidance for and oversight of the program as a whole. A subset of five committee members serves as an executive committee. As a general guideline, the five member executive committee includes an American and a Swiss by virtue of the fact that these two countries currently provide the bulk of PAGES funding, and at least one member from a less developed country. Under direction of the SSC, the staff of the small International Project Office (IPO) carries out the day to day running of the PAGES program as a whole. These activities include maintaining the PAGES website and database, organizing meetings and workshops, editing and writing PAGES publications, and serving as a liaison with other global change programs. In addition, the office regularly hosts both short-and long-term (sabbatical) visits from paleoscientists around the world.

Links with other international programs

PAGES continues to be primarily concerned with understanding the past operation of the Earth system. The PAGES domain includes the physical climate system, biogeochemical cycles, ecosystem processes and, human dimensions. Thus, PAGES activities are not restricted to IGBP, but overlap substantially with IGBP's sister programs within the "earth system science partnership," the WCRP, the International Human Dimensions Program on Global Environmental Change (IHDP) and Diversitas. Facilitating publicly accessible paleodata access, engaging with the climate modeling community, and strengthening the role of developing countries in PAGES research are the stable tripod upon which the wider PAGES scientific program rests.

PAGES has built bridges with many other international scientific programs. Although only two of the foci are officially shared (Focus 2 with WCRP-CLIVAR and Focus 3 with SCOR), all of them have substantial interactions with other programs. PAGES has launched joint initiatives with all of the other components of the IGBP, including both the core projects of IGBP phase 1. In the newly developing IGBP phase 2, which runs from 2003 to 2013, PAGES is expected to serve in a central synthesizing role, and thereby interact strongly with all of the new IGBP programs (Figure P2). A full listing of PAGES science partnerships is available on the PAGES website; some examples include the Global Network for Isotopes in Precipitation (GNIP), shared with the WCRP and the International Atomic Energy Agency (IAEA), and the International Mountain Research Initiative, co-sponsored by three other IGBP core projects, IHDP, GTOS (Global Terrestrial Observing System), and UNESCO. Through these intersection activities, PAGES provides the historical context for global change programs.

Outreach, communication, and publications

One major task for PAGES is to provide easy access to paleoenvironmental information to active researchers in paleosciences, researchers in other aspects of global change research, and the public. One of the most important communication platforms is the website, www.pages-igbp.org. This site is modified regularly and includes lists of new products, links to paleoenvironmental databases, science highlights, a calendar of upcoming events, and information on how to become involved in PAGES activities.

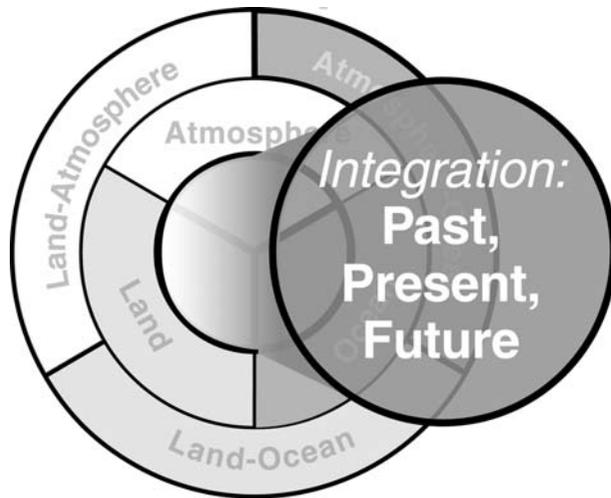

Figure P2 Schematic diagram of the core projects expected to be active in phase 2 of the International Geosphere Biosphere Programme (IGBP), which runs from 2003 to 2013. These new projects are based around the three Earth system components, land, atmosphere, and ocean, and the three interfaces between them. Two further projects, GAIM (AIMES) and PAGES will serve as integrating projects, providing past and future time dimensions to the program. PAGES will play a central, integrating role in the new IGBP structure.

Another important element in the PAGES communication strategy is the newsletter. PAGES NEWS is produced three times a year and sent free of charge to more than 3,000 subscribing scientists in more than 70 countries. All issues are made available as pdf files on the PAGES website. Such wide distribution, coupled with a high degree of proactive submission by the research community, has made the newsletter an important vehicle for the dissemination of research results, workshop reports, and program news, especially in countries with limited access to western journals. Most issues are developed around a specific theme, which might be a PAGES program or a particular paleoarchive. In addition to its newsletter and website, PAGES strongly encourages publications in the peer-reviewed literature as one outcome of all of its scientific activities.

Data archives

Internationally accessible data archives are one of the primary foundations for paleoclimatic research that seeks to go beyond reporting results on a site by site basis. PAGES is committed to ensuring the preservation of all data needed for long-term, global change research and making them openly available. PAGES endorses a number of such data repositories, including the World Data Center for paleoclimatology, Boulder (www.ngdc.noaa.gov/paleo/, appendix B) and PANGAEA (<http://www.pangaea.de>). PAGES supports a data board with a primary responsibility for assuring compatibility and accessibility of available existing paleo-databases. The PAGES data board is open to all interested participants and includes members from most major database centers and focus leaders.

Capacity building – encouraging north-south research partnerships

PAGES has a strong interest in capacity building. The majority of paleo-environmental data are extracted in less developed countries. Recent high profile examples include ice cores from

Kilimanjaro, tree rings and lake sediments from Siberia, loess records in China, tropical tree rings in SE Asia, and speleothems in Oman. Bringing these records together into a synthesis view of past environmental change requires that a global community of independent working scientists matching the diversity of these records also exists. PAGES therefore allocates approximately 20% of its budget directly to activities geared towards building the capacity of scientists residing in developing countries to carry out active participation in paleoenvironmental research. In addition, most PAGES workshop and summer school support is earmarked for participants from developing countries. In addition to finances, PAGES seeks to follow up one-time support wherever possible, by enhancing the number of young scientists from developing countries in the database, nominating outstanding individuals for various awards, and entraining them directly in PAGES major scientific initiatives. PAGES occasionally hosts visits at the PAGES office, usually when tied to academic visits at a department at the nearby University of Bern or the Swiss Climate summer school.

The PAGES Regional, Educational and Infrastructure Efforts (REDIE) project seeks to:

1. enlist scientists and technicians in developing countries in international paleoenvironmental research activities, and
2. promote the development of paleoscience research within developing countries.

Within the REDIE program, a number of approaches are used. Financial support is made available for the attendance of active young scientists at key conferences and summer schools. PAGES publications are made available free of charge to libraries and university laboratories in less-developed countries. Scientists from Asia, Africa, and South America sit on the PAGES Science Committee and act as liaisons with their regional communities. PAGES scientific meetings are regularly organized in developing countries, with ample support and presentation time provided for the attendance of scientists from the region.

PALEOBOTANY

Introduction

Plants are ideally suited as records of, or proxies for, terrestrial climate because they are sessile organisms. As climate changes around them, they must adapt or perish. Over evolutionary time, many aspects of plant growth have been constrained by adaptation to specific climate regimes (e.g., Parkhurst and Loucks, 1972; Chaloner and Creber, 1990; Uhl and Mosbrugger, 1999). The sessile nature of plants combined with the tendency for most plant parts to be preserved relatively close to the site at which they grew means that plant fossils can be used as a record of local paleoclimate (Spicer, 1989; Greenwood and Wing, 1995).

Three main techniques are often used to determine paleoclimate from fossil plants. The first is referred to as the nearest-living-relative technique. The nearest-living-relative technique compares fossil plants to the modern plants to which they are most closely related and assumes that the climatic tolerances for both have remained similar through geologic time. The second technique uses plant structures as vegetation proxies for climate. These methods use various aspects of leaves and wood, such as leaf morphology, tree rings or stomatal index, as proxies to determine the climate in which these plant organs grew. The final technique involves measuring isotopic ratios of plant tissue to determine the climatic surroundings of the plant.

Nearest-living-relative technique

The nearest-living-relative technique is widely used in paleoclimate reconstructions. This technique is taxon based and compares fossil plants to their most closely related modern plants, which are usually determined by finding similar morphological characters in a fossil and in a living taxon. The main assumptions are that the climatic tolerances for both fossil and modern plants are similar and the identifications and relationships proposed between the fossil and living taxa are reliable. Dilcher (1974, 2000) suggests that upwards of 60–75% of taxa identified for Paleogene and Cretaceous fossil angiosperms are incorrect. One advantage to this technique is that it can be used with many different plant organs, including leaves, pollen, wood, fruits and seeds. For some plant assemblages, a combination of different plant organs can be used to establish a more robust determination of paleoclimate. In general, assemblages with fruits and seeds or combinations of plant organs give more accurate results than those that preserve only leaves, as taxonomic affinity is often difficult to determine with leaf material. The best results are obtained when a large number of taxa are used, the taxonomic identifications are correct and the taxonomic identifications are at the species level. Use of this technique assumes that the ecological tolerances of the fossil and extant relatives are similar, and have not changed through time. The more recent the fossil, the more likely it is that the ecological tolerances are similar. Thus Holocene and Neogene climate reconstructions are more likely to be accurate than Paleogene and Mesozoic comparisons. Paleozoic plants are too dissimilar to recent plants to use this technique (Chaloner and Creber, 1990).

Species level comparisons are the most robust, because ecological tolerances of species are often better defined than those of higher taxonomic groups. However, in many instances determination of the fossil can be made only to the genus or family level, especially when using pollen or wood. Some genera and families have similar tolerances throughout the group. For example, palms and gingers have been said to live only in subtropical and tropical areas (Wing and Greenwood, 1993), although palms often grow and reproduce in warm temperate areas of southeastern North America and South America. However, some genera have broad ecological tolerances, (e.g., *Quercus* and *Acer*), and most plant families have an extremely broad ecological range (e.g., *Fabaceae*). This problem is somewhat circumvented by using large numbers of taxa to reconstruct paleoclimate, which reduces the likelihood that one broad-ranging taxon will influence the results.

The nearest-living-relative technique is used both to estimate paleoclimate with absolute values and to determine vegetation or climatic zones. The former method requires knowledge of the climatic tolerances of many different modern species, while the latter relies on determining which combinations of taxa are commonly found together in modern vegetation or climate zones. Absolute climate values can be determined from individual modern taxonomic relatives of fossil taxa, and a range of temperatures or precipitation values may result. However, combining many modern climate ranges should result in a more precise estimate for the fossil assemblage, with the resulting climatic estimate being the range where all of the modern taxa align (Figure P3). Combining many taxonomic ranges decreases the likelihood that a single problem taxon will skew the resulting climate range. One application of this method has been termed the coexistence approach (Mosbrugger and Utescher, 1997) and uses a database of modern ecological tolerances of leaves, fruits and seeds from

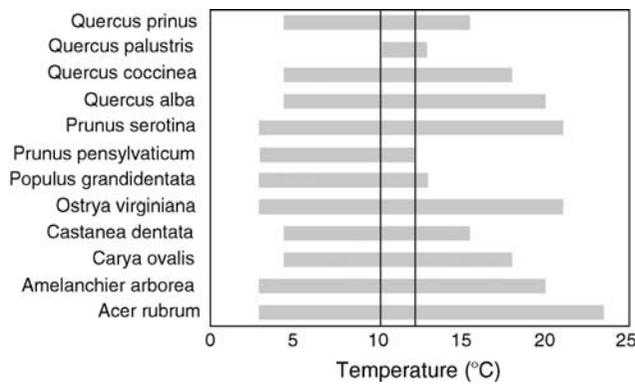

Figure P3 A hypothetical list of modern relatives based on a flora from southern Pennsylvania. If these modern taxa had represented the modern relatives of a fossil flora, the estimated mean annual temperature of the fossil site would be between approximately 10°C and 12°C, the range of overlap between all taxa present.

Europe to apply the nearest-living-relative technique to fossil assemblages. This approach works for Tertiary and younger-aged fossil assemblages and has resulted in temperature estimates with ranges as small as 1–4°C.

Using the nearest-living-relative technique to determine vegetation and climatic zones is more common than finding absolute climate values, as it is the method preferred by palynologists. This application of the method relies on finding similar taxonomic combinations in both modern and fossil assemblages. As with the coexistence approach, using many taxa is preferable in determining a paleovegetation or paleoclimatic zone. This is especially true when using pollen grains, which are often only determined on the genus level and thus may have large individual ecological tolerances, but a smaller tolerance as an assemblage. However, on occasion, the presence of a small number of extremely indicative taxa can constrain the paleovegetation or paleoclimatic zone regardless of the other taxa involved (Martin, 1997). Sinka and Atkinson (1999) have used factor analysis to determine the overlapping climate zones of modern plant assemblages, and then map the unknown fossil ranges onto a “climate space.” This technique is a more objective method of determining climatic zones of fossil assemblages, and eliminates the bias that one taxon may have in the overall zonation.

Plant structure proxies

Similar combinations of wood or leaf characters tend to be common in floras that live in similar climates (Dilcher, 1973; Givnish, 1987; Woodcock and Ignas, 1994), even those that are widely separated spatially and compositionally (Halloy and Mark, 1996). Thus, specific plant characters are emergent properties of a flora living under a specific climate regime. The presence or absence of these characters in a fossil floral assemblage allows for a paleoclimatic determination of the assemblage site. Climatic interpretation is based on modern relationships between climate and specific plant characteristics. Unlike the nearest-living-relative technique, foliar and wood physiognomy approaches do not require specific or correct taxonomic identification, although knowledge of the number of taxa present and some aspects of their morphological or anatomical characters are needed. This can be done using a parataxonomical or morphotype based approach (Woodcock and Ignas, 1994; Davies-Vollum, 1997), which interprets suites of morphologically similar plant

fossils as species groups. Exact taxonomic identification is needed for stomatal indices and leaf venation density methods, as these proxies are species dependent.

Leaves

Angiosperm leaves are often used in paleoclimatic reconstructions, with common proxies including leaf physiognomy, stomatal density or stomatal index, and leaf venation density. Leaf physiognomy is often used to determine annual and seasonal temperature and precipitation. Stomatal density and stomatal index are used to determine paleoCO₂ levels, moisture availability and temperature. Leaf venation density is used to determine transpiration stress.

Leaf physiognomic methods have their basis in numerous qualitative relationships between leaves and climate that have been quantified using modern climatic and floral data from a range of climates and areas. By quantifying the proportions of certain leaf characteristics present in specific modern climates, predictive equations have been formed to determine climate from fossil leaves. The most common equations correlate leaf morphological characters with mean annual temperature and mean annual precipitation, but others have been used to quantify other climatic variables such as growing season precipitation, and cold month or warm month mean temperatures (Wolfe, 1993; Gregory-Wodzicki, 2000; Jacobs, 2002).

Simple linear regression has been shown to be a relatively direct and accurate means of predicting both mean annual temperature and mean annual precipitation. The correlation between leaf margin state (toothed or smooth) and mean annual temperature is robust (Figure P4), and results in a fairly precise and accurate predictive equation. As a consequence, this has been the most studied and refined relationship within leaf physiognomic studies (e.g., Dilcher, 1974; Wilf, 1997; Kowalski and Dilcher, 2003). The resulting mean annual temperature estimates generally have a suggested minimum standard error of 2°C (Wilf, 1997). For precipitation, equations correlating leaf area and mean annual precipitation have shown the most promise, and are slowly being refined by different researchers (e.g., Wilf et al., 1998; Jacobs, 2002). However, most authors have expressed caution in relying on the resulting mean annual precipitation estimates, as the estimates have high standard errors.

Several authors have started using a multi-character approach to climate prediction from leaf morphology, as the morphology of most leaf characters is thought to be the result of the complex interaction of many climate parameters. Multiple regression equations using from two to nine or ten leaf characters have shown some refinement of climate prediction (e.g., Wing and Greenwood, 1993; Gregory-Wodzicki, 2000; Jacobs, 2002), and are often more accurate than simple linear regression equations for paleoclimate prediction (Kowalski, 2002). Wolfe (1993) has compiled a large, worldwide database of modern climate and floral data, called CLAMP, to use with canonical correspondence analysis, a multivariate statistical approach for paleoclimate prediction. His database uses 31 leaf characters to predict numerous climate parameters, including mean annual temperature, growing season temperature and precipitation, enthalpy and range of temperature. Nearest neighbor analysis uses only the sites from the CLAMP database that are closest to the unknown site in multivariate space to form predictive equations for paleoclimate (Stranks and England, 1997). This technique has refined multivariate prediction further by restricting the predictor set to similar floras and often results in smaller estimate error.

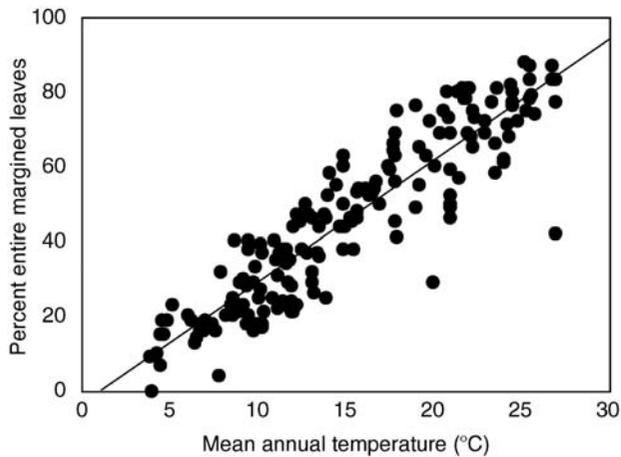

Figure P4 Percentage of entire margined leaves in a flora versus mean annual temperature for 177 sampled floras worldwide. Data from Wolfe (1993); Gregory-Wodzicki (2000); and Kowalski, (personal observation).

