ENCYCLOPEDIA OF PALEOCLIMATOLOGY AND ANCIENT ENVIRONMENTS

Volume Editor

Vivien Gornitz is a Senior Research Scientist, Center for Climate Systems Research, Columbia University and NASA Goddard Institute for Space Studies. She holds a B.A. from Barnard College and a Ph.D. from Columbia University. Her research interests include global sea level rise—past, present, and future, coastal hazards, climatic implications of land cover transformations, and planetary geology, including Mars. In addition to numerous scientific publications, she has edited *Geology of the Planet Mars* (Benchmark Papers in Geology, v. 48, Dowden, Hutchinson & Ross, Inc., 1979) and has contributed articles to several of the encyclopedias in the Earth Sciences Series. She was a Contributing Author for the IPCC in 1990, 1995, 2001, and 2007.

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to <http://www.springerlink.com/reference-works/> to visit the "Earth Sciences Series" on-line.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than 8 volumes in the *Encyclopedia of Earth Sciences Series*. For the past 25 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Principal Marine Geologist with Coastal Planning & Engineering, Inc. and Research Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; Southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Contents

List of Contributors	xi	Astronomical Theory of Climate Change	51
Preface	xxv	<i>André Berger</i>	
Acknowledgements	xxvii	Atmospheric Circulation During the Last Glacial Maximum	57
Aerosol (Mineral)	1	<i>David Rind</i>	
<i>Ina Tegen</i>			
Albedo Feedbacks	2	Atmospheric Evolution, Earth	61
<i>Andrew A. Lacis</i>		<i>James Farquhar</i>	
Alkenones	4	Atmospheric Evolution, Mars	66
<i>Mark Pagani</i>		<i>David C. Catling</i>	
Ancient Cultures and Climate Change	6	Atmospheric Evolution, Venus	75
<i>Vivien Gornitz</i>		<i>Bruce Fegley, Jr.</i>	
Animal Proxies, Invertebrates	10	Banded Iron Formations and the Early Atmosphere	85
<i>Robert R. Gaines and Mary L. Droser</i>		<i>Bruce M. Simonson and Alan J. Kaufman</i>	
Animal Proxies – Vertebrates	13	Basal Ice	89
<i>Thomas H. Rich and Patricia Vickers-Rich</i>		<i>Peter G. Knight</i>	
Antarctic Bottom Water and Climate Change	16	Beachrock	89
<i>Stan Jacobs</i>		<i>Ian D. Goodwin</i>	
Antarctic Cold Reversal	22	Beetles as Quaternary and Late Tertiary Climate Indicators	90
<i>Vincent I. Morgan</i>		<i>G. Russell Coope</i>	
Antarctic Glaciation History	24	Beryllium-10	92
<i>Kathy Licht</i>		<i>Jürg Beer</i>	
Antarctic Sea Ice History, Late Quaternary	31	Binge-Purge Cycles of Ice Sheet Dynamics	94
<i>Xavier Crosta</i>		<i>Martin J. Siegert</i>	
Archean Environments	34	Bolide Impacts and Climate	96
<i>William H. Peck and John W. Valley</i>		<i>Michael R. Rampino</i>	
Arctic Sea Ice	38	Bølling-Allerød Interstadial	100
<i>Anne de Vernal</i>		<i>Wim Z. Hoek</i>	
Arid Climates and Indicators	45		
<i>Andrew Goudie</i>			