Leaf physiognomy predictions are relatively accurate, but several assumptions do exist. The first assumption is that the relationship between leaf morphology and climate has remained constant through time. The second is that taphonomic biases are small, though they are known to exist (Roth and Dilcher, 1978; Greenwood, 1992). The third is that regional differences due to climatic or taxonomic history are not great. Several authors have suggested that it is important to use predictor data sets that are similar geographically, taxonomically or climatically to those likely to be encountered in the fossil assemblage (Stranks and England, 1997; Gregory-Wodzicki, 2000; Jacobs, 2002; Kowalski, 2002). This restriction should reduce the problems that might be encountered by the third assumption above. Leaf physiognomy methods also require a relatively high number of fossil taxa (~20) to reduce paleoclimate estimate errors. Only the leaf characters of woody angiosperms have been shown to correlate with climate, restricting the use of the method to the Cretaceous and Cenozoic.

Both stomatal density (number of stomata per area) and stomatal index (the ratio of the number of epidermal leaf cells to the number of stomata in a defined area, multiplied by 100) can be used to determine atmospheric CO₂ concentrations, temperature or moisture availability. Stomata pores are surrounded by guard cells that control the size of the stomatal opening and thus the gas exchange and water loss from the leaf to the atmosphere. The number of stomata that differentiate is determined at the time of leaf unfolding (Kurschner et al., 1998) when the leaf acts as a biosensor of atmospheric CO₂. Stomatal index is used more often than stomatal density, as it eliminates the effect of leaf size on density counts (large leaves with large cells might have a decreased stomatal density, but not a decreased stomatal index). *Quercus*, *Ginkgo* and *Metasequoia* have been used, among other taxa, to calibrate CO₂-stomatal index curves from which to estimate paleoCO₂ levels (e.g., Kurschner et al., 1998; Royer, 2001; Beerling and Royer, 2002). All species have a stomatal density and stomatal index with a negative relationship to atmospheric carbon concentration. These taxa are broad-ranging temporally (both *Ginkgo* and *Metasequoia* are termed “living fossils”) and can track atmospheric carbon changes over long periods of time.

Like all methods, stomatal index and stomatal density have advantages, but must be used with caution. As CO₂ rises, stomatal index responds non-linearly. Thus, problems arise when estimating paleoCO₂ during periods of higher than modern atmospheric CO₂ concentrations (Kurschner et al., 1998; Beerling and Royer, 2002). Stomatal index decreases as temperature increases, even under the same ambient CO₂ (Beerling and Chaloner, 1993). This can influence atmospheric CO₂ estimates if temperature is not constant over the time period being analyzed. However, temperature can be estimated in combination with other leaf physiognomy methods, which can minimize potential interpretation problems. Stomatal density also appears to correlate, at least qualitatively, with precipitation amount, especially in shade leaves (Sun et al., 2003). Stomatal index does not seem to reflect this correlation and as such is a better measure for atmospheric CO₂ concentration. A major benefit to using stomatal index and stomatal density to estimate CO₂ is that this method can be used from the Paleozoic to the Recent (Chaloner and McElwain, 1997).

Leaf venation density is a method that is more recently being refined as a way to estimate paleomisture parameters. Leaf venation density changes in response to the amount of leaf transpiration, which is due to water availability or temperature (Uhl and Mosbrugger, 1999; Uhl et al., 2002). Leaf venation density is influenced by climate factors during leaf production in one growing season; thus, this method can record small-scale changes that may vary on the order of seasons. However, several problems still exist with this method, including density differences with leaf size dependent on species, how to define density, and differences between sun and shade leaves. However, if these problems are addressed, this method could potentially be used from the Paleozoic to the Recent.

Wood

Several aspects of wood can be used to determine paleoclimate, including wood anatomy, tree rings and charcoal. Wood is often found in fossil environments that are not suited for leaf preservation. Thus, using wood as a climate proxy can increase the number of environments in which paleoclimatic reconstruction is possible from plants.

Paleoclimate reconstruction from wood anatomy is based on cellular level proxies, such as the presence, organization or size of vessel elements, ray cells, axial parenchyma and fiber cells (Wiemann et al., 1999; Woodcock and Ignas, 1994). The relationship between wood anatomy and climate has been demonstrated qualitatively based upon relationships observed between vessel density and diameter with moisture, vessel diameter as a function of temperature, and the presence of ring porosity as an indicator of seasonality. Quantitative equations have been derived, most notably by Wiemann et al. (1998, 2001), that result in numerical climate estimates from these same features. These equations ideally predict temperature to within 5 °C, although equations using differing predictive characters from the same site can differ by almost 6 °C. Temperature correlates fairly well with wood anatomical characters, but precipitation correlates poorly (Wiemann et al., 1998, 2001). These equations need a relatively large number of taxa (~25) to estimate climate in order to reduce error. However, Terral and Mengal (1999) have shown that it is possible to use one species through time to estimate climate, if that species shows variation in anatomical characters with respect to climate. In their study, olive wood was used to estimate Holocene paleoclimate.

Both qualitative and quantitative climate estimates, based upon wood anatomy, work relatively well to distinguish tropical from more temperate or seasonal sites. The cellular anatomy of wood grown in temperate or seasonal climates is more influenced by climate than wood grown in tropical environments. As such, climate reconstruction using wood allows for broad categorical statements about paleoclimate, and can distinguish well between worldwide sites. However, in smaller areas (e.g., eastern North America), taxonomic overlap between sites can result in temperature differences that are not reflected in the wood assemblage (Kowalski, personal observation). In some areas, anatomical characters used in this type of climate reconstruction, such as the presence or absence of spiral thickening, do not vary significantly within species.

Cautions with using wood anatomy to determine paleoclimate are similar to those using leaf methods, such as the assumption that the relationship between climate and anatomy has been constant through time. Ideally, wood anatomy techniques could be used back into the Paleozoic. However, some wood characters used to estimate climate are derived (e.g., vessel characters such as vessel density and ring porosity). These wood characters developed with the evolution of angiosperms in the late Mesozoic (Francis and Poole, 2002), and thus these wood characters cannot be used to estimate the paleoclimate of the Paleozoic and early and middle Mesozoic.

Dendrochronology or tree ring analysis can be used to determine climate over several seasons, as each ring records aspects of moisture and temperature of one growing season. The resulting information details a long series of annual climate and climate changes, with a precision that few other records approach. Most information regarding the response of tree ring characteristics to climate has come from studies of conifers (Francis and Poole, 2002), although angiosperms are occasionally studied as well. A continuous record of annual tree rings has been established in the southwestern USA, extending back nearly 9,000 years. Changes in moisture and temperature of local climates often can be correlated to ancient human habitations and migrations. The presence/absence of tree rings is an indication of seasonality, often related to temperature (Francis and Poole, 2002). Ring presence, as an indicator of seasonality of temperature, is best determined from more than one taxa, as some tropical tree species possess rings and could be confused with temperate species. Tropical tree rings are most likely due to seasonality of precipitation or seasonal leaf loss (Woodcock and Ignas, 1994). Ring width is useful in determining growing conditions, with wide rings the product of warmer and wetter conditions or increased CO₂ (Beerling, 1999), and narrow rings produced under cooler or drier conditions (Francis and Poole, 2002). Occasionally, false rings occur, which can indicate a halt during the growing season due to fire, drought, insect damage or frost. Ring widths are best used for broad floral comparisons, rather than estimating the absolute temperature or humidity of one flora. Mean sensitivity measures the variability of tree rings from year to year, and gives an indication of the constancy of climate regime (Francis and Poole, 2002). Tree ring analyses can be performed on floras from the Recent to the Paleozoic but most applications have documented climate during the last 10,000 years.

Finally, the presence of charcoal in an assemblage can determine whether paleoO₂ levels are within the relatively narrow range associated with charcoal formation. Charcoal can only form within a relatively narrow O₂ range (Chaloner and McElwain, 1997). This area needs more research because plant parts are

frequently charcoaled and found in sediments from the Devonian to the Recent. Such fragments are known as mesofossils and can be used in floristic studies to assign nearest-living-relative climatic relationships.

Chemical signatures

Plants take up carbon, oxygen and hydrogen isotopes from atmospheric CO₂ and water during growth. These isotopes are incorporated into the plant structure. They preserve a record of the atmosphere and climate in which the plant grew. These records can show an individual season's values by looking at leaves or individual tree rings, or can show long-term fine-scale variations by comparing tree ring values over the life of the tree. $\delta^{13}\text{C}$ measurements are used to estimate paleoclimate, but have also been used to match CO₂ records of tree rings with ice core data to determine the exact ages of the trees being measured. ^{13}C is the most commonly measured isotopic ratio used to determine paleoclimate from plants, and is taken into the plant from CO₂ in the atmosphere during growth. In wood, ^{13}C ratios are measured in the cellulose and show a negative relationship with relative humidity and temperature (Edwards et al., 2000). ^{13}C measurements from the leaf cuticle also show a negative correlation between ^{13}C ratios and precipitation or humidity (Sun et al., 2003), (Figure P5).

In addition to ^{13}C , both $\delta^{18}\text{O}$ and $\delta^2\text{H}$ have been measured using wood cellulose and wood nitrite to determine variability in meteoric water, seasonal moisture (relative humidity and precipitation) and precipitation amount (Buhay and Edwards, 1995; Edwards et al., 2000). In addition, $\delta^2\text{H}$ shows a relationship with mean annual and seasonal temperature, though this relationship is best measured in areas where the water supply has a constant isotopic value (Buhay and Edwards, 1995). Because of the complex interaction between precipitation and temperature, climate estimates using measurements from only one isotope may be misleading. Using a combination of $\delta^{13}\text{C}$,

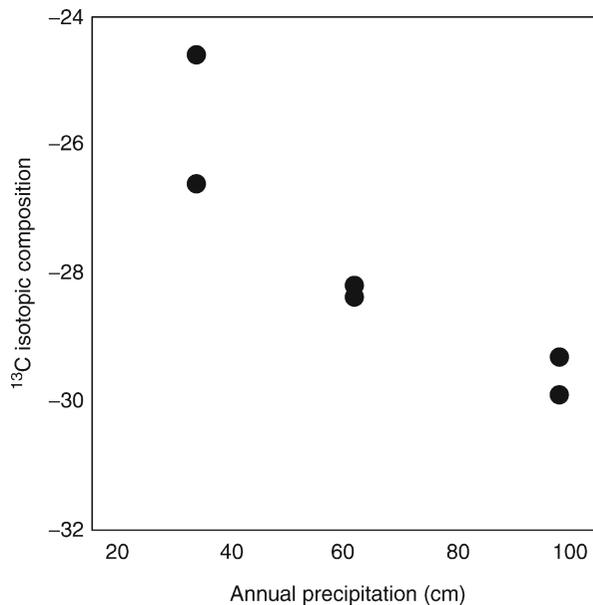

Figure P5 ^{13}C isotopic composition of modern *Ginkgo* leaves versus annual precipitation for three sites in China. Data from Sun et al. (2003).

$\delta^2\text{H}$ and $\delta^{18}\text{O}$ measurements seems to offer the most paleoclimatic information from plants (Edwards et al., 2000).

PALEOCEAN MODELING

Introduction

Paleoceanographic (paleocean) modeling is the application of analytic or numerical techniques to predict and understand the ocean's past circulation, biogeochemical interactions, and climate. Paleocean modeling is primarily a tool for exploring

the mechanistic functioning of the ocean and for making concrete predictions testable against paleoenvironmental proxies.

Paleocean modeling may be used to investigate such specific questions as: (a) What was the current structure and tracer distribution of a given past time interval? (b) How sensitive are major oceanographic features, e.g., the Gulf Stream or the meridional overturning circulation (MOC) to boundary condition changes? (c) How might modes of variability, e.g., interannual, interdecadal, and millennial-scale variability change under different conditions? It may also answer some more general questions, such as: (d) What is the role of the ocean in governing the Earth system's response to greenhouse gas (GHG) forcing, and what is the ocean's role in GHG storage and release through Earth's history? (e) To what degree are ocean heat transport (OHT) changes important for understanding climate change, and to what is OHT sensitive: GHGs, gateways, multiple equilibria? Due to recent advances in modeling, answers to these questions are now in the offing, once suitable data and a framework with which to interpret them can be developed.

Conditions are sufficiently close to the present for modeling intervals within the past several million years, such that modern numerical ocean modeling techniques are likely to work as well for the past as they do for modern times. Analytic, "box," and simplified physical models are general enough that they can be applied as readily to paleoceanographic problems. Biogeochemical models are crucial but difficult to extend into the deep past because many ecological and biogeochemical processes that only are moderately understood today are poorly known in the deep past.

This article will focus largely, therefore, on the use of sophisticated numerical models in time periods deep in the past (>3 Ma), before continents and climate had reached their near-modern states – first, on the unique challenges that arise in these periods; and next, on the techniques used to overcome these challenges. These special challenges are balanced by unique opportunities to study the evolution of climate and the Earth system over its full dynamic range. If chosen carefully, i.e., only when the environmental "signal" provided by proxies is much greater than the "noise" inherent in the uncertain physics of models, paleocean modeling answers questions that are impossible to answer within near-modern settings. We conclude with the main results of this young field and discuss some important future directions.

Challenges of paleocean modeling

The ocean is coupled to climate through its surface: via its state, i.e., sea surface temperatures (SSTs), and via fluxes of sunlight, heat, water, and momentum. It is also biogeochemically coupled to the biosphere, through fluxes of sunlight, carbon dioxide, and dust, and traces of organic and inorganic chemicals.

Thus, in order to understand the ocean's dynamics and phenomenology and to predict its role in climate and biogeochemical cycles it is necessary to constrain the state of – and fluxes through – the interface between ocean and atmosphere (Power and Kleeman, 1994; Seager et al., 1995).

Because the ocean is driven, to first order, from its top boundary – the conditions of which are poorly known in the past – paleocean modeling requires that either these surface conditions be quantitatively estimated, or in the best case, objectively prognosed within a coupled ocean-atmosphere model. There are, furthermore, only weak constraints on paleobathymetry, an important boundary condition for paleo-oceanographic modeling (Crowley, 1998), and vertical and horizontal ocean current

velocities that might be used as a test of model predictions are poorly known. Thus, there are two sets of problems – even given a perfect ocean model. How does one: (a) set up the model experiment, given significant sources of uncertainty, and (b) test model predictions if significant mismatches occur between what models predict and what proxies record? We begin with (a).

Setting up deep paleocean model experiments

Beyond the normal challenges associated with ocean modeling (e.g., Gent et al., 1998), deep past paleoceanographic simulations face three challenges: uncertainty introduced by choice of initial conditions, boundary conditions, and model spin up.

Initial conditions. Proxies that might be used as initial conditions for modeling experiments are sparsely distributed in time and space, have inherent uncertainties associated with them, and may not constrain important quantities (e.g., salinity). This challenge is usually overcome by specifying an initial sea surface temperature (SST) distribution derived from proxies or using output from an atmospheric general circulation model (AGCM), which in turn has predicted SSTs, assuming some distribution of oceanic mixed layer depth and heat transport. Surface salinities are normally based on output from such AGCM simulations after assuming an empirical relationship between precipitation minus evaporation (P–E) distributions and surface salinity, or alternatively, a global constant value can be specified as an initial condition. In paleoceanographic simulations carried out with a coupled ocean-atmosphere model, these initial conditions values may strongly deviate as a consequence of the model's evolution. In simulations that are not coupled to an atmospheric model, these distributions are more or less fixed (discussed below). Deep ocean temperatures are normally taken from benthic foraminifera-derived temperature estimates (where available) and salinity is frequently set at the modern global mean value or sometimes set to a different global mean value designed to include past variations in global mean salinity.

Boundary conditions. These include the way in which heat, moisture, and momentum fluxes are passed to the ocean model throughout the simulation as well as static features such as bathymetry. Fluxes have traditionally been handled through the use of so-called Haney restoring (Haney, 1971) of temperature and the specification of net virtual salt fluxes, i.e., mixed boundary conditions. In general, the "weaker" the restoring the more closely this boundary condition mimics atmospheric interaction, but mixed boundary conditions have been shown to be susceptible to spurious multiple equilibria (Weaver and Sarachik, 1991; Zhang et al., 1993; Power and Kleeman, 1993, 1994; Saravanan and McWilliams, 1995). The use of so-called bulk forcing (Brady et al., 1998; Doney et al., 1998), or preferably inclusion of even a simple representation of atmospheric fluxes as in Nong et al. (2000) and Najjar et al. (2002), is best in those cases in which a coupled model is not used. Surface wind stress patterns are normally specified based on modern conditions or a theoretical distribution, or produced by an AGCM.

Since a non-interactive atmosphere – i.e., one in which winds, temperature, and freshwater fluxes cannot adapt to changing ocean conditions – is inherently unrealistic, in most cases a coupled model is preferable to an uncoupled model, even when the focus is strictly oceanographic (Doney et al., 1998). This also allows for a more realistic pattern of surface state and flux variations, and for OHT to be a well-posed prognostic variable, which

it is not if surface temperature patterns are specified (Seager et al., 1995; Nong et al., 2000; Huber et al., 2003).