Borehole Climatology <i>Hugo Beltrami and Daniela Nitoiu</i>	103	Cordilleran Ice Sheet <i>John J. Clague</i>	206
Carbon Cycle <i>Abraham Lerman</i>	107	Cosmogenic Radionuclides <i>Jürg Beer</i>	211
Carbon Dioxide and Methane, Quaternary Variations <i>Bernhard Stauffer</i>	118	Cretaceous Warm Climates <i>Erle G. Kauffman and Claudia C. Johnson</i>	213
Carbon Dioxide, Dissolved (Ocean) <i>Richard E. Zeebe and Dieter A. Wolf-Gladrow</i>	123	Cretaceous/Tertiary (K-T) Boundary Impact, Climate Effects <i>Elisabetta Pierazzo</i>	217
Carbon Isotope Variations Over Geologic Time <i>Ján Veizer</i>	128	Cryosphere <i>Philippe Huybrechts</i>	221
Carbon Isotopes, Stable <i>Steven W. Leavitt</i>	133	Cyclic Sedimentation (Cyclothem) <i>Allen W. Archer</i>	226
Carbonate Compensation Depth <i>Torsten Bickert</i>	136	Dansgaard-Oeschger Cycles <i>Irene A. Mogensén</i>	229
Carbonates, Cool Water <i>Jonathan Clarke</i>	138	Dating, Amino Acid Geochronology <i>Gifford H. Miller</i>	233
Carbonates, Warm Water <i>Dan Bosence</i>	143	Dating, Biostratigraphic Methods <i>Peter M. Sadler</i>	237
Cenozoic Climate Change <i>James D. Wright</i>	148	Dating, Dendrochronology <i>Brendan M. Buckley</i>	239
Cirques <i>Peter G. Knight</i>	155	Dating, Fission-Tracks <i>John I. Garver</i>	247
CLAMP <i>Robert A. Spicer</i>	156	Dating, Luminescence Techniques <i>Glenn W. Berger</i>	249
CLIMAP <i>James D. Hays</i>	158	Dating, Magnetostratigraphy <i>Wout Krijgsman and C. G. Langereis</i>	252
Climate Change, Causes <i>Thomas J. Crowley</i>	164	Dating, Radiometric Methods <i>Chris M. Hall</i>	255
Climate Forcing <i>Andrew A. Lacis</i>	174	Deep Sea Drilling Project (DSDP) <i>William W. Hay</i>	260
Climate Variability and Change, Last 1,000 Years <i>Michael E. Mann</i>	178	Deltaic Sediments, Climate Records <i>Steven L. Goodbred, Jr.</i>	265
Coal Beds, Origin and Climate <i>C. Blaine Cecil and Sandra G. Neuzil</i>	181	Dendroclimatology <i>Brendan M. Buckley</i>	269
Coastal Environments <i>Robert W. Dalrymple and Kyungsik Choi</i>	183	Desert Varnish as a Paleoclimate Proxy <i>Ronald I. Dorn</i>	275
Coccoliths <i>Jeremy R. Young</i>	187	Deuterium, Deuterium Excess <i>Gilles Delaygue</i>	278
COHMAP <i>Thompson Webb III</i>	188	Diamicton <i>John Menzies</i>	278
Continental Sediments <i>Marc S. Hendrix</i>	192	Diatoms <i>Amy Leventer</i>	279
Corals and Coral Reefs <i>John E. N. Veron</i>	198	Dinoflagellates <i>Anne de Vernal</i>	280

Dole Effect <i>Georg Hoffmann</i>	282	Glacial Isostasy <i>Kurt Lambeck</i>	374
Drumlins <i>Peter G. Knight</i>	284	Glacial Megalakes <i>Victor R. Baker</i>	380
Duricrusts <i>David J. Nash</i>	284	Glacial Sediments <i>Douglas I. Benn</i>	382
Dust Transport, Quaternary <i>Karen E. Kohfeld and Ina Tegen</i>	286	Glaciations, Pre-Quaternary <i>Emmanuelle Arnaud and I. Peter Martini</i>	384
Early Paleozoic Climates (Cambrian-Devonian) <i>Arthur J. Boucot</i>	291	Glaciations, Quaternary <i>Shawn J. Marshall</i>	389
Earth Laws and Paleoclimatology <i>Rhodes W. Fairbridge (deceased)</i> <i>and Vivien Gornitz</i>	294	Glaciofluvial Sediments <i>Douglas I. Benn</i>	394
Eccentricity <i>Marie-France Loutre</i>	301	Glaciomarine Sediments <i>Kathy Licht</i>	395
Eemian (Sangamonian) Interglacial <i>Ulrich C. Müller</i>	302	Glendonite/Ikaite <i>Ian P. Swainson</i>	396
Electrical Conductivity <i>Kendrick Taylor</i>	308	“Greenhouse” (Warm) Climates <i>Darren R. Gröcke</i>	397
Eolian Dust, Marine Sediments <i>David K. Rea</i>	308	Heat Transport, Oceanic and Atmospheric <i>Dan Seidov</i>	407
Eolian Sediments and Processes <i>Daniel R. Muhs</i>	312	Heinrich Events <i>Sidney Hemming</i>	409
Eolianite <i>David B. Loope</i>	319	History of Paleoclimatology <i>Rhodes W. Fairbridge (deceased)</i>	414
Eskers <i>Peter G. Knight</i>	320	History of Paleoclimatology – Biographies <i>Rhodes W. Fairbridge (deceased)</i> <i>and Vivien Gornitz</i>	428
Evaporites <i>Stefano Lugli</i>	321	Holocene Climates <i>Neil Roberts</i>	438
Evolution and Climate Change <i>David A. T. Harper</i>	325	Holocene Treeline Fluctuations <i>Mel A. Reasoner and Willy Tinner</i>	442
Faint Young Sun Paradox <i>James Farquhar</i>	333	Human Evolution and Climate Change <i>Gail M. Ashley</i>	446
Flood Basalts: Climatic Implications <i>Andrew D. Saunders</i>	335	Hypsithermal <i>Rhodes W. Fairbridge (deceased)</i>	451
Foraminifera <i>Harry J. Dowsett</i>	338	Ice Cores, Antarctica and Greenland <i>Dominique Raynaud and Frédéric Parrenin</i>	453
Geochemical Proxies (Non-Isotopic) <i>Matthew J. Higginson</i>	341	Ice Cores, Mountain Glaciers <i>Lonnie G. Thompson</i>	457
Glacial Erratics <i>Patrick M. Colgan</i>	354	“Icehouse” (Cold) Climates <i>Paul K. Link</i>	463
Glacial Eustasy <i>Stephen F. Pekar</i>	354	Ice-Rafted Debris (IRD) <i>Julian A. Dowdeswell</i>	471

Integrated Ocean Drilling Program (IODP) <i>Manik Talwani</i>	473	Maunder Minimum <i>Drew T. Shindell</i>	550
Interstadials <i>Wim Z. Hoek</i>	477	Medieval Warm Period <i>Rhodes W. Fairbridge</i> (deceased)	551
Iron and Climate Change <i>David Archer</i>	478	Mesozoic Climates <i>Gregory D. Price</i>	554
Isotope Fractionation <i>Dieter A. Wolf-Gladrow and Richard E. Zeebe</i>	479	Messinian Salinity Crisis <i>Stefano Lugli</i>	559
Kames <i>Peter G. Knight</i>	483	Methane Hydrates, Carbon Cycling, and Environmental Change	560

Preface

The growing levels of atmospheric greenhouse gases generated by anthropogenic activities are already beginning to affect the Earth's climate, according to the latest report by the Intergovernmental Panel on Climate Change, and concern is mounting over potential adverse consequences to society. However, Earth's climate has shifted dramatically and frequently during the last few million years, alternating between ice ages, when vast glaciers covered Northern Europe and much of North America, and interglacials—warm periods much like today. Farther back in geologic time, climates have differed even more from the present. Could human actions push the Earth's climate system into an unstable mode, beyond the relatively mild oscillations of the last few millennia? To fully understand the unusual changes of the 20th century and possible future trends, these need to be placed in a longer-term context extending well beyond the period of instrumental records. Paleoclimatology—the study of climates of the past—may provide us with insights into the workings of the modern climate system. By reconstructing ancient climates using natural “archives” of environmental change recorded in trees, corals, cave deposits, ice cores, lake and ocean sediments, and running computer models, paleoclimatologists can place bounds on past climate variability and help us anticipate possible future changes.

The *Encyclopedia of Paleoclimatology and Ancient Environments*, a companion volume to the recently-published

Encyclopedia of World Climatology, provides the reader with an entry point to the rapidly expanding field of paleoclimatology. Highly interdisciplinary, paleoclimatology integrates information from a broad array of disciplines in the geosciences, spanning across stratigraphy, geomorphology, glaciology, paleoecology, paleobotany, isotope geochemistry, geochronology, and geophysics, among others. The encyclopedia covers the entire span of the Earth's climate history from the early Precambrian to the Little Ice Age, and also offers an interplanetary comparison with the contrasting climates of Mars and Venus in 230 informative articles written by over 200 well known international experts. The climates of the past were the product of closely inter-connected processes that shaped the Earth's atmosphere, lithosphere, and biosphere. Therefore, the separation between topics is somewhat arbitrary and a certain degree of overlap is inevitable. However, since authors often approach similar topics from differing perspectives, these differences can provide a fuller picture overall. The volume is abundantly illustrated with line-drawings, black-white and color photographs. Articles are arranged alphabetically, with extensive bibliographies and cross-references.