Ocean bathymetry is a boundary condition that has frequently been a subject of concern in the construction of paleocean modeling experiments (Bice et al., 1998). Some studies have employed a flat bottom configuration, eschewing bathymetric variation altogether (Barron and Peterson, 1991; Bush and Philander, 1997) and dynamical arguments suggest that most ocean current patterns and transports are not sensitive to bathymetric variations (summarized in Bush, 1997). Nevertheless, the details of some currents certainly involve bathymetry (Bice et al., 1998). Perhaps more importantly, the degree of upwelling from the abyss is governed to a large extent by the presence of abyssal bathymetric rises (e.g., geostrophically balanced meridional flows along ocean ridges) and thus some representation is probably important even for the gross features of the ocean circulation (e.g., Toggweiler and Samuels, 1995; Vallis, 2000).

The freshwater (salt) forcing of the ocean is another potentially important variable, with potential issues being the placement of continental runoff into marginal seas and determination of the overall meridional P–E. The former issue is important for determining the exact location of deep water formation (Bice et al., 1997) and the latter is a factor in determining strength of the MOC. However, neither of these issues proves fatal to the study of paleoclimates with ocean models (see below).

Deep ocean spin up procedure. Another difficulty with performing paleocean modeling experiments has been in integrating the entire system, including the deep ocean, to a quasi-steady state. Nevertheless, ocean models – at least the non-eddy resolving models employed in climate and paleoclimate studies – are computationally inexpensive relative to their atmospheric cousins. In ocean-only ocean general circulation model (OGCM) studies, it is now feasible to integrate the model to equilibrium without so-called deep ocean acceleration, although accelerating the deep ocean tracer fields during spin up has been shown to speed equilibration without unduly affecting the final climate state (Danabasoglu et al., 1996, 2004).

However, as described above, a coupled model is preferred for most climate purposes, so that surface temperature, salinity fields, ocean heat, and freshwater transport are fully prognostic. Many coupled models historically display a “drift” of climate away from modern values even under modern conditions, which have precluded them for use in paleoclimatology, but this modeling challenge has been overcome in the recent generation of models. It has not been feasible with existing computational resources to attempt the ideal solution with a coupled general circulation model (CGCM), which is to integrate several multi-millennial simulations. Two options exist: (a) using a simplified coupled model that is computationally less expensive, or (b) using a technique to accelerate convergence of a full CGCM.

Many simplified CGCMs or “intermediate” complexity models now exist, and in general, they are a useful tool in the modeling toolbox (Saravanan and McWilliams, 1995; Poussart et al., 1999; Weaver et al., 2001; Claussen et al., 2002). When these tools are not sufficient, iterative accelerated spin up techniques have been developed to allow several thousand years of deep ocean simulation to be carried out in only several hundred years of surface ocean computation using fully coupled GCMs.

There is a variety of techniques – most draw on two existing procedures: iteration of coupled and uncoupled modeling steps, and deep ocean acceleration. The iteration technique has been used and validated in somewhat different forms by Sausen and Voss (1996), Kutzbach and Liu (1997), Liu et al. (1999),

Vavrus et al. (2000), Huber and Sloan (2001), Otto-Bliesner et al. (2002), and Liu et al. (2004). Shin et al. (2003) describe a different technique that employs deep ocean acceleration directly in the fully coupled integration and this has been shown to produce convergent climates with the iterative technique in the Eocene, thus either family of techniques is a potential candidate for use. There are no guarantees that a given acceleration technique will apply equally well to all time intervals or that it can be generalized for different models or model configurations. Therefore, initial validation of the convergence of a given modeling framework to a reference condition (presumably the present) to some appropriate level of similarity is a primary requirement of any technique.

Minimal tests of model suitability. Although the models used in paleoceanography are usually well-validated for modern day conditions, even a “perfect” model for the present may not be perfect for the correct physical reasons (instead, tuning may be responsible), nor nearly as accurate with less accurate boundary conditions. Our incomplete knowledge of boundary and initial conditions for paleocean modeling, simplification of model physics, and/or use of acceleration techniques introduces errors into the simulation. Therefore, paleocean modeling investigations should be tailored to answering questions that can be answered with the level of detail available for the specified time interval. One method to assess the suitability of a model is a process called “degradation” (Huber and Sloan, 2001). This involves simplifying boundary conditions in the control case (i.e., changing bathymetry) and appropriate “detuning” of the model. A degraded control solution provides a benchmark to determine what model-predicted variables might potentially be robustly determined in the past. Degradation has been shown to provide one (minimum) estimate of the errors introduced into model predictions by misrepresenting multiple aspects of the system (Huber et al., 2003).

Modeling choices. No model is perfect, and many parameterizations and models in existence are better for some purposes than others. Nevertheless, there are some general guidelines, at least with complex, GCM caliber models, that should be considered. Oceanic vertical diffusion is one of the most important and most contentious issues in modern oceanography. It is likely to have been even more important in the past. The absolute “background” value of the diffusivity and the physical processes that increase it above this background value are much debated. While some spread exists for an estimate of this background value, a reasonable observed number is $0.1 \text{ cm}^2 \text{ s}^{-1}$, and values in this range should be the default in paleoceanographic applications. Values 10–100 times greater than this are commonly used even in modern simulations, which highlights the deficiencies in those models. The inclusion of state-of-the-art treatments of diapycnal and isopycnal eddy mixing is important, and currently it appears that a combination of the KPP and Gent-McWilliams treatments of these processes is best from the point of view of the tracer circulation and tracer properties (Gent et al., 1998). There is substantial room for improvement in these parameterizations and ideally several vertical diffusion methods should be tested because the resulting ocean circulations can be fundamentally different (e.g., Nilsson et al., 2003).

Predictions of paleocean modeling

Horizontal ocean currents. These are prognosed by OGCMs as well as a host of simplified models, and are the quantities most directly tied to the well-understood and well-represented

dynamics of the ocean. In general, an OGCM is not necessary to predict velocities. The surface and upper ocean flows largely reflect the driving wind fields, and consequently “shallow water” ocean models, or even analytic calculations such as the “island rule” or the Sverdrup transport allow estimates of the strength, shape, and disposition of gyre circulations as well as the western boundary currents in equilibrium with them for a given wind field (Huber and Nof, 2006; Nof, 2000; Nof and Van Gorder, 2002; see Figure P6). In the deep ocean, OGCM results have mainly reproduced features that were adducible from Stommel-Arons theory (see results in Huber et al., 2003). Such predictions may be verified with records of paleocirculation intensity and direction.

Unfortunately, current directions are weakly constrained and current magnitudes are among the most poorly known features in “deep-time” paleoceanography, since these features are not strongly constrained by direct proxies, and the indirect proxies are qualitative (Carter et al., 1996; McGowran et al., 1997; Watkins and Kennett, 1972). Nevertheless, a substantial amount of work has been done in predicting paleocean current directions and testing these against proxy interpretations. Some notable studies include those in the Permian (Winguth et al., 2002), the Cretaceous Tethyan current regime (Barron and Peterson, 1991; Bush and Philander, 1997), and in the global ocean (Poulsen et al., 1998, 2001), and on a regional scale, in the Turonian seaway (Slingerland et al., 1996). For more recent periods, attempts have been made to understand changes in flow direction between the Atlantic and Pacific, i.e., during the Miocene (Nof and Van Gorder, 2002; Nisancioglu et al., 2003; Omta and Dijkstra, 2003), although explicit model-data comparison has been lacking in these studies. The more widespread use of sediment and biological transport and dispersal models in such investigations would substantially assist in the

comparison to proxy records. Some first steps in that direction have been taken in Huber et al. (2004).

Upwelling and productivity. Upwelling is a feature more closely tied to the proxy record than ocean current direction because it is more directly linked to an observable quantity (productivity and burial). Understanding how upwelling patterns may have changed during the past can provide us with clues to the nature of circulation changes (Toggweiler and Samuels, 1995; Vallis, 2000), primary productivity shifts (Moore et al., 2004), and alterations in global cycling of chemical species that may have occurred. Upwelling predictions may be especially useful for placing constraints on organic carbon burial rates (Handoh et al., 1999, 2003) over these time intervals.

For the purely wind-driven component of upwelling, an OGCM is not particularly necessary; a “shallow water” model is adequate to the task (Handoh et al., 1999, 2003). Calculation of Ekman pumping from the wind fields produces nearly identical results.

Quantitatively tying the upwelling velocity to a sediment accumulation rate involves a deep understanding of many ecological and biogeochemical processes. Currently, our ability to make quantitative predictions on productivity, burial, and the carbon cycle in the past is more limited by our understanding of past biogeochemical cycles and paleoecology than by insights into past physical oceanography (more below).

Deep water formation and MOC

Transformation of surface waters into shallow mode and intermediate and deep waters, and subsequent recycling of these waters into the surface, is an important and complex process. It is fundamental to the redistribution of heat, nutrients, and other tracers in the ocean and is consequently of great interest in paleoceanography.

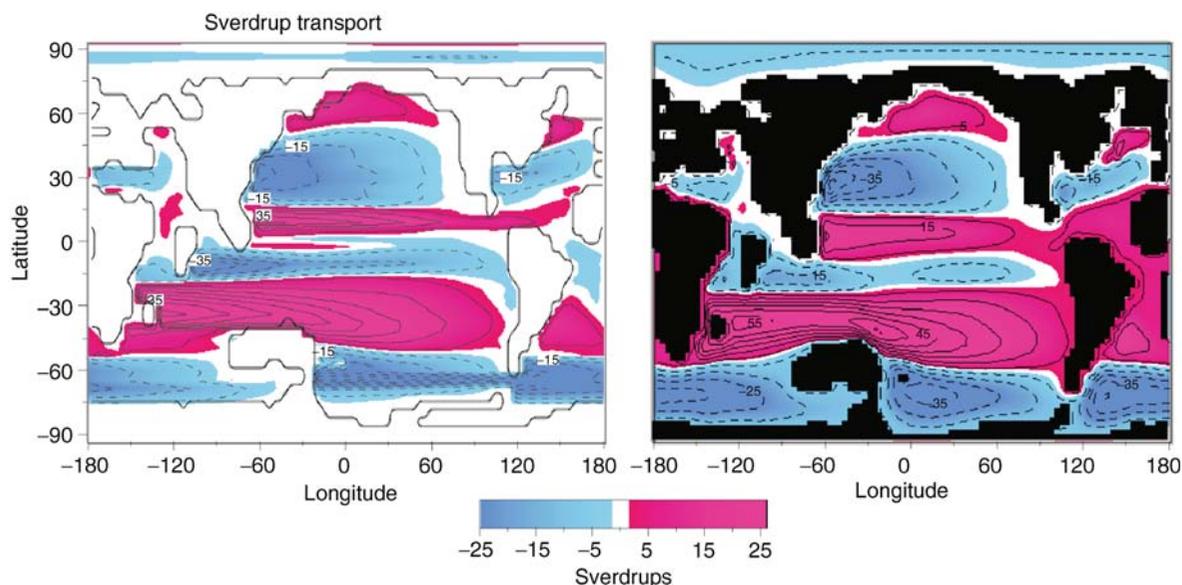

Figure P6 Results from Huber et al. (2004) for the theoretical wind-driven and general circulation model derived ocean circulations. The estimated wind-driven ocean gyre transport in equilibrium with the AGCM-derived winds calculated from the Sverdrup transport driven by the wind stress curl. Theory suggests to first order that barotropic velocities should correspond closely to the Sverdrup transport. Right, this is confirmed by comparison to the barotropic stream function produced by the ocean model. Clockwise gyres are indicated in *blue*, counterclockwise gyres in *red*. The flow is contoured at 10 Sverdrup intervals. The correspondence between the upper ocean velocities shows clearly that – if wind fields are well-known, or simply prescribed – the major ocean current systems will be entirely governed by this distribution.

Just as there are weak data-based constraints on ocean velocity, there are weak constraints on its integral properties, such as the meridional overturning streamfunction. One commonly applied constraint is the calculation of vertical and spatial gradients of $\delta^{13}\text{C}$, which is an isotopic tracer related to nutrient distribution and the carbon cycle (e.g., Corfield and Norris, 1996). Where sufficient $\delta^{13}\text{C}$ gradients exist, the location of regions of deep water formation can be ascertained and bulk flow patterns may be estimated. The use of other water mass tracers, such as neodymium (e.g., Thomas, 2004), is a recent innovation that may add significant detail to the picture that has developed from $\delta^{13}\text{C}$ tracer distributions.

Rates of deep water formation and deep water flow are not currently predictable from these methods, which is unfortunate because these are the quantities that bear directly on the critical paleoceanographic questions, whereas the *location* of deep water formation reveals little, by itself, about the ability of the circulation to transport heat or nutrients.

The rate at which heat is transported by circulation is a function of the velocities, diffusion, and temperature gradients, and analogous balances obtained for the transport of all tracers. Thus the main importance of the location of deep water formation, i.e., whether it occurs at high latitudes or at low latitudes, is indirect, through its relationship with the resulting transport rates and tracer gradients. Some debate exists as to whether true deep water formation at low latitudes was physically possible in the Earth's past – results and interpretations vary from model to model (compare Saravanan and McWilliams, 1995; Bice and Marotzke, 2002; Zhang et al., 2002). In general, even in simulations in which low latitude deep water formation occurs, it is either weak or transient, and is associated with a decrease in OHT (see below).

Proxy records of benthic oxygenation have been employed as constraints on overturning circulation rates in the oceans. These records are difficult to interpret because they involve deconvolution of the competing influences of the supply of organic matter and oxygen to the deep. Both factors may increase as the overturning rate increases – increased oxygen supply occurs as the overturning strengthens, but increased upwelling of nutrient rich waters may enhance export of organics out of the surface and into the deep. For a revealing view of the divergences of interpretation that can occur, compare Zhang et al. (2001) and Hotinski et al. (2001).

Without improvement of our understanding of past biogeochemical cycles and the development of multiple and independent proxies for upwelling, productivity, oxygenation, and deep water formation, it is unlikely that it will be possible to discriminate between different models of the ocean's overturning circulation in the deep past.

Ocean gateways and heat transport

Past climate changes have been frequently attributed to ocean gateway changes – such as the opening of Drake Passage and closing of the Panamanian Gateway (Kennett, 1977; Crowley 1998; Lawver and Gahagan, 1998). This belief finds its support in the approximate correlation between major gateway changes and climatic change (Zachos et al., 2001). A number of modeling studies have demonstrated that the ocean's overturning circulation, heat transport, and resulting temperature distribution are somewhat sensitive to changes in ocean gateways (Mikolajewicz et al., 1993, 1997). There is, furthermore, a strong line of theoretical and modeling evidence that backs

up the theory that wind-driven upwelling of deep water in the Southern Ocean plays a dominant role in modern day ocean circulation (Toggweiler and Samuels, 1995; Nof, 2000) and that past changes in this upwelling may have been especially important at both high latitudes (Toggweiler and Bjornsson, 2000) and low latitudes (Hotinski and Toggweiler, 2003). The most frequently cited example of a direct impact of gateway changes on OHT is due to the creation of the Antarctic Circumpolar Current (ACC). As noted in Toggweiler and Bjornsson (2000), creation of the ACC leads to a cooling of the Southern Hemisphere, and a warming of the Northern Hemisphere, because the flows associated with the ACC “steal” heat across the equator.

While all of the above studies yield similar predictions with respect to the physical oceanographic responses to gateway changes, the surface temperature response, i.e., the climatic impact of this change shows a wide spread. In studies in which a simple representation of coupling of ocean-atmosphere exchanges has been included, opening and closing of Southern Ocean gateways result in Southern Ocean surface temperature changes from a low value of 0.8°C (Mikolajewicz et al., 1993), to a middle range of ~1.5°C (Nong et al., 2000), and a high value of ~3.5°C (Toggweiler and Bjornsson, 2000; Najjar et al., 2002). When a CGCM is used, the resulting change within the Southern Ocean is in the middle of the range of previous estimates (Huber and Sloan, 2001; Huber et al., 2003). The spread of values represents differences in the treatment of the “top” boundary condition, including sea ice feedbacks and damping by the atmosphere, rather than representing an important difference in predicted ocean dynamics behavior.

The mechanism that links gateways to climate change is usually presumed to be ocean heat modifications induced by shifts in ocean currents. The impacts that such ocean current changes have had on ocean productivity and burial and hence global inventories of atmospheric GHGs have received less attention in comparison (Huber et al., 2003).

Some lessons learned

Paleocean modeling has been applied to a suite of paleoclimate problems in Earth's history – mostly, it has focused on the leading role played by changes in greenhouse gas concentrations. Results from this work indicate that, within a sophisticated coupled modeling framework, ocean temperatures in line with proxies for both past “greenhouse” and “icehouse” intervals are generally achievable without major changes in ocean circulation, but are driven by changes in deep water temperatures (Huber and Sloan, 2001; Otto-Bliessner et al., 2002; Poulsen et al., 2002; Shin et al., 2002; Peltier and Solheim, 2004). See Figure P7 for a Cretaceous example.

The main current limitation of physical paleocean modeling in paleoclimatology is the availability and accuracy of data for inclusion in initial and boundary conditions and the need for a suite of proxies sufficient to verify and validate the model predictions. Fully coupled modeling offers the advantage of increasing the range of model predictions testable against proxies (Huber and Caballero, 2003). Modeling of biological, isotopic, ecological, and geochemical processes for the deep past lags behind physical modeling by a significant margin and the current sophistication of these efforts may be considered rudimentary, despite significant efforts to improve the situation (e.g., Heinze and Crowley, 1997). The next main challenge of paleoceanographic modeling is to close the gap

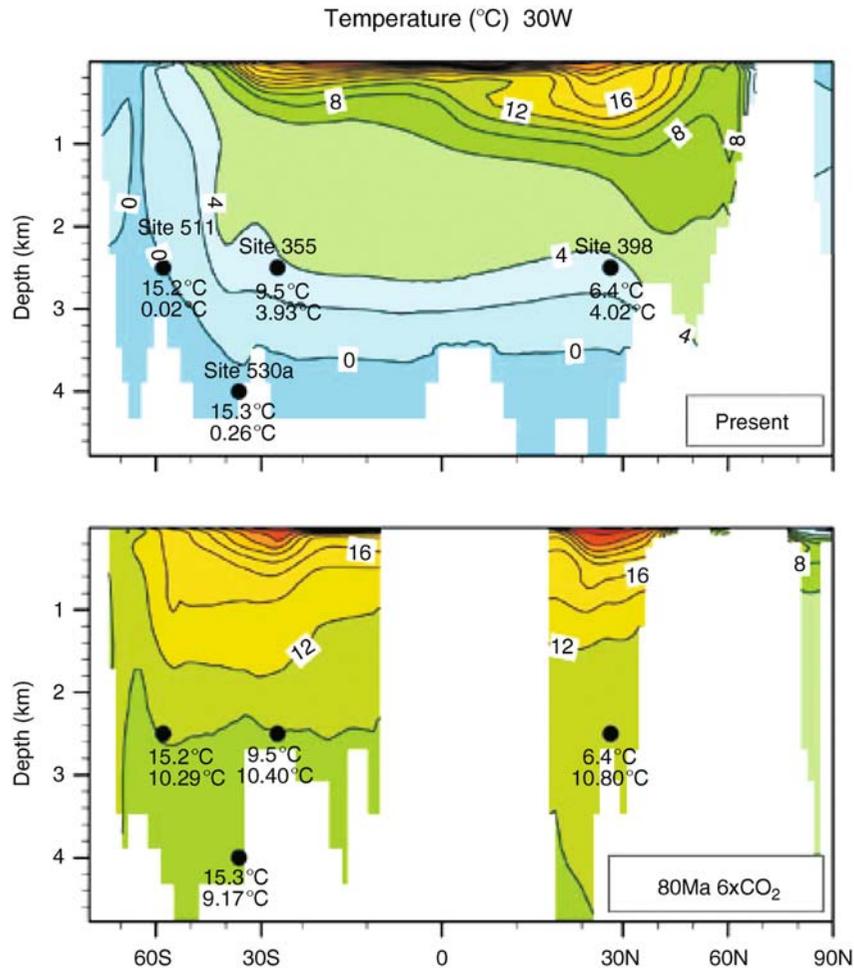

Figure P7 Cretaceous paleotemperature estimates published from ODP and DSDP cores based on deep-dwelling fauna are sparse and exhibit a wide range of values, but point to a much warmer deep ocean. For a transect in the Atlantic Ocean, the NCAR Climate System Model predicts ocean temperatures below 2.5 km depth of approximately 10°C (*bottom values*) compared with proxy estimates of 6–15°C (*top values*). The model simulation indicates that the source of the warmer deep ocean temperatures is sinking of warmer southern polar waters. See Otto-Bliesner et al. (2002) for more details.

between the physics of the ocean and the biology, sedimentology, and chemistry that provides key constraints on the paleoclimatic record as well as being of fundamental importance to paleoclimate itself.

PALEOCEANOGRAPHY

Introduction

Paleoceanography is the study of the history of the oceans. It encompasses aspects of oceanography, climatology, biology, chemistry and geology. The main sources of information are biogenic and inorganic marine sediments, as well as corals. Biogenic sediment includes planktonic and benthic fossils whereas inorganic sediment includes ice-rafted debris and dust. On land, paleo-shorelines and erosional features as well as outcroppings of paleomarine sediments are the principal sources of proxy data. Glaciological records can also give indirect information about paleoceans. The ocean's high heat capacity and its ability to transport energy and to sequester and release greenhouse gases give it an important role in helping to determine the state of the planet's climate. Thus, paleoceanographic research is also intimately linked to paleoclimatology.

Methods

The reconstruction of paleocean characteristics and dynamics requires climatic detective work. It involves the dating and interpretation of paleoclimatic records as well as the definition of physical and dynamical constraints which specify possible circulation patterns and characteristics.

Reconstructions (Proxy Data)

Direct measurements of the quantities of interest to oceanographers extend only into the relatively recent past and in most cases do not go further back than the mid-nineteenth century. To study the ocean during periods for which there are no direct measurements one must rely on indirect evidence. Historical documents can be used as sources of data. Ship logbooks and sailing times across frequently traveled routes have provided estimates of the directions and strengths of past prevailing winds (Brazdil et al., 2005). The frequency and intensity of El Niño events since the 1500s have been reconstructed based partially on historical accounts of large floods and crop losses (Quinn and Neal, 1987). This type of analysis furnishes qualitative descriptions of the past.

Quantitative reconstructions are possible by proxy, where a quantity which is preserved in a natural archive and can be measured, stands as a surrogate of the parameter of interest. A basic requirement is that the relationship between the proxy parameter and the quantity of interest has to be known. When this is the case, the history of the proxy variable can be converted into the history of the variable of interest by the use of mathematical expressions of the type:

$$Int_t = f(Prx_t) \quad (1)$$

which state that the parameter of interest, Int_t , is a function of the proxy quantity, Prx_t . The t index refers to time. Equations of this kind are commonly called *transfer functions*. The confidence with which Int_t can be estimated will depend on a series of factors, starting with the quality of the proxy measurements. Also relevant, and a common source of uncertainty, is how well f represents the relationship between Prx_t and Int_t .

In most cases, transfer functions are obtained empirically by comparing directly measured values of the quantity of interest to a pertinent set of proxy data. A potential source of error is that the function obtained by this procedure might not be general, but in fact could represent a relationship between Prx_t and Int_t that is peculiar to the data sets used to generate f . This problem can be minimized by expanding the spatial and temporal coverage of the data used to establish the transfer function. Still, even assuming that f is a perfect representation of how the proxy and the quantity of interest are connected to each other in the present, there is no guarantee that the relationship between them was the same in the past.

Another source of error can be easily understood by re-writing Equation (1) so that it expresses the proxy quantity as a function of the variable of interest. It is reasonable to assume (and in many cases it has been demonstrated) that Int_t is not the only factor controlling Prx_t , so that in fact we end up with:

$$Prx_t = f^{-1}(Int_t, E_{1t}, E_{2t}, \dots, E_{nt}) \quad (2)$$

where E_1, E_2, \dots, E_n represent environmental parameters that also influence the proxy variable but are independent of the quantity of interest. An immediate conclusion is that reconstructions of Int_t based on Prx_t will be "contaminated" by other

factors so that part of the variability observed in the proxy quantity is not related to changes in the parameter of interest. Comprehensive analysis of the relationships between proxies and a series of observed parameters can offer some insight into how to remove part of the undesired influence of other factors from the reconstruction.

Given the complexity involved in developing skillful transfer functions as well as in identifying and correcting for potential sources of error, a common strategy is to reconstruct the same parameter of interest using different proxies. Such analyses are known as multi-proxy reconstructions (Fischer and Wefer, 1999).

Types of proxies:

The systematic use of proxies in quantitative reconstructions of past oceanic environments originated in the second half of the twentieth century. Since then, a large number of proxy techniques have been established and more are constantly being developed. Proxies can be grouped in six broad categories, based on the type of direct measurement (Fischer and Wefer, 1999). These are listed below, together with brief descriptions of the main variables of interest associated with each proxy. The following chapters on paleotemperature, paleoproductivity and paleocirculation present in more detail the proxies relevant to each of these fields. Comprehensive discussions of oceanographic proxies can be found in the literature (Bradley, 1999; Fischer and Wefer, 1999; Henderson, 2002).

- *Microfossil assemblages.* The relative abundance of planktonic and benthic species of foraminifera, coccoliths, radiolaria, diatoms and other organisms can be used to estimate past ocean temperature, productivity and sea ice distribution. This proxy type was used for the CLIMAP project, which produced the first global distribution of sea surface temperature for the Last Glacial Maximum (CLIMAP – Project Members, 1976).
- *Stable isotopes* are based on the ratio between different isotopes of an element. The ratios are usually standardized by a reference value and named after the heavier isotope. The ratio between ^{18}O and ^{16}O , for example, is represented by $\delta^{18}\text{O}$. Isotope readings are retrieved mainly from foraminifera skeletons (tests), organic matter or other sources (e.g., water molecules in continental ice sheets). The amount of ^{18}O incorporated by organisms like foraminifera and corals increases as temperature decreases. Continental ice is relatively depleted in ^{18}O compared to sea water. This makes $\delta^{18}\text{O}$ a proxy for both temperature and the extent of continental ice sheets. $\delta^{11}\text{B}$ is used as a proxy for pH. Productivity, nutrient concentration and past circulation can be reconstructed from $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ (^{12}C is taken up with slight preference to ^{13}C during photosynthesis). Together with microfossil assemblages, $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ are the paleoceanographic proxies with the most widespread use.
- *Radiogenic isotopes.* The different solubilities of uranium and two products of its naturally occurring decay, thorium (Th) and protactinium (Pa) can be used to estimate the rate of deep water flow and the flux of particles from the water column to the sediments. This flux can also be used as a productivity estimate. ^{14}C preserved in organic matter is used to estimate the age difference between near surface and deep waters and hence, ventilation rates.
- *Biogenic compounds.* The concentrations of some compounds, mainly organic carbon, calcium carbonate and opal,

are used as estimates of past productivity. Calcium carbonate is also an indicator of the calcite compensation depth. Alkenones are long chained organic molecules resistant to degradation. The alkenones produced by some coccolithophors can have two or three double bonds in their structure. The ratio between molecules with two and three double bonds reflect the temperature at the time of synthesis.

- *Elements.* The concentrations and ratios of certain elements in the sediment, organic remains, tests and corals are also used as proxies. The ratios of strontium to calcium (Sr/Ca) and magnesium to calcium (Mg/Ca) in biologically precipitated marine carbonates are temperature dependent. The cadmium to calcium (Cd/Ca) ratio is used for nutrient reconstructions. Barium concentration and the Ba/Ca ratio are proxies for productivity and alkalinity, respectively.
- *Sedimentology.* Grain size distribution can provide qualitative information about bottom current speeds and act as an indicator of ice rafted debris. Information about past tides can be inferred from layered sediments called rhythmites. The mineralogy of the sediments can be used to establish source areas and direction of transport for both water and wind borne sediments.

Conspicuously absent from the quantities of interest listed above is salinity, a fundamental parameter which influences many aspects of the ocean environment. There is, at the moment, no independent proxy for this quantity. As salinity also influences $\delta^{18}\text{O}$, an indirect measurement can be obtained by using independent estimates of temperature (alkenones, for example) to remove the temperature signal from existing $\delta^{18}\text{O}$ series. Attempts have also been made to infer salinity from microfossil assemblages. Unfortunately, both approaches generate errors of ~ 1 psu, very large compared to the range of salinity variability in the oceans (Fischer and Wefer, 1999).

Reconstructions (Models)

The theoretical approach to paleoceanography uses quantitative ocean and climate models to reconstruct paleoconditions of the ocean and interpret observations. A number of different ocean and coupled climate models have been used in the past and we will give a very short overview of the hierarchy and use of these models in the broad research area of paleoceanography.

It is, of course, impossible to build an exact model of the climate system; for the ocean alone, the position and momentum of approximately 5×10^{46} molecules would have to be calculated at each instant of time. As an alternative, the ocean, atmosphere, sea ice, or land surface is split into discrete macroscopic elements with measurable characteristics such as temperature, density, velocity, etc. The state of and exchange between these discrete elements follow physical laws and can therefore be determined with numerical models. Small scale processes within each element can also influence the large scale pattern and therefore have to be parametrized. Existing ocean (and climate) models differ in regards to:

- their temporal and spatial resolution (resolution is defined as the spatial scale which defines the boundary between processes that are resolved by the model and those which are parametrized)
- the nature of processes which are resolved (for example, some models include biogeochemical cycles whereas other models resolve physical processes only)

- the number of subsystems taken into account (for example, an ocean model needs boundary conditions at the surface which can either be provided by data, or by an atmosphere model which is physically interacting with the ocean model)

As the different subsystems (ocean, atmosphere, sea ice, continental ice sheets, vegetation, etc.) of the climate system interact with each other in a complex manner and on a very broad range of timescales, climate modelling reduces to the process of identifying isolable subsystems and processes that are relevant to the problem at hand. While identifying these subsystems and processes, the researcher has also to keep in mind that these processes have to be suitable to be simulated by limited mathematical models and will provide results in a reasonable computational time (Crowley and North, 1991).

The simplest class of climate models includes one-dimensional Energy Balance Models which were first developed by Budyko (1969) and Sellers (1969). It is interesting to note that these simple models yield two stable solutions under present day boundary conditions: the present day climate and a completely frozen Earth (also called “Snowball Earth”).

Today’s physical ocean models can be classified based on the following categories:

- geography (regional models, global models)
- physics (hydrodynamic, thermodynamic or hydro-thermodynamic models)
- surface approximation (free surface, rigid lid)
- vertical discretization (fixed level, isopycnal, sigma-coordinate, semi-spectral)
- density variation (barotropic, baroclinic)

Because the boundary data for paleoclimatic simulations tend to contain large uncertainties, global models are better suited for this research area than regional models. The most comprehensive results are given by global ocean general circulation models (OGCMs). These models can be driven with reconstructed data specifying the boundary conditions. For example, numerous modelling studies restored the ocean surface characteristics to the CLIMAP data set (CLIMAP – Project Members, 1976) for simulations of the Last Glacial Maximum.

A better approach than using ocean-only models is to use coupled ocean-atmosphere models; by computing the surface boundary conditions, one can bypass the data problem. However, coupled ocean-atmosphere GCMs often need flux adjustments. Flux adjustments balance surface fluxes at the ocean-atmosphere interface to avoid a numerical drift of the coupled system. As flux adjustments have been “tuned” to the present day climate, the use of these adjustments to simulate past climates is not very reliable. However, some recent studies use coupled atmosphere-ocean GCMs which do not need artificial flux adjustments (e.g., LeGrande et al., 2006).

Some studies use simple atmosphere models which still provide reasonable boundary conditions for the ocean model (Weaver et al., 2001). Other climate subsystems may also have an important influence on the state of the ocean (continental ice sheets, sea ice and land surface processes for example). The class of Earth System Models has been developed recently and comprise all models which take into account more than two subsystems of the climate system. Today, Earth System Models are widely used for paleoceanographic and paleoclimate simulations. There is also growing evidence that geochemical interactions between the subsystems are more important than initially thought (carbon cycle, nitrogen cycle, methane, etc.) and some initial attempts in integrating these

cycles in Earth System Climate models for paleoclimatic simulations have been made (Crucifix, 2005). The modelling community is continuously integrating new processes and subsystems in their models to obtain a better representation of the climate system dynamics.

Combining models and proxy data

The interpretation of paleoproxy data is an ongoing challenge for paleoclimate scientists. As a striking example, one could compare the studies of Clark et al. (2002) and Bond et al. (2001). Both papers are highly regarded, yet draw opposite conclusions from the atmospheric $\Delta^{14}\text{C}$ record. Whereas Bond et al. (2001) relate the variability of atmospheric $\Delta^{14}\text{C}$ to changes in solar radiation, Clark et al. (2002) interpret the same type of record as a signature of variability in the thermohaline circulation and ocean heat transport. On the other hand, model simulations of past climates depend strongly on boundary conditions, assumptions, and the model used for the study. The simulated climate for a certain time span can be radically different depending on the model and boundary conditions used. Interpretation of measured paleoclimate data is thus urgently needed through collaboration between modellers and observers.

One possible approach to combine proxy data with climate models is that of “data assimilation.” Data assimilation involves the construction of a field that accommodates best the information obtained from paleoproxies with the physical (and dynamical) constraints of the climate system using coupled climate models (e.g., Paul and Schäfer-Neth, 2005).

Another possible approach is to incorporate paleoproxy data (e.g., $\delta^{18}\text{O}$, deuterium excess, $\Delta^{14}\text{C}$, $\delta^{13}\text{C}$, $\delta^{10}\text{Be}$, etc.) as prognostic active tracers in climate models. Perturbations (such as meltwater events or changing solar activity) and other climate states (e.g., the Last Glacial Maximum) can then be simulated and the behaviour of these simulated proxies can be compared to observed proxy data obtained from ice cores, marine sediments and other records. This has been done with uncoupled ocean (or atmosphere) general circulation models (e.g., Schmidt, 1999; Werner et al., 2000; Butzin et al., 2005), vegetation models (Kaplan et al., 2002) and continental ice sheet models (e.g., Clarke et al., 2005). However, the importance of interactions between atmosphere, oceans and other systems such as the biosphere and the cryosphere point to the necessity of using coupled models. To date, there have been only a few studies simulating paleoproxy data with either coupled ocean-atmosphere GCMs or Earth System Models (e.g., Stocker and Wright, 1996; Meissner et al., 2003; Roche et al., 2004; Crucifix, 2005; LeGrande et al., 2006).