March 2008

Acknowledgements

This volume is offered in tribute to the memory of Rhodes W. Fairbridge, Senior Editor of the Encyclopedia of Earth Sciences Series, who sadly passed away before this encyclopedia could be completed. It was upon his recommendation and inspiration that this project was undertaken. Rhodes Fairbridge took a keen interest in paleoclimatology, which ties together many aspects of the geosciences. He wrote several articles especially for this encyclopedia, including a detailed history of paleoclimatology and “Earth Laws and Paleoclimatology”, which summarizes many of the ideas he had covered in his long and distinguished career. He was way ahead of his time in his early acceptance of Wegener’s theory of continental drift, the role of orbital cycles in climate change (i.e., the Milankovitch theory), solar influences on climate, and recognition of general aridity during glacial periods. He was among the first to report the twentieth century rise in global sea level in the 1960s. One of the recurrent themes in Rhodes’ many publications is the role of cyclical phenomena on all timescales. A 1961 symposium that he organized at Columbia University was among the earliest to explore the connections between Earth cycles and paleoclimates. With his

colleagues, he investigated planetary alignments, their possible effects on solar activity, and ultimately on Earth’s paleoclimates. While still controversial, a growing body of literature points to some solar influence on climate and one of the articles in this volume addresses this particular issue. His ability to see beyond the minutiae of narrow specialties combined with an amazing memory served him well as senior series editor. He will be sorely missed and fondly remembered.

I thank the contributing authors for their efforts in bringing this Encyclopedia to fruition. Thanks are also extended to the members of the Editorial Advisory Board for their helpful suggestions and recommendations. Appreciation is also expressed to Ms. Eden Licardo, for her secretarial assistance, to Mr. José Mendoza for graphics support, and to Dr. Cynthia Rosenzweig, Head, Center for Climate Systems Research, Columbia University and NASA Goddard Institute for Space Studies, New York, for her encouragement and understanding during this lengthy undertaking.

A

AEROSOL (MINERAL)

General

Wind-blown mineral aerosol consists of micrometer-sized airborne soil dust particles. Estimates of modern global dust emissions range from 1,000 to 3,000 Mt yr⁻¹ (Houghton et al., 2001). Dust aerosol has a high spatial and temporal variability; large uncertainties exist in quantitative estimates of large-scale dust loads. Modern global dust distribution and properties can be characterized by satellite retrievals and concentration measurements at surface stations. Dust deposition data from ice cores, marine sediments, and terrestrial sites provide information on dust in modern and past climate periods (Kohfeld and Harrison, 2001). Such records show that dustiness was increased 2- to 20-fold during glacial periods compared with interglacials, as a consequence of increased aridity, reduced vegetation, increased availability of fine, loose sediment, and more vigorous surface wind speeds in glacial climates.

Dust sources

Mineral aerosol is generated in arid and semi-arid continental regions. Major dust sources include the Saharan/Sahelian region, the Arabian Peninsula, the Gobi and Taklamakan Deserts in Asia, and the Australian Desert (Duce, 1995). Dust emission occurs when the surface wind stress exceeds a threshold value, which is a function of surface properties like roughness elements, grain size, and soil moisture. Theoretical considerations and wind tunnel experiments show a dependence of dust emissions on the surface wind stress to the third or fourth power (Gillette and Passi, 1988; Shao et al., 1993). Fine soil particles that can be transported over large distances are released when larger wind-blown sand impacts on the soil, mobilizing smaller particles (saltation). Dust emissions occur preferentially in areas that contain fine, loose sediment. Prospero et al. (2002) find a good agreement of satellite-observed dust emission maxima with the location of topographic depressions, where fine sediment can accumulate. Rough surfaces containing structural elements like rocks or vegetation

increase the threshold velocity required for dust emission (Marticorena and Bergametti, 1995) since wind energy is partly absorbed by the obstacles. Crusting of soil surfaces can reduce the possible dust release from a source region. Dust deflation can decrease over time due to loss of available fine soil material. Surface disturbance and disruption of the vegetation cover can lead to increased dust emissions, for example during the “dust bowl” events in the United States in the 1930s and 1950s following cultivation of the soils in dry regions.