A third way to bridge the gap between the modelling and proxy data approach is to find locations of proxy data records of special interest with the use of climate models. A simulation including prognostic paleoproxy tracers can determine the geographical region of greatest impact on a given paleoproxy data during a given climate event.

In conclusion, large amounts of paleoproxy data have been retrieved from various types of archives, but attempts to use numerical models for verification and interpretation of this data are sparse. The science of using three-dimensional climate models to interpret paleo records is still in its infancy.

Processes

In this Section, we give a short overview of the processes and boundary conditions which might have influenced the oceans in the past.

Paleotides

The history of tides over geological time is associated with the evolution of the Earth-Moon system and the shape of ocean basins. Tidal currents generate friction at the bottom of the ocean resulting in the transfer of energy and angular momentum associated with the Earth's rotation to the Moon's orbital motion. This process has been gradually slowing the Earth's spin and increasing the radius of the Moon's orbit. According to some estimates, at ~620 million years ago (Ma), days were approximately 22 h long and the Earth-Moon distance was about 96% of its present day value (Williams, 2000). The main proxy for tidal (and Earth-Moon system) changes over periods of millions of years is based on the analysis of tidal rhythmites, laminated sediments whose deposition is associated with tidal currents (Williams, 2000).

Tidal dissipation depends strongly on the shape of ocean basins. As tectonic processes cause the basins to change, the effects of tidal friction should also change. There are many indications that this is the case. For example, the present rates of dissipation appear to be higher than the average rates over the planet's history (Kagan, 1997; Gills and Ray, 1999).

Over the Quaternary, the shape of ocean basins was altered due to changes in sea level and the presence or absence of ice shelves. Numerical models show that in the Labrador Sea, tidal amplitudes during the last glacial were about twice as large compared to present day conditions. This has led to the suggestion that these higher tides could have destabilized floating ice shelves and caused Heinrich events (Arbic et al., 2004). Another connection between tides and climate relates to a millennial tidal cycle. It has been proposed that very high tides, occurring every 1,800 years, can cause increased mixing and cooling of the sea surface. This cooling would be related to abrupt climate change observed with similar periodicity (Keeling and Whorf, 2000). Some researchers contest this hypothesis, arguing that tidal forcing at these frequencies is very weak (Munk et al., 2001).

Radiation

Incoming short wave radiation from the Sun is the ultimate source of energy for ocean dynamics, the hydrological cycle and life in the oceans. Geographic and seasonal variations in the intensity of insolation result in temperature and pressure gradients which have an important influence on ocean dynamics and the climate system. Although the ocean surface circulation is mostly wind driven, the winds themselves are the result of the uneven distribution of energy on Earth. Density driven currents on the other hand depend strongly on temperature (and thus indirectly on energy distribution) and salinity gradients (which result from precipitation/evaporation patterns and are thus closely linked to the hydrological cycle).

Incoming solar radiation changes over a range of very different timescales. Firstly, the solar luminosity has gradually increased throughout the Earth's lifetime. It is estimated that, during the early days of our planet, the solar luminosity was 25–30% weaker than today's value. According to model results, such a reduction in incoming shortwave radiation should result in a completely frozen planet ("Snowball Earth"). However, even if evidence exists for snowball Earth conditions in early Earth's climate history, there is also counter evidence that during long periods of time the paleoceans were ice-free. Thus, it is inferred that, at these times, greenhouse gas concentrations must have been higher than present day levels in order

to prevent the system from slipping into an icehouse state (see *Faint young Sun paradox*, this volume).

On shorter timescales (order of tens to hundred thousands of years), the incoming solar radiation is modulated by changes in the Earth's orbital parameters which describe the character of the Earth's orbit around the Sun. These three parameters change continuously, causing a variation in the total amount of solar radiation received on Earth as well as the seasonal and latitudinal distribution of insolation. The first parameter, called eccentricity, describes the degree of ellipticity in the Earth's orbit around the Sun and hence the shape of its orbit. The characteristic periods of changes in eccentricity are 95,000, 131,000, 413,000, and 2,100,000 years. Eccentricity is the only parameter which modulates the total global amount of solar energy received at the top of the atmosphere. The change in Earth's axial tilt through time is described by obliquity and has a distinct period of 41,000 years. Finally, the precession of the equinoxes combines the axial precession (wobbling of the axis) and the precession of the ellipse (rotation of the elliptical shape of Earth's orbit) and consists of a strong cycle with a 23,000 year period and a weaker one with a 19,000 year period (Ruddiman, 2000). Precession and obliquity do not alter the total amount of solar radiation received, however, they change the distribution of incoming radiation by latitude and by season. All the frequencies of these parameters can be found in climatological records of the paleocean. Thus, orbital parameters play an important role in driving the climate system and ocean dynamics.

Finally, short-term variability in solar luminosity (which is correlated with changes in the number of sunspots visible on the Sun's surface) acts on timescales of decades to millenia. Over the last hundred years, the global mean temperature has followed a trend similar to the sunspot record. Some climate scientists have hypothesized that periods of global cooling (e.g., the Little Ice Age (~1560–1850)) have been partly caused by a minimum in sunspots (Spörer sunspot minimum (1460–1550) and Maunder sunspot minimum (1645–1715)).

Ocean basin changes

The shape of the ocean basins sets the boundary conditions for the ocean circulation. Different continent configurations result in different flow patterns. Understanding how the boundaries influenced past circulation patterns might offer insight into the dynamics and other important processes of the present day oceans. For example, the existence of an unobstructed low latitude passage in the Tethys Ocean (~160–14 Ma) has been associated with increased poleward heat transport (Hotinski and Toggweiler, 2003). Of course, both reconstructions and simulations of ocean currents this far into the past are subject to many uncertainties. For example, even the existence of a prominent, large scale feature such as the Tethys circum-equatorial current is still not unequivocally accepted (Barron and Peterson, 1989; Bush, 1997; Poulsen et al., 1998; Hotinski and Toggweiler, 2003).

A number of proxy and modelling studies show that the opening and closing of passages between two basins can have a large impact on ocean circulation and climate. The closing of the isthmus of Panama which is the gap between the North and South American continents at ~5–3 Ma is thought to have intensified the Gulf Stream and the associated northward transport of heat and salt into the North Atlantic (Haug and Tiedemann, 1998). The closure of the isthmus of Panama has

also been associated with the onset of Northern Hemisphere glaciation (Keigwin, 1982; Lear et al., 2003; Mudelsee and Raymo, 2005) as well as with changes in water mass properties and the overturning circulation of the North Pacific (Motoi et al., 2005). The opening of the Drake passage between Antarctica and South America (~28–33 Ma) and subsequent establishment of the Antarctic Circumpolar Current is associated with the glaciation of the Antarctic continent (Kennett, 1977; Toggweiler and Bjornsson, 2000). It has been proposed that the relative stability of the Atlantic Meridional Overturning Circulation (MOC) during the Holocene is related to the open connection between the Arctic and Pacific Oceans provided by the Bering Strait (De Boer and Nof, 2004). According to this scenario, low salinity anomalies in the North Atlantic make the MOC unstable when the strait is blocked (as during the last glacial). On the other hand, the flux of low salinity water from the Pacific into the Arctic through a wide open Bering Strait during conditions with higher sea levels (last interglacial, ~115–130 ka BP) has been linked to the more unstable MOC (Shaffer and Bendsten, 1994).

Oscillations in sea level result in changes of the surface's land to ocean ratio which in turn influences the planetary albedo. According to model results, alteration of the planet's albedo caused by a sea level drop of approximately 400 m during the late Ordovician (~455–445 Ma) was one of the factors that could have driven the climate into a cooler state (Herrmann et al., 2004). By submerging vegetated areas or making new land available to plants, changes in sea level can also impact carbon storage. The amount of carbon present on shelves inundated by the rise in sea level since the Last Glacial Maximum appears to be equivalent to the increase in the atmospheric stock of carbon during the same period (Montenegro et al., 2006).

Ice

A gradual cooling over the last 55 million years led to the presence of extensive continental ice sheets in both the Southern and Northern Hemisphere. Intensification of Northern Hemisphere glaciation in Eurasia and North America occurred between 2.7 and 2.5 Ma. With increasing terrestrial ice sheets, sediment records show an intensification of climate oscillations between extreme cold glacial maxima and interglacial warm periods on timescales related to the orbital parameters. The boundary conditions for paleoceans varied dramatically between glacial and interglacial periods. The formation and melting of extensive ice sheets in North America and Eurasia, important variations in atmospheric CO₂ concentrations as well as shifts in the extent of sea ice changed the radiation balance, salinity distribution, dynamical forcing and productivity of the oceans.

Continental ice sheets

Continental ice sheet growth and decay during glacial cycles may have influenced the ocean circulation in several ways:

- Sea level changes due to the storage of freshwater on continents and bedrock depression may have led to different circulation patterns in the ocean.
- Extraction of freshwater from the ocean to build up continental ice sheets led to changes in the global average and distribution of ocean salinity. These changes in salinity (and therefore density) may in turn have influenced the circulation and heat transport (Meissner and Gerdes, 2002).

- Changes in land surface albedo altered the local radiation balance over continental ice sheets, which in turn must have changed sea surface temperatures and circulation.
- Elevation changes in regions of continental ice sheets could also have caused changes in atmospheric circulation (Lehman, 1993) by affecting the atmosphere's stationary wave pattern (Jackson, 2000) and therefore the dynamic forcing of the ocean circulation.
- Changes in global atmospheric temperatures resulting from the presence or absence of ice sheets led to changes in ocean temperatures which may in turn have affected the circulation and heat transport.

Climate variability on millennial time scales has been more important during glacial periods than during interglacials. Dansgaard-Oeschger temperature oscillations, which seem to be part of slow-cooling cycles occurring every 10–15 kyr (Dansgaard et al., 1993), have been related in several studies to changes in the strength of the meridional overturning (MOC, see *Thermohaline Circulation*, this volume). Local sea surface salinity perturbations at high latitudes due to meltwater and/or iceberg discharges (Heinrich Events) may have weakened the MOC (e.g., Rahmstorf, 1995 and references therein) leading to abrupt climate change (Broecker, 1994; Manabe and Stouffer, 1995).

Sea ice

Sea ice regulates exchanges of heat and freshwater between ocean and atmosphere and can change sea surface salinity through melting or freezing (brine rejection). It insulates the relatively warm ocean water from the cold polar atmosphere, changes the surface albedo (and therefore the local radiation balance) dramatically and influences evaporation and therefore local cloud cover and precipitation. By changing the surface characteristics of the oceans, sea ice plays an important role in deep water formation and meridional heat transport in the ocean. The positive ice-albedo climate feedback might have led to a "run away" icehouse feedback in the Precambrian ("Snowball Earth," Hoffman et al., 1998).

Conclusion

Paleoceanography is an exciting research area that unifies specialists with a broad range of backgrounds. Scientists in each of the two classical schools of paleoceanography (reconstructions through proxy data and theoretical quantitative analysis using models) are more and more exchanging expertise and working together for a better understanding of the past oceanographic environment. However, inherent problems associated with the poor spatial and temporal resolution of proxy data as well as uncertainties related to the proxy data themselves make their interpretation difficult and sometimes impossible. At the same time, models are limited by resolved processes, resolution and the quality of boundary conditions. Overall, there is much progress to be made in both fields. In spite of these problems, the geological data as well as model simulations provide a substantial set of results which gives us some insight on how the ocean and the whole climate system functions. This knowledge is of ultimate importance to understand and predict future climate changes due to anthropogenic perturbations.

PALEOCENE-EOCENE THERMAL MAXIMUM

Approximately 55.5 Ma ago in marine and terrestrial sections all around the globe, there was an exceptionally large carbon isotope ($\delta^{13}\text{C}$) excursion (CIE) which is unique in the Tertiary for its size and rapidity of its onset. This event, which was first recognized in multiple cores by Kennett and Stott (1991), is contemporaneous with a significant warm anomaly (and oxygen isotope anomaly) and has thus been named the Paleocene-Eocene Thermal Maximum (PETM) (Figure P8). Due to the singular nature of this perturbation and the ecological, faunal and physical gradients across it, the base of this event is now used to define the boundary of the Paleocene-Eocene transition. The previous definition of the P/E boundary was significantly later (at the base of the Ypresian section in Europe), and thus placed the CIE in the late Paleocene. Previously authors had therefore referred to this event as the Late (or Latest) Paleocene Thermal Maximum (LPTM). Some authors have since referred to it as the Initial Eocene Thermal Maximum (IETM). The CIE is contemporaneous with the Clarkforkian/Wasatchian transition, long accepted as the Paleocene-Eocene boundary in the North American Land Mammal Series.

Full characterization of the event has been handicapped by the number of incomplete sections and frequent hiatuses found near the Paleocene-Eocene transition. The Global Stratigraphic Section and Point (GSSP) for this transition has been defined to be the Dababiya Section, 35 km south of Luxor, on the right bank of the Nile Valley. The event lies within Nano-Plankton zone 9 (NP-9) and reverse-polarity magnetic period Chron 24r. The dating of the PETM is estimated to be around 55.5 Ma, based on the chronology of (1996) using interpolation between well-dated ash layers.

Background

The Paleocene was a time of large shifts in the global environment following the disruptions that occurred at the Cretaceous-Tertiary boundary (65 Ma). Evolutionary increases in diversity, and increasing ocean productivity marked this epoch, leading to the most positive carbon isotope values in the Tertiary.

Temperatures were generally warm, and the polar regions (such as Ellesmere Island) were replete with sub-tropical fauna and flora (crocodiles, ferns etc.). There is no evidence of extensive glacial ice, though evidence for absence of sea ice in high northern latitudes is not as convincing. Tropical temperature estimates do not show as much (if any) change compared to present, but tropical proxies are known to suffer more from diagenetic alteration and the possibly complicating factors relating to the tropical hydrological cycle.

Focusing more specifically on the ≈ 2 Ma late Paleocene to early Eocene transitional period, global temperatures increased (to an estimated 2–4 °C warmer than present day), deep ocean temperatures increased by approximately 3 °C and $\delta^{13}\text{C}$ values

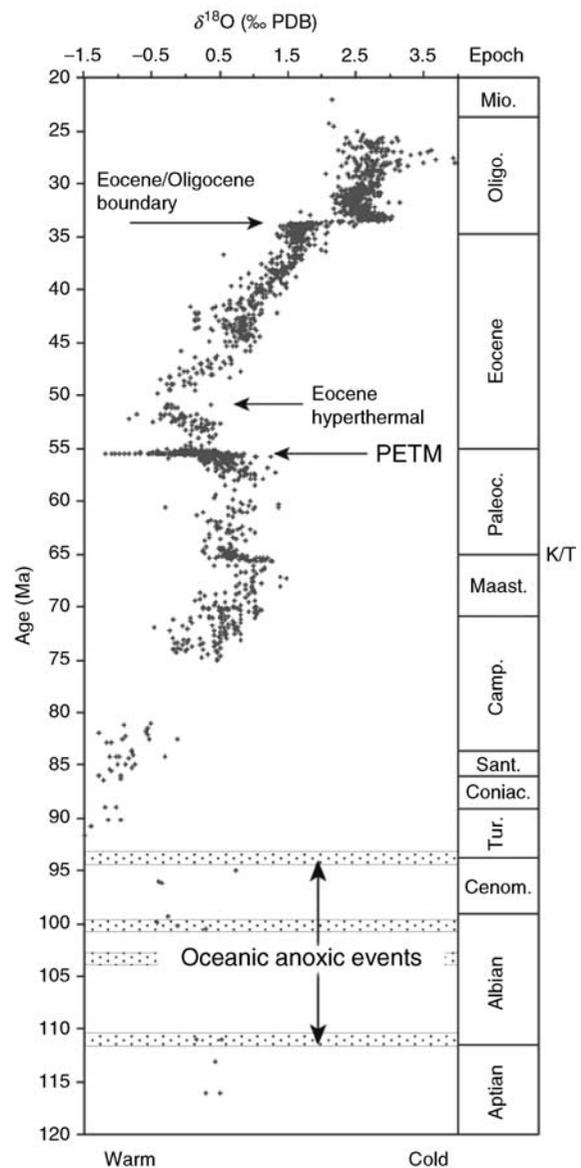

Figure P8 A compilation of $\delta^{18}\text{O}$ values in marine carbonate sediments since the Cretaceous showing the PETM anomaly in the context of Cenozoic variability (after Zachos et al., 2001).

decreased over this long term (Figure P9; Aubry et al., 1998, and references therein). This led to the Eocene Hyperthermal (or early Eocene climatic optimum), the warmest period in the Cenozoic. The collision of the Indian and Asian plates continued throughout this period although a land bridge may have already existed in the late Maastrichtian period. At some point during the late Paleocene, the island arc volcanism at this plate boundary would have ceased. However, the opening of the North Atlantic was perhaps accompanied by increased volcanism along the spreading ridge there. It is likely that a land bridge between North America and Europe was established during this period due to rapid extrusion of lava flows in the Faroe-Rockall area. In the Gulf of Alaska accretionary prism large amounts of sediment were being sequestered (peaking between 65 and 55 Ma) (Hudson and Magoon, 2002). These tectonic processes may have affected climate through the carbon cycle by removing sinks of organic carbon, global temperatures through a limiting of volcanic aerosol input, sea level and possibly ocean circulation through the closing of important gateways (in particular the Tethys ocean and access to the Northern Atlantic). The vegetation over this period was predominantly tropical and sub-tropical with climatic boundaries significantly further poleward than at present. Wetlands have been estimated to be significantly more extensive (Sloan et al., 1992, 1999). Similarities in deep and intermediate water masses point to a single, southern ocean source for deep water for most of this period (Corfield and Norris, 1998).

CO₂ levels have been estimated to be relatively high based on geochemical cycling models, but there are many conflicting lines of evidence from paleosol $\delta^{13}\text{C}$, or leaf-based stomatal density proxies, leaving a consensus elusive (Berner, 1994; Pearson and Palmer, 2001; Royer et al., 2001; Sinha and Stott, 1994). The levels of other radiatively active constituents (CH₄, O₃, volcanic aerosols) are even more highly uncertain. Dustiness appears to have decreased significantly across this interval, possibly indicating a long-term decrease in winds (Rea, 1994). However, the link between changes in radiative forcing and the long term warming, although much discussed, remains speculative.

It must be made clear that changes over the whole Paleocene-Eocene boundary interval (54–57 Ma) were large and significant, but not necessarily connected with the much shorter duration PETM event to which we now turn.

Characterization of the PETM event

The principle and unique definer of the PETM is the carbon isotope excursion (Figure P9). Since this was first recognized it has been found in many deep ocean cores and terrestrial sequences. In the deep ocean the excursion is 3–4‰ and has a very rapid onset (<10,000 years) (Zachos et al., 2000). The initial carbon isotope excursions appear to have been stepped and extremely rapid, occurring in bursts of less than 1 kyr over this interval (Bains et al., 1999; Röhl et al., 2000). The terrestrial excursion is

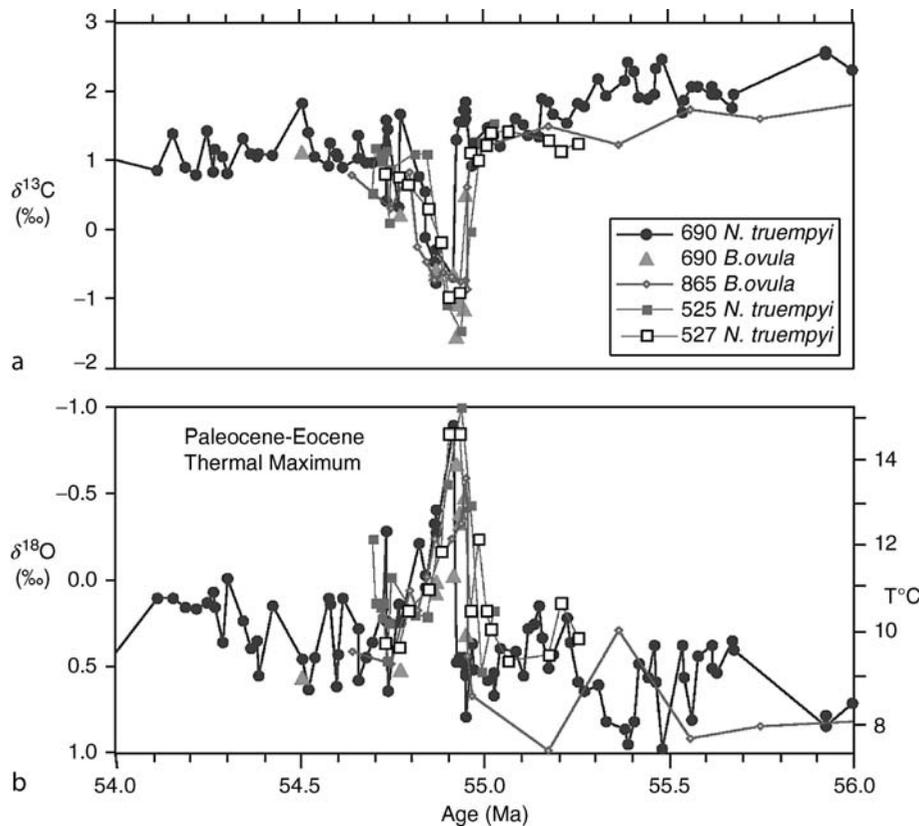

Figure P9 Detailed benthic foraminiferal carbon and oxygen isotopic series across the PETM event (Zachos et al., 2000) from ODP sites 690 (Maud Rise, South Atlantic), 865 (Allison Guyot, Equatorial Pacific), 525 and 527 (Walvis Ridge, South Atlantic).

higher (up to 7‰) measured in both paleosol carbonates and mammalian tooth enamel (hydroxyapatite) (Koch et al., 1992).

Contemporaneous with this excursion, though possibly slightly lagged, is a large increase in deep ocean temperatures (up to 5–7 °C) as indicated by $\delta^{18}\text{O}$ values in carbonate sediments. Isotope signals from upper ocean-dwelling planktonic foraminifera also register a similar change, indicating that the warming occurred over the whole ocean column, particularly at higher latitudes. Tropical temperatures, although more uncertain, may have also increased by 1–2 °C (Bralower et al., 1997). The deep water changes have been hypothesized to have been due to a switch from high latitude deep water production to a tropical source of warm saline bottom water (WSBW), but unequivocal evidence for this is not yet available (Kennett and Stott, 1991).

There also seems to have been a widespread (but not universal) increase in carbonate dissolution at this point, complicating attempts to find continuous sequences across the event. There was an increase in kaolinite clay deposition in coastal locations at the CIE, which indicates increased weathering, or at least, increased transport of weathered material to the ocean (Robert and Kennett, 1994). Some coastal regions saw an increase in the deposition of black shales, indicative of increased productivity. There are widespread discontinuities at the Paleocene-Eocene transition, and evidence of massive slope failures at Blakes Nose, in particular, in the North Atlantic (Katz et al., 1999).

There is a coincident benthic foraminiferal extinction (BFE) event at the onset of the carbon isotope excursion, which saw approximately 50% of the extant benthic species disappear at this time (Thomas and Shackleton, 1996). This extinction has been related to a decrease in dissolved O_2 , increased pH (consistent with the increased carbonate dissolution) and large temperature changes. In addition to foraminifera, other benthic species groups (ostracodes, molluscs) also underwent significant turnover. In particular, there was a widespread expansion of exotic planktonic taxa and dinoflagellates. On land, the CIE marked the final appearance of a number of archaic mammal orders, and the onset of a more “cosmopolitan” range of mammalian fauna in both North America and Eurasia. Large-scale ecological turnover is also indicated at this point.

The duration of any climate event deep in the geological record is particularly difficult to assess. The most useful methods rely upon estimates of Milankovitch cycle variability (mostly precessional cycles ≈ 20 Kyr) in $\delta^{13}\text{C}$ records which can be counted across the event. Other estimates are based on interstellar dust accumulation rates (as measured by $^3\text{He}/^4\text{He}$ ratios). Best estimates for the duration of the event as determined by the $\delta^{13}\text{C}$ excursion are between 90–200 Kyr. These estimates are consistent with present day estimates for the residence time of perturbations to the carbon cycle. Climate perturbations would be shorter than this timescale since the equilibrium of atmospheric and oceanic carbon happens much more quickly than the recycling time for carbon isotopes.

Mechanisms of PETM climate change

The size and rapidity of the PETM CIE serve to usefully eliminate many candidates for a primary cause. A perturbation of up to 4‰ in the global carbon cycle implies a very large input of depleted carbon. Given reasonable estimates of the isotopic signature of terrestrial carbon, the necessary mass of carbon from any source can be estimated. For instance, if the land biosphere were to provide the source, three times the total carbon content of the current biosphere would need to be added, and since no disruption on this kind of scale is observed at this

time, this source can be ruled out. Similarly, the amount of volcanism ($900\times$ present) required would have certainly left other geochemical traces (Dickens et al., 1995). An intriguing alternative is a carbonaceous extraterrestrial bolide impact, for which there is little evidence as yet (Kent et al., 2003).

The most compelling theory to date for the source of this light carbon comes from the large scale dissociation of methane from gas hydrates sequestered on the continental shelf (Dickens et al., 1995). The methane is produced by methanogenic bacteria that live off the organic material in sediment in predominantly anaerobic situations. Methane hydrates (or clathrates) are stable only when cold and under pressure. If the oceans warm, or pressure is reduced, the methane gas can be released. The carbon in such hydrates at present has an approximate value of -60‰ , and approximately 1,500–2,000 Gt (1 Gt = 10^{15} g) of carbon would be required to match the CIE. This amount is significantly less than the present-day known reserves of gas hydrates in the ocean. The maximum in $\delta^{13}\text{C}$ in the mid-Paleocene may be an indication that significantly more methane was sequestered by the late Paleocene. The methane hydrate hypothesis implies carbon additions to the global ocean that are consistent with the widespread carbonate dissolution at this time.

The main issue with this hypothesis is how the dissociation was triggered. Was it caused by a long-term ocean warming that crossed a threshold, a massive slope failure, or an abrupt change of ocean circulation, possibly related to a switch to WSBW formation (Bice and Marotzke, 2002; Katz et al., 1999; Kennett and Stott, 1991)? Was the warming actually caused by the greenhouse effect related to the CH_4 (and its oxidation product CO_2)? All of these possibilities have been tackled in the numerous modeling studies related to the PETM.

Modeling

A hierarchy of models from simple box models of the carbon cycle to full atmospheric and oceanic general circulation models have been applied to the PETM. Box models of the Paleocene carbon cycle have been used to constrain the total amount of depleted carbon required to match the CIE at about 1,500–2,000 Gt of carbon (Dickens, 2001). These models have also been used to assess processes that would eventually remove the excess carbon from the systems by increased organic carbon burial, increased weathering, or a recharging of the methane ‘capacitor’. None of these mechanisms have yet been eliminated as possibilities.

Inputs from methane would have important effects on atmospheric chemistry if emissions went directly into the atmosphere, leading to a reduced oxidation capacity and increased lifetimes for methane, other hydrocarbons (such as isoprene) and CO (Sloan et al., 1999). The radiative effects of these elevated methane (and subsequently CO_2) concentrations are important and have been estimated to be sufficient to have been the cause of the contemporaneous warming (Schmidt and Shindell, 2003). However, uncertainties in timing, background climate state, and Paleocene background emissions make this a tentative conclusion at best. Even more speculative is a possibly increased radiative role for polar stratospheric clouds (due to increased stratospheric water vapour associated with increased methane oxidation in the stratosphere) (Sloan and Pollard, 1998).

The use of full GCMs has necessarily been limited by the lack of well constrained boundary conditions (sea surface temperatures (SSTs), vegetation distributions, continental configurations, etc.); however a series of interesting experiments that

may have implications for the PETM have been published. Simulations using estimates of the varying equator-pole temperature gradient as a forcing function may give insight into the climatic consequences of those changes (Huber and Sloan, 2001). However, models that attempt to predict the SST changes (by using increased greenhouse gases for instance) are not necessarily consistent with these reconstructions (Sloan and Rea, 1995). In particular, whether the main westerly wind belts strengthen or not at the PETM is model dependent (Schmidt and Shindell, 2003; Sloan and Rea, 1995). Ocean-only model results, although limited by the lack of an interactive atmosphere, have been used to: (a) estimate whether hydrates could be destabilized in sufficient quantities by a shift in deep water circulation, or alternately, (b) whether radiatively-forced climate changes are sufficient to match the changes in ocean structure reflected in the benthic and planktonic isotope data (Bice and Marotzke, 2001, 2002). No definitive conclusions have yet been drawn, but no study has yet been able to demonstrate the existence of WSBW. Particular problems for ocean models are the depth of important sills (in the North Atlantic, the Walvis ridge and the Isthmus of Panama, for instance) and finding consistent surface freshwater and heat fluxes. Other ubiquitous problems with GCM simulations of warm climates are also relevant here (e.g., too cold continental interiors and apparently too large tropical warming).

Future studies are likely to yield further insights into possible mechanisms as dynamical oceans are interactively coupled to atmospheric models for this period, and carbon cycle models start to take the methane component (including atmospheric chemistry and subsequent radiative forcing) into account. Some work is also required to better define the vegetation distribution (which has consequence for the albedo, chemical emissions and deposition of other chemical species (such as O₃) which impact the oxidation capacity of the atmosphere (Beerling, 2000)) and also river drainage systems and wetland extent.

Mesozoic analogs

It has been hypothesized that similar CIE have occurred in the past. While none of the other excursions in the Cenozoic period have a documented size and rapidity of the PETM, excursions associated with ocean anoxic events in the Cretaceous, Jurassic, or possibly at the end of the Neoproterozoic glaciations do have similarities. However, the quality of data for these earlier events is significantly poorer, and so these possible analogs will probably remain ambiguous for some time (Hesselbo et al., 2000; Jahren et al., 2001).

Relevance

Estimates of exogenous carbon inputs during the PETM are comparable to the rates of fossil fuel-derived emissions at the present day. Therefore understanding the fate of the carbon during this episode may lead to insights into the eventual fate of anthropogenic carbon.

The PETM is also one of the first short-term climatic events that have been closely studied prior to the Quaternary. It is clear that the high resolution study of deep-time climate events is likely to be an increasingly fruitful line of research in understanding the earth system (Zachos et al., 2000). The singular example of the PETM has already led to re-assessments of the role of methane hydrates in the carbon cycle, the time-scales for carbon recycling, and the importance of atmospheric

chemistry in paleo- (and present day) climate, and it is likely that further insights will be forthcoming as data become more precise and widespread.

PALEOCLIMATE MODELING, PRE-QUATERNARY

Introduction

Pre-Quaternary paleoclimate modeling is the science of simulating climate change over the earliest 99.9% of Earth's history using numerical models of the climate system. The record of pre-Quaternary climate documents enormous climate swings with global ice-covered and ice-free end members. A number

of climate factors shaped Quaternary and pre-Quaternary paleoclimate on timescales ranging from hundreds of thousands to several years. However, in contrast to Quaternary paleoclimate, tectonically-controlled processes (including continental drift, orogenies, and fluctuations in the long-term carbon cycle) and solar evolution were also important controls on pre-Quaternary climate. Understanding how these factors have influenced climate change through the Precambrian, Paleozoic, Mesozoic, and Cenozoic eras, and how they are expressed in the geological record is a principal objective of pre-Quaternary paleoclimate modeling.

The utility of pre-Quaternary paleoclimate modeling has been several-fold. Pre-Quaternary climate modeling has contributed to ocean, atmosphere, and geological sciences by: (a) identifying mechanisms of climate change; (b) quantifying the climate response to a variety of forcing factors; (c) recognizing climatic feedbacks that amplify/dampen climatic forcings; (d) identifying limitations of climate proxies from the geological record; and (e) demonstrating strengths/shortcomings in numerical climate models. Pre-Quaternary paleoclimate modeling has made fundamental contributions to climate science. Among these, the recognition that the Earth's climate has experienced enormous variability on a multitude of temporal and spatial scales as a result of complex interactions between multiple climate factors is one of the most profound.

Methodology

Today, "paleoclimate models" are synonymous with numerical climate models implemented to study past climates. Prior to the wide availability of numerical climate models, paleoclimate models also referred to conceptual models constructed using physically-based rules about the general circulation of the atmosphere and ocean (e.g., Ziegler et al., 1977; Parrish et al., 1982). Numerical climate models are mathematical expressions of the theoretical laws that govern the climate system, approximated and written in computer code for fast, efficient computation. The model domain, frequently global in extent, is discretized into an array of horizontal and vertical grid cells. Not all models incorporate the full suite of governing equations in three dimensions. In fact, a hierarchy of numerical climate models has been used to study past climates. Numerical climate models can range in complexity from zero-dimensional energy balance models (EBMs) that simply express the conservation of energy, to three-dimensional general circulation models (GCMs) of the ocean and atmosphere that predict fluid flow on a rotating sphere heated by solar radiation. Many aspects of the climate system cannot be explicitly calculated, frequently because specific phenomena develop and act on sub-grid cell scale (i.e., over distances that are much smaller than represented by a model grid cell). Clouds provide an instructive example. Cloud motions vary over a horizontal scale of tens to hundreds of meters. Yet, the horizontal resolution of a GCM is typically tens to hundreds of kilometers. In order to represent clouds in GCMs, cloud processes are approximated or parameterized. Many of the differences between common types of numerical climate models (e.g., GCMs) arise from different parameterizations. To date, there are several different classes of GCMs, including atmosphere-only GCMs, ocean-only GCMs, coupled atmosphere-ocean GCMs, and GCMs coupled to models of the biosphere, cryosphere, and lithosphere. Climate models also differ in their horizontal and vertical resolution. As computational speed and efficiency has increased, so has the complexity and resolution of numerical

paleoclimate models. For a more detailed description of numerical climate models, the reader is referred to one of several good texts on the subject (e.g., Washington and Parkinson, 1986; Trenberth, 1992; McGuffie and Henderson-Sellers, 1997).