Dust cycle

Dust injected into upper levels of the atmosphere can be transported over thousands of kilometers by strong wind systems. Most prominently, Saharan dust is transported across the North Atlantic to North and Central America, and is found as far downwind as the Amazon Basin. Dust from Asia is transported over the North Pacific towards mid-Pacific islands and North America.

Dust is removed from the atmosphere by precipitation (wet deposition) or through gravitational settling and turbulent mixing at the surface (dry deposition). Close to the source regions, gravitational sedimentation is responsible for most dust deposition, while wet deposition determines the removal rate of far-traveled dust particles over remote ocean areas. Unless removed by precipitation, the length of time that dust aerosols remain in the atmosphere depends on the deposition velocities of the different particle sizes. Atmospheric lifetimes of dust range from a few hours for particles larger than 10 μm to 10–15 days for submicron particles (Ginoux et al., 2001).

Properties

The particle size of mineral aerosols determines their atmospheric lifetime and thus the distance that the particles can travel. Close to source regions the median dust particle radii are around 30–50 μm. Dust that has been transported away from the sources has a median radius around 1 μm (e.g., Duce, 1995).

The mineral composition of dust particles reflects the mineralogy of the rocks at the Earth’s surface; some main constituents are quartz, feldspars, carbonates and clays. Dust particles from different source regions have specific mineralogical

compositions and as a consequence, different refractive indices determining their optical properties. For example, Saharan dust is richer in iron and therefore darker and redder than Asian dust. Refractive indices for different minerals span a wide range for solar and thermal wavelengths (Sokolik and Toon, 1999). Data on dust refractive indices are currently limited to only a few regions.

Dust effects on climate

Dust can influence the climate in several ways. Aerosols significantly impact on the climate system by changing the energy balance of solar and thermal radiation (Houghton et al., 2001). Dust not only scatters but also partly absorbs incoming solar radiation, and also absorbs and emits outgoing long-wave radiation. Any changes in atmospheric dust loads, like the increase in dust during glacial periods, would cause a change in the radiation balance and consequentially, in surface temperatures. The magnitude and even the sign of the direct radiative dust forcing is uncertain; it depends on the optical properties of the dust, cloud cover, and the albedo of the underlying surface (Liao and Seinfeld, 1998).

The presence of dust may alter cloud optical properties by changing the number of cloud condensation nuclei. The efficiency of dust particles in forming nuclei for water clouds may alter during transport due to mixing with soluble aerosol species. This can influence both the brightness of clouds and the formation of rainfall. Dust particles can potentially change chemical reactions in the atmosphere because of their large surface areas, and therefore have a significant impact on the ozone and nitrogen cycles. Micronutrients (e.g., Fe) deposited with dust aerosol possibly impact the productivity of marine and terrestrial ecosystems, thus influencing the carbon cycle and potentially changing the atmospheric greenhouse gas content. The impacts of these indirect dust effects on climate are uncertain, since the underlying processes are not yet fully understood.

ALBEDO FEEDBACKS

Technically, the term albedo refers to the reflecting power of a body, or a surface area, and is the fraction of light reflected by the body relative to the total light that is incident on the body, or surface. Thus, a perfect absorber has an albedo of zero while a perfect reflector has an albedo of unity. In general, the albedo of a given surface is a function of wavelength. It is also dependent on the angle at which the incident light strikes the reflecting surface. This leads to more specialized terminology such as “spectral albedo” and “plane albedo,” which refer to the wavelength and solar zenith angle dependence of the reflected radiation, respectively. Reflected radiation that has been averaged over all possible angles of incidence is called “spherical albedo.” It is also referred to as the Bond albedo, which is the ratio of the total light reflected by a spherical body, such as a planet, to the total radiation that is incident on the planet.

In the context of terrestrial climate where interest is primarily directed toward describing the radiative energy balance of the Earth, there is an implicit assumption that the spectral albedo of the Earth is then directly related to the solar energy that is available to drive atmospheric dynamics and for maintaining the temperature of the Earth-atmosphere system. It is also useful to differentiate between “surface albedo,” which is the reflectivity of the bare ground and ocean surface without including atmospheric scattering effects, and “planetary albedo,” which includes all atmospheric and surface scattering contributions and refers to the outgoing solar radiation at the top of the atmosphere that is reflected back to space.