Most models used in pre-Quaternary climate studies were initially developed and fine-tuned for the modern climate, and then modified for use in pre-Quaternary studies. The modifications for “paleo” use are generally limited to changes in the model’s initial and boundary conditions. Table P1 lists the boundary conditions that have been explored in paleoclimate studies of the pre-Quaternary. A critical aspect of paleoclimate modeling is accurately defining the boundary conditions for a past age. For example, consider the difficulty of reconstructing the Cretaceous sea-surface temperatures (SSTs), continental vegetation, bathymetry, or atmospheric $p\text{CO}_2$. The task of reconstructing past boundary conditions is often made difficult or impossible because: (a) the geological record has been destroyed, incompletely sampled, or was never preserved; (b) the temporal resolution of the proxy is too coarse or too uncertain; (c) the spatial resolution (e.g., a single drill or field site) may be incompatible with the model resolution; or (d) the geological proxy may have lost its original signal through alteration or have an equivocal interpretation. In the absence of a detailed reconstruction of a particular boundary condition, a generalization or simplification has often been made (e.g., specification of globally uniform vegetation type or zonally-averaged SSTs). Numerous studies have demonstrated that differences within the uncertainty of a boundary condition can have regional or global climatic consequences (e.g., Kutzbach and Ziegler, 1993; Otto-Bliesner, 1998; Poulsen et al., 1998; Sewall et al., 2000; Huber and Sloan, 2000). In pre-Quaternary paleoclimate studies, initial conditions have usually been paid little attention for two reasons. First, the initial conditions are unknown. Second, very few pre-Quaternary proxy reconstructions have centennial or better resolution. Consequently, most paleoclimate modeling studies time-average the model results to mask interannual and interdecadal climate variability. Insofar as multiple climate states are possible, initial conditions may be important, and have been examined to a

limited degree (e.g., Bice and Marotzke, 2001; Herrmann et al., 2003).

Pre-Quaternary paleoclimate modeling studies have tended to focus on specific intervals or time slices of Earth’s history (e.g., the mid-Cretaceous), rather than the continuum spanning all or a portion of Earth’s 4.6 billion years. Practical limitations, including the computational costs incurred by long (i.e., greater than a few thousand years) simulations, the relative incompleteness of the paleoclimate proxy records, and the technical complexity of dynamically varying boundary conditions (specifically geography or orography), have motivated this time-slice approach. As these limitations diminish, long climate simulations may be possible, particularly for simpler or coarse-resolution models. The timescales of interest have varied tremendously, ranging from tens of millions of years to only a few years, and are mainly constrained by the resolution of paleoclimate proxy records.

Pre-Quaternary paleoclimate models have been utilized in several fashions. Due to the limitations of boundary condition reconstructions, many paleoclimate modeling studies fall within the category of sensitivity experiments – modeling experiments in which one parameter is varied at a time and compared to a control case. Alternatively, some studies have attempted to “simulate” a particular time interval by specifying the “best” boundary conditions and then comparing the simulation to proxy reconstructions. In practice, many studies mix these two approaches.

Paleoclimate modeling contributions

In this section, progress achieved on a number of pre-Quaternary paleoclimate problems through paleoclimate modeling has been summarized. As much as possible, the types of models used have been described in order to provide a sense of the evolution of the paleoclimate modeling field.

Faint Young Sun paradox

Stellar evolution models indicate that solar luminosity was 25–30% lower during the early Precambrian than today. Yet, the earliest one-dimensional EBMs and atmospheric GCMs predicted that much smaller decreases (2–5%) in solar luminosity would have triggered climate instability once sea ice had reached $\sim 30^\circ$ latitude, leading to a runaway ice-albedo feedback (Budyko, 1969; Sellers, 1969). Subsequent EBM experiments showed that the critical latitude for a runaway ice-albedo feedback was not entirely fixed; increasing the heat transport caused the instability to move to higher latitudes (Held and Suarez, 1974). The prediction of an early Precambrian ice-covered Earth is inconsistent with the presence of sedimentary rocks early in Earth history and evidence of primitive life at 3.5 Ga. Moreover, EBM calculations indicate that the formation of highly reflective CO_2 clouds would have made an ice-covered Earth irreversible (Caldiera and Kasting, 1992). This conflict between climate model predictions and the geological record has become known as the Faint Young Sun paradox.

Several climatic factors have been hypothesized to resolve the Faint Young Sun paradox, including the atmospheric concentration of greenhouse gases, the extent and configuration of continents, and the rotation rate and obliquity of the early Earth. Calculations using one-dimensional radiative-convective models indicate that high concentrations of NH_3 (Sagan and Mullen, 1972), CO_2 (Owen et al., 1979; Kuhn and Kasting, 1983;

^aIn some studies, boundary condition may not be necessary if the parameter is explicitly calculated. For example, sea-surface temperatures are not necessary if a mixed-layer or fully dynamic ocean model is implemented.

Kasting et al., 1984; Kiehl and Dickinson, 1987) and/or CH₄ (Kiehl and Dickinson, 1987; Pavlov et al., 2000) in the atmosphere could have maintained surface temperatures above freezing by enhancing the Earth's greenhouse effect.

Theories of continental formation suggest that the extent of continental crust was considerably less than today. The small continental area may have affected the Precambrian climate by reducing the Earth's albedo (Henderson-Sellers and Henderson-Sellers, 1989; Kuhn et al., 1989; Gérard et al., 1992; Jenkins et al., 1993), increasing poleward heat transport (Endal and Schatten, 1982), and altering the global cloud fraction (Jenkins et al., 1993; Longdoz and François, 1997). These changes are hypothesized to compensate for the low solar luminosity at least partially, by impeding the equatorward growth of sea ice and increasing the solar radiation captured at the Earth's surface. However, the influence of continental configuration on Precambrian climate is highly model dependant. For example, in response to a global ocean, the cloud coverage decreased in the atmospheric GCM used by Jenkins et al. (1993) due to a shift from non-convective to convective cloud types, which have a smaller cloud fraction. In contrast, cloud coverage increased in the quasi-three-dimensional model used by Longdoz and François (1997) due to a more active hydrological cycle.

The Earth's rotation velocity has decreased through its history, causing day length to increase from 14-h days at 4.0 Ga to 24-h days (Walker and Zahnle, 1986). The dynamical consequences of an enhanced rotation rate during the Precambrian have been studied using EBMs and GCMs (Hunt, 1979; Kuhn et al., 1989; Jenkins et al., 1993). A faster rotation velocity reduces the scale size of synoptic disturbances, leading to a reduction in poleward heat transports, cold high latitude temperatures, and larger meridional temperature gradients (Hunt, 1979). Dynamical changes in eddy and mean motions may also reduce global cloud coverage, causing a 2 °C increase in global average air temperature that potentially compensated for the low Precambrian solar luminosity (Jenkins et al., 1993).

Snowball Earth hypothesis

The late Precambrian witnessed the most severe glaciations in Earth history. Paleomagnetic evidence from South Australia and Northwest Canada confirm the low-latitude (<10°) settings of late Precambrian glacial deposits. Paleoclimate models have been used extensively to evaluate the factors responsible for the low-latitude glaciation, and have examined the influences of paleogeography (Crowley and Baum, 1993; Chandler and Sohl, 2000; Poulsen et al., 2002), atmospheric CO₂ concentrations (Chandler and Sohl, 2000; Hyde et al., 2000; Baum and Crowley, 2001), continental surface characteristics (Baum and Crowley, 2001), ocean heat transport (Chandler and Sohl, 2000; Poulsen et al., 2001b), and ice-sheet dynamics (Hyde et al., 2000; Donnadieu et al., 2003). These modeling studies demonstrate that a combination of climate forcings can produce conditions for low-latitude glaciation (Chandler and Sohl, 2000; Hyde et al., 2000).

The low-latitude glacial deposits, and other sedimentary (deposition of banded iron formations and thick post-glacial carbonates) and geochemical evidence (carbon isotopes from carbonates), has been cited as confirmation that the entire Earth may have been completely ice-covered during the late Precambrian (Kirschvink, 1992; Hoffman et al., 1998). This idea, known as the Snowball Earth hypothesis, has gained support from some climate models. EBMs and atmospheric GCMs have simulated an ice-covered Earth under late Precambrian

conditions (when the solar luminosity was about 6% less than present) (Jenkins and Smith, 1999; Baum and Crowley, 2001; Poulsen et al., 2001). However, this result is highly model dependent. Climate models that explicitly calculate ocean circulation and heat transport do not permit an ice-covered Earth under late Precambrian conditions. The energy released by convection at the sea-ice margin and the large heat capacity of the ocean work against the ice-albedo feedback (Poulsen et al., 2001; Bendtsen, 2002). The extent of late Precambrian ice is critical to the Earth's recovery – escape from an ice-covered state would have required ~300–1,000 × present atmospheric levels (PAL) of CO₂ (Caldiera and Kasting, 1992), while escape from a world with water at the equator would have required as little as 4 × PAL CO₂ (Crowley et al., 2001).

An alternative explanation for low-latitude glaciation is that the Earth's obliquity was substantially greater than at any time in the Phanerozoic (Williams, 1975, 1986). If the obliquity were higher than 54°, the poles would be the warmest region on Earth, and the equator would be the coldest. Atmospheric GCMs confirm that an extreme obliquity (≥60°) would produce freezing temperatures on low-latitude continents while maintaining above freezing conditions at high latitudes (Oglesby and Ogg, 1999; Jenkins, 2000; Donnadieu and Ramstein, 2002). The missing ingredient in this hypothesis is a reasonable physical mechanism for causing large changes in Earth's obliquity.

Ordovician glaciation

Geological evidence exists for a late Ordovician (~440 Ma) glaciation. This short-lived (~1 million year) glaciation (Brenchley et al., 1995, 2003) was remarkable because atmospheric CO₂ levels were high (14 ± 6 × PAL) during the late Ordovician (Yapp and Poeths, 1992). Numerical climate models of increasing complexity have been used to determine the conditions permitting glaciation at high CO₂ levels. Early studies using 2-D EBMs focused on the role of the late Ordovician paleogeography (Crowley et al., 1987; Crowley and Baum, 1991a), and specifically the orientation of Gondwanaland relative to the South Pole. With an edge of Gondwanaland near the South Pole, the thermal inertia of the ocean prevented continental summer temperatures from rising above freezing, thus allowing permanent snow cover (Crowley et al., 1987; Crowley and Baum, 1991a). Subsequent GCM experiments have confirmed the EBM result (Gibbs et al., 2000), but have also shown that the continental configuration of Gondwanaland is not a sufficient condition for glaciation. The influences of additional climatic factors on Ordovician glaciation have since been tested, including atmospheric CO₂, topography, ocean heat transport, orbital parameters, and snow/ice albedo (Crowley and Baum, 1995; Gibbs et al., 1997; Poussart et al., 1999; Herrmann et al., 2003). These studies generally conclude that glaciation is possible with high (8–14 × PAL) atmospheric CO₂ levels given favorable orbital parameters (i.e., a cold Southern Hemisphere summer configuration) and continental topography. With orbital forcing varying from cold-summer to warm-summer configurations, ice-sheet model calculations indicate that CO₂ levels must fall to 8 × PAL to grow a permanent ice sheet (Herrman et al., 2003).

Gondwanan glaciations

Ice sheets on Gondwana persisted for ~55 million year during the Permo-Carboniferous (275–330 Ma), and reached a size

comparable to that of the Pleistocene ice sheets (Crowley and Baum, 1991b). The presence of ice sheets on a supercontinent is surprising since enhanced seasonality would have produced summer temperatures on the Gondwana ice sheet that may have been 15 °C greater than temperatures over the Laurentide Ice Sheet (Crowley, 1994). Two-dimensional EBM calculations indicate that a reduced solar luminosity (~3% less than modern) and favorable orbital parameters could compensate for the supercontinental effect, allowing freezing summer temperatures over the Gondwanan ice sheet (Crowley et al., 1991). Crowley and Baum (1992a) used a series of two-dimensional EBM experiments with a combination of evolving climatic factors (geography, geography + solar luminosity, geography + solar luminosity + CO₂) to simulate the estimated extent of the Gondwanan ice sheet. To simulate both the initiation and demise of the ice sheet, changes in geography, solar luminosity, and, most importantly, CO₂ were required (Crowley and Baum, 1992a).

EBM and GCM modeling of the Permo-Carboniferous glaciation has demonstrated that the onset and growth of the Gondwanan ice sheet may have been highly nonlinear due to a Small Ice Cap Instability (SICI) (Baum and Crowley, 1991; Crowley et al., 1994). A coupled climate-ice sheet model of the Gondwanan ice sheet also shows critical behavior with small changes in solar luminosity (0.0005%) leading to large differences (>10×) in the simulated ice volume (Hyde et al., 1999). The model also exhibits multiple equilibria. The melting of a large ice sheet due to an increase in CO₂ to 2 × PAL results in a small, stable Gondwanan ice sheet. Yet, no ice sheet is simulated given ice-free initial conditions and 2 × PAL CO₂ (Hyde et al., 1999).

Pangean climate

Paleogeography has been recognized as a first-order control on climate. During the late Paleozoic and early Mesozoic, the continents were agglomerated into the supercontinent Pangea. The supercontinental configuration had large consequences for Earth's climate. Typical features simulated by climate models include extreme continentality (i.e., a seasonal temperature range (>45 °C) that surpassed that of modern Eurasia) resulting from the small heat capacity of land (Crowley et al., 1989; Kutzbach and Gallimore, 1989; Kutzbach and Ziegler, 1993; Crowley and Baum, 1994; Wilson et al., 1994; Gibbs et al., 2002), strong monsoonal systems along the Tethyan coast (Kutzbach and Gallimore, 1989; Kutzbach and Ziegler, 1993; Wilson et al., 1994; Gibbs et al., 2002), and intense aridity in continental interiors due to the depletion of atmospheric moisture over the long continental trajectories (Kutzbach and Gallimore, 1989; Kutzbach and Ziegler, 1993; Wilson et al., 1994; Fawcett and Barron, 1998; Gibbs et al., 2002). Two-dimensional EBM calculations predict that Pangean surface temperatures would have been greatly influenced by orbital parameters with a maximum range of ~14–16 °C between maximum and minimum orbital insolation values (as determined from Pleistocene fluctuations) (Crowley and Baum, 1992b). In addition, atmospheric GCM experiments using an idealized Pangean paleogeography indicate that tropical and subtropical precipitation and runoff would have varied by 50% between the extreme phases of the precessional cycle with enhanced hydrology when perihelion (aphelion) occurred in summer (winter) (Kutzbach, 1994).

Mountains and plateaus may have played an important secondary role in controlling Pangean climate. The intensification of radiative heating and cooling over plateaus produced more

extreme high and low pressure systems, which acted with the topography to guide the winds and focus precipitation (Kutzbach and Ziegler, 1993; Otto-Bliesner, 1993, 1998; Wilson et al., 1994; Hay and Wold, 1998). The effects of uplift were greatest in low latitude regions because of the influence of mountains on the position of the Inter-Tropical Convergence Zone (ITCZ) (Otto-Bliesner, 1998; Hay and Wold, 1998). Otto-Bliesner found that the presence of high (1,000–3,000 m) Central Pangean Mountains impeded the seasonal northward migration of the ITCZ, enhancing local precipitation by 68% in July and possibly explaining the extensive occurrence of tropical, late Carboniferous coals.

Considerable effort has been made to evaluate, through comparison with climate proxies, the ability of atmospheric GCMs to simulate elements of the Pangean climate (Kutzbach and Ziegler, 1993; Fawcett et al., 1994; Pollard and Schulz, 1994; Wilson et al., 1994; Rees et al., 1999, 2002; Gibbs et al., 2002). In general, atmospheric GCM simulations tend to do a “fair to good” job of simulating the requisite conditions for lithologic climatic indicators (Pollard and Schulz, 1994; Wilson et al., 1994; Gibbs et al., 2002) and sedimentary structures generated by severe weather (PSUCLIM, 1999a; PSUCLIM, 1999b). In comparison to climate inferred from Permian paleobotanical data, an atmospheric GCM predicts temperatures that are too cold in the high latitudes of the Southern Hemisphere (Rees et al., 1999, 2002). The absence of ocean dynamics (particularly the absence of warm polar currents, upwelling zones, and the explicit calculation of ocean heat transport) and the coarse model resolution (particularly the poor or nonexistent resolution of narrow mountain ranges, lakes, and coastlines) in the atmospheric GCMs have been implicated as potential reasons for the discrepancies between the model predictions and the proxy indicators (Pollard and Schulz, 1994; Rees et al., 1999, 2002; Gibbs et al., 2002).

Several atmospheric GCM studies have focused on the Jurassic (Chandler, 1994; Chandler et al., 1992; Moore et al., 1992; Valdes and Sellwood, 1992; Valdes, 1994), a geological interval that saw the rifting of Pangea. The large continental blocks shared many features with that of Pangea, including high continentality, intense continental aridity, and strong monsoonal systems (Moore et al., 1992). The latter conclude that the Jurassic warmth evidenced by climate proxies may be explained by elevated atmospheric CO₂. In contrast, Chandler et al. (1992) suggested that a Jurassic simulation with specified, warm SSTs was in energy balance without high atmospheric CO₂, implying that a warm Jurassic climate could have been the product of enhanced poleward heat transport through the ocean. However, in a Jurassic experiment with a specified, reduced meridional sea-surface gradient, the implied ocean heat transport was much smaller than in a present-day simulation, suggesting that enhanced ocean heat transport may not be viable for the Jurassic (Valdes, 1994). A comparison of Jurassic climates simulated using different GCMs has confirmed that the treatment of the ocean is an important variable that likely explains model differences in high latitude climate prediction. Furthermore, mixed-layer ocean models without poleward heat transport exaggerate the equator to pole temperature gradient, while specified SSTs may not be sustainable (Valdes, 1994).

Cretaceous greenhouse climate

The Cretaceous was a period of global warmth with ice-free continents and globally averaged surface temperatures 6–14 °C higher than present (Barron, 1983). The focus of

the earliest Cretaceous modeling studies was to understand the factors that led to a warm Cretaceous period. Using a simple planetary albedo model, Thompson and Barron (1981) concluded that reductions in albedo resulting from reduced land area, snow cover, and sea ice, could account for all of the Cretaceous warmth. Subsequent calculations using a one-dimensional EBM (Barron et al., 1981), a mean-annual atmospheric GCM coupled to an energy balance ocean model with no thermal inertia (Barron and Washington, 1982), and an atmospheric GCM with seasonally varying solar insolation and a mixed-layer ocean (Barron et al., 1993a) indicated that the role of continental geography on global-average Cretaceous surface temperature was minor. On the other hand, an increase in atmospheric CO₂ levels (2–10 × PAL) caused substantial global-average warming (Barron and Washington, 1985; Barron et al., 1993) due to a decrease in global albedo resulting from melting of snow/ice and an increase in water vapor. In fact, an increase to 4 × PAL CO₂ levels caused a global-average warming of 3.6–5.5 °C. An additional CO₂ feedback, enhanced high-latitude cloud cover, may further contribute to Cretaceous high-latitude warming (Sellwood and Valdes, 1997).

Ironically, the greenhouse gas solution to Cretaceous global warmth introduced a new climate problem: model-predicted Cretaceous tropical temperatures exceeded the estimates from climate proxies and approached the thermal tolerance of some tropical organisms while high-latitude regions were still too cold (Barron and Washington, 1985; Barron et al., 1993). Efficient poleward heat transport was suggested as a way to reduce the Cretaceous surface thermal gradient (Barron et al., 1981; Barron, 1983), but this flew in the face of classical theories that suggested a reduced thermal gradient would displace large-scale circulation features towards the poles and cause sluggish atmospheric and oceanic circulation. However, early atmospheric and coupled ocean-atmosphere GCM simulations demonstrated that a reduction in the surface thermal gradient did not cause sluggish circulation (Barron and Washington, 1982; Manabe and Bryan, 1985; Bush and Philander, 1997). Rather, the vertically integrated meridional temperature gradient was maintained or slightly increased through compensation by differential latent heating, leading to slightly increased zonal-average wind speeds at many latitudes (Barron and Washington, 1982).

Because of its enormous heat capacity, the ocean was identified as a possible source of enhanced poleward heat transport (Barron et al., 1981; Barron and Washington, 1982, 1985; Schneider et al., 1985; Covey and Barron, 1988; Covey and Thompson, 1989; Rind and Chandler, 1991). The idea of enhanced ocean heat transport was strengthened by atmospheric GCM experiments that demonstrate that an increase in ocean heat transport is only partially compensated by a reduction in atmospheric heat transport (Covey and Thompson, 1989) and could produce substantial global climate warming (Covey and Thompson, 1989; Rind and Chandler, 1991; Barron et al., 1993). Cretaceous atmospheric GCM simulations with enhanced oceanic heat transports predict high-latitude warming and low-latitude cooling, reducing the meridional surface temperature gradient (Barron et al., 1993; Barron et al., 1995; Poulsen et al., 1999). Yet, to date, a mechanism for sustaining high ocean heat transport has not been identified, though some modeling studies suggest the possibility of intensified surface circulation (Bush and Philander, 1997; Hotinski and Toggweiler, 2003).

Despite the specification of elevated atmospheric CO₂ and enhanced ocean heat transport in atmospheric GCMs of

the Cretaceous, mean-annual temperatures in the continental interiors remained subfreezing, and at odds with the paleobotanical and sedimentological evidence (Schneider et al., 1985; Barron et al., 1995). This problem has been markedly ameliorated by including non-uniform vegetation, either by direct specification or by prediction with a vegetation-ecology model, in atmospheric GCM experiments (Otto-Bliesner and Upchurch, 1997; DeConto et al., 1999; Upchurch et al., 1999). The inclusion of high-latitude forest, in particular, produced a large warming effect that contributed to a 2.2 °C increase in global average temperature. These low-albedo forests warmed the high-latitude continents, which then transferred more heat to the high-latitude oceans, impeding sea-ice formation and warming coastal regions (Otto-Bliesner and Upchurch, 1997).

Ocean circulation in a warm Cretaceous climate has received considerable attention, because of the possibility that the thermohaline circulation may have reversed, resulting in subtropical deepwater formation (i.e., warm saline deepwater) and sluggish meridional ocean circulation (Chamberlin, 1906; Brass et al., 1982). Ocean GCM studies have largely undermined the hypothesis that the global thermohaline circulation was completely reversed. Using a coarse 5° × 5° ocean GCM with mean-annual forcing, Barron and Peterson (1990) reported significant subtropical deepwater formation in eastern Tethys with elevated (4 × PAL) CO₂ levels. However, subsequent finer-resolution ocean GCM simulations with seasonal forcing have predicted only limited convection at subtropical sites with most convection occurring at high-latitude Southern Hemisphere locations (Brady et al., 1998; Poulsen et al., 2001). Cretaceous GCM studies also do not support the notion of a sluggish, global meridional circulation; meridional overturning circulation is similar in experiments with different meridional surface temperature gradients (Manabe and Bryan, 1985; Brady et al., 1998).

On the basis of biogeographic and paleogeographic reconstructions, a Tethys circumglobal current has been inferred for the Cretaceous. Ocean GCM results indicate that a Tethys circumglobal current may have driven high rates of upwelling, cooling tropical temperatures and warming northern high latitudes, thereby reducing the Cretaceous meridional thermal gradient (Hotinski and Toggweiler, 2003). However, ocean GCMs have had mixed success simulating a Tethys circumglobal current (Seidov, 1986; Barron and Peterson, 1989; Bush, 1997; Bush and Philander, 1997), because the current is very sensitive to continental geometry (Poulsen et al., 1998). Regional ocean circulation and water properties may also have been highly sensitive to opening/closing of Cretaceous gateways (Poulsen et al., 2001; 2003). In addition to global models of ocean circulation, regional circulation models have been implemented to predict detailed Cretaceous circulation in the Western Interior Seaway of North America (Ericksen and Slingerland, 1990; Kump and Slingerland, 1999).

Warm “equable” Paleocene-Eocene climate

The early Eocene was the warmest interval in the Cenozoic, with global-average surface temperatures 2–4 °C warmer than present (Barron, 1987). Floral and faunal proxies suggest that continental temperatures were warm with a small annual range. Yet, on the basis of perpetual January and July atmospheric GCM simulations with specified SSTs, Sloan and Barron (1990) reported that warm, equable continental interiors could not be maintained in light of the small thermal inertia of land surfaces. Subsequently, a number of studies have attempted to

reconcile the GCM predictions with early Eocene proxy evidence from the continental interiors (Sloan and Barron, 1990, 1992; Sloan and Cirbus, 1994; Sloan and Morrill, 1998; Sloan and Pollard, 1998; Sloan et al., 2001). Several factors have been identified that ameliorate the model-predicted high-latitude continental temperature range, including the presence of a large interior lake (Sloan and Cirbus, 1994), enhanced atmospheric CO₂ levels (Sloan and Cirbus, 1994; Shellito et al., 2003), cold summer-warm winter orbital parameters (Sloan and Morrill, 1998), and the specification of seasonally-varying, warm SSTs (Sloan et al., 2001).

Atmospheric GCM results indicate that elevated atmospheric CO₂ levels (at least 3 × PAL) could explain the Eocene global warmth, but introduce a problem familiar to warm climates – tropical overheating (Sloan and Rea, 1995; Shellito et al., 2003). As in the Cretaceous studies, enhanced oceanic heat transport has been proposed as a possible mechanism for reducing the Eocene meridional surface temperature gradient (Barron, 1987; Covey and Barron, 1988; Rind and Chandler, 1991). Again, a mechanism for enhancing ocean heat transport has not been identified. Using an uncoupled ocean GCM forced by atmospheric GCM fields, Bice et al. (2000) suggest that the distribution of ocean heat transports between the Northern and Southern Hemisphere may be sensitive to the basin configuration. However, a coupled ocean-atmosphere model of the Eocene demonstrated reduced heat transports relative to the modern (Huber and Sloan, 2001). Polar stratospheric clouds, frozen water vapor clouds that form in polar regions, may be a partial solution for producing warm climates with low surface temperature gradients (Sloan and Pollard, 1998). By absorbing outgoing, long-wave radiation, prescribed polar stratospheric clouds in an atmospheric GCM caused warming of the troposphere and melting of sea ice, leading to significant (up to 20 °C) high-latitude warming (Sloan and Pollard, 1998).

Paleoclimate modeling studies have been conducted to determine how the ocean circulated in a warm Eocene climate. Atmospheric GCM experiments with specified SSTs displayed an intensification of the Hadley circulation and associated extremes in equatorial precipitation and subtropical evaporation, leading O'Connell et al. (1996) to suggest that conditions might have been ripe for warm, saline deepwater formation in the eastern Tethys Ocean. Indeed, Eocene ocean GCM experiments support the possibility of limited convection of warm, saline subtropical water (Barron and Peterson, 1991), provided the moisture flux from the atmosphere is favorable (Bice et al., 1997; Bice and Marotzke, 2001). In an attempt to simulate a “haline” mode circulation, Bice and Marotzke (2001) show that large perturbations to the atmospheric moisture flux (evaporation-precipitation) enhance subduction of warm, saline water to the depths, but do not increase subtropical convective mixing (the mechanism controlling deepwater formation). A coupled ocean-atmosphere simulation of the Eocene exhibits sluggish meridional circulation and warm, saline deep water (Huber and Sloan, 2001); however, the published results do not indicate whether the warm, saline water was formed by subduction or convection.

Late Cenozoic climate deterioration

After the warm, ice-free climate of the Cretaceous and early Cenozoic, a long-term cooling trend ensued, punctuated by the development of the Antarctic Ice Sheet near the Eocene/Oligocene boundary, and culminating in the Pleistocene ice age. Several mechanisms have been cited as instigators of the

Cenozoic cooling, including changes in continental distribution, plateau uplift, oceanic gateways, and atmospheric CO₂. Barron (1985) used an annual-average atmospheric GCM to test the hypothesis that the evolution of the distribution and size of continental land masses caused the Cenozoic cooling trend. This model exhibited minor sensitivity to the Cenozoic paleogeographic changes, including changes in topography and continental position, and did not demonstrate a systematic decrease in global-average surface temperature.

Geologic evidence supports a significant increase in uplift rates and absolute elevation in southern Asia (the Tibetan Plateau and Himalayan Mountains) and the American West during the Cenozoic (Ruddiman et al., 1989), though the details of the uplift history remain uncertain. In a series of atmospheric GCM sensitivity experiments testing the influence of mountain elevation on climate, Kutzbach et al. (1989, 1993) showed that progressive uplift in Southern Asia and the American West resulted in largely linear changes in heating rates, vertical motion patterns, and low-level winds over the plateaus. In a similar series of experiments, Manabe and Broccoli (1990) and Broccoli and Manabe (1992) observed that large-amplitude stationary waves occur in response to the plateaus; general subsidence and infrequent storm development upstream of the troughs of these waves contribute to continental aridity. Changes in circulation associated with uplift led to patterns of regional climatic changes (colder winters over Northern Hemisphere continents; drier summers along the American Pacific coast and in the interior of Eurasia; winter drying of the American northern plains and the interior of Asia; and maintenance of warm/wet conditions along the southeast coasts of Asia and the United States), which are consistent with those in the Northern Hemisphere during the last 10 or 15 million years (Ruddiman and Kutzbach, 1989; Manabe and Broccoli, 1990). Atmospheric GCM experiments have also shown that Tibetan uplift and increased summer radiation through orbital changes are also primary controls on monsoon strength (Prell and Kutzbach, 1992). Despite the large regional climate response, plateau uplift contributes little to global cooling, indicating the need for additional climatic forcing to explain the Cenozoic cooling (Ruddiman and Kutzbach, 1989).

Ocean gateways have also been implicated in Cenozoic cooling. Kennett (1977) hypothesized that the opening of the Drake Passage near the Eocene/Oligocene boundary created an Antarctic Circumpolar Current (ACC), which thermally isolated Antarctica, leading to growth of the Antarctic Ice Sheet. Ocean GCMs that test the effect of the Drake Passage predict the formation of an ACC-reduced poleward heat transport in the high-latitude Southern Hemisphere, cooling high-latitude surface temperatures up to several degrees (ranging from 0.8–4 °C), depending on the type of sea-surface boundary conditions (restoring vs. non-restoring) (Mikolajewicz et al., 1993; Toggweiler and Samuels, 1995; Bice et al., 2000; Toggweiler and Bjornsson, 2000). In contrast, atmospheric GCM results indicated that warmer SSTs favor snowfall in the continental interior, promoting Antarctic Ice Sheet growth (Oglesby, 1989). Ocean GCMs also exhibit large circulation changes in response to an open Central American Isthmus, which existed prior to 3–4 Ma (Maier-Reimer et al., 1990; Mikolajewicz et al., 1993). In the open isthmus case, North Atlantic surface water is diluted by low salinity Pacific water, collapsing North Atlantic deepwater production. Because the North Atlantic circulation is an important source of heat in the high latitudes of the North Atlantic, Maier-Reimer et al. (1990) speculate that a

compensating climatic factor must have warmed the region prior to the initiation of Northern Hemisphere Pleistocene glaciation.

Results from an asynchronously coupled ice sheet-atmosphere GCM suggest that Antarctic glaciation was induced primarily by declining atmospheric CO₂ (DeConto and Pollard, 2003). The ice sheet model exhibits highly nonlinear behavior; once an atmospheric CO₂ threshold (between ~3 and 2 × PAL) is crossed, Antarctic ice caps expand rapidly, with large orbital variations. A parameterization of the Drake Passage opening and ACC formation has a modest (and secondary) effect on ice sheet mass balance (DeConto and Pollard, 2003). Vegetation changes may also have contributed to Cenozoic cooling. Using an atmospheric GCM, Dutton and Barron (1997) propose that the evolution of grasslands and tundra in the Miocene may have caused a 1.9 °C global cooling, mainly due to the higher albedos of these vegetation types.

Warm Pliocene climate

The middle Pliocene was the most recent period in Earth history that was significantly warmer than the present. In contrast to other pre-Quaternary intervals, the boundary conditions for the Pliocene are fairly well-known as a result of the concerted efforts of the U.S. Geological Survey's PRISM (Pliocene Research, Interpretations, and Synoptic Mapping) Group. Several modeling groups have utilized the PRISM data sets to simulate the middle Pliocene climate (Chandler et al., 1994; Sloan et al., 1996; Haywood et al., 2000a,b). Despite incremental enhancements to the PRISM data set and the use of different atmospheric GCMs with varying resolution, the Pliocene simulations agree in several respects. As compared with the present, the Pliocene simulations exhibit global warming, a reduction in the equator-to-pole surface temperature gradient and zonal wind strength, and enhanced Northern Hemisphere high-latitude precipitation (Chandler et al., 1994; Sloan et al., 1996; Haywood et al., 2000b). The GCM results support the possibility that enhanced thermohaline circulation and concomitant increases in ocean heat transport could explain the middle Pliocene warmth (Chandler et al., 1994; Sloan et al., 1996). Alternatively, regional intensification of atmospheric and oceanic circulations may have induced greater heat transports from the equatorial region, warming Europe and the Mediterranean (Haywood et al., 2000a). Modeling results indicate that warmer SSTs and reduced ice cover in the Northern Hemisphere gave way to intensification of the Icelandic low-pressure and Azores high-pressure systems in the North Atlantic. The resulting surface pressure gradient increased the annual westerly wind velocity and wind stress, ultimately enhancing the flow of the Gulf Stream and North Atlantic Current as well (Haywood et al., 2000a).

Summary

Pre-Quaternary paleoclimate modeling is the science of simulating Earth's climate prior to the Quaternary using numerical climate models. The pre-Quaternary witnessed climate states that were fundamentally different to those of the Quaternary and the modern day. Since the earliest paleoclimate modeling studies using EBMs, considerable progress has been achieved in understanding the factors that have controlled Earth's past climates. Paleoclimate modeling studies have directly contributed to reshaping and debunking climate hypotheses, recognizing new climatic processes, and quantifying the climate response to various climatic factors. Much of the scientific progress has proceeded hand-in-hand with the development of

increasingly sophisticated climate models. Yet, many outstanding questions remain about the evolution of Earth's climate. Future progress will be realized through further improvement and enhancement of paleoclimate models, the continued documentation of Earth's environmental and climatic history, and the persistent ingenuity of paleoclimate scientists.