Figure A1 shows the zonally averaged annual mean surface albedo (*dashed line*) and planetary albedo (*solid line*) of the Earth as computed with a general circulation climate model. Characteristically, the ocean and land are areas of low reflectivity with typical albedos in the 6–12% range. Substantially higher surface albedos due to snow and ice are evident in the polar regions where the albedo of fresh snow may exceed 90%. Globally averaged, the surface albedo of the Earth is about 12%. The planetary albedo is generally larger than the surface albedo due primarily to the high reflectivity of clouds. As in the case of fresh snow, the albedo of optically thick clouds can sometimes exceed 90%. However, because of absorption by atmospheric gases and multiple scattering effects between the atmosphere and ground surface, the planetary albedo in the polar regions is frequently lower than that of the highly reflecting snow surface. Globally averaged, the planetary albedo of the Earth, also called the global albedo, is approximately 30%. Thus, about 70% of the solar

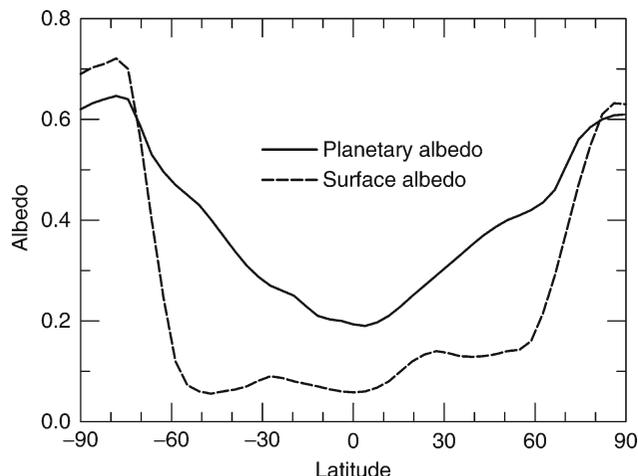

Figure A1 Zonally averaged annual mean surface albedo (*dashed line*) and planetary albedo (*solid line*) of the Earth as computed with a general circulation climate model.

radiation that falls on the Earth is absorbed by the Earth-atmosphere system, with most of the solar energy being absorbed at low latitudes and relatively little within the polar regions. This serves to establish the characteristic equator-to-pole temperature gradient and the corresponding atmospheric and oceanic circulation patterns that work to redistribute the absorbed solar energy more evenly.

Despite the high surface albedo at high latitudes, the atmospheric contribution to the global albedo exceeds that of the ground surface by about a factor of 2.5, with clouds being the single largest contributor. Smaller contributions to the global albedo are made by atmospheric aerosols and by Rayleigh scattering due to air molecules. Rayleigh scattering, which accounts for about 5% to the global albedo, is essentially a constant offset factor in climate considerations since it is not significantly affected by changes in atmospheric conditions. Snow, ice, and clouds on the other hand have specific temperature and humidity thresholds at which they form and dissipate. The large albedo contrast that occurs when snow, ice, and cloud amounts change strongly affects the amount of solar radiation that is absorbed by the Earth-atmosphere system. This in turn affects the atmospheric temperature distribution, leading to mutual interactions between regions of snow, ice, and cloud fields and the local surface and atmospheric temperature distributions. These physical interactions comprise the basic climate “feedback” effects whereby a given change in temperature directly or indirectly induces a change in snow, ice or cloud amount, which in turn affects the amount of solar energy that is absorbed, thus magnifying the original temperature perturbation.

Albedo feedbacks associated with changes in snow and ice cover are generally positive. This is because for an initial increase in temperature, ΔT_o , due to whatever cause, the expected result is the melting of a certain amount of snow and ice with a corresponding decrease in local albedo, which leads to increased absorption of solar energy and a subsequent increase in temperature. This results in a geometric series of temperature increments that converges to some equilibrium temperature that is ΔT_{eq} higher than the initial reference temperature. The ratio, $f = \Delta T_{eq}/\Delta T_o$, is called the feedback factor by which the initial forcing is magnified. Accordingly, if f is

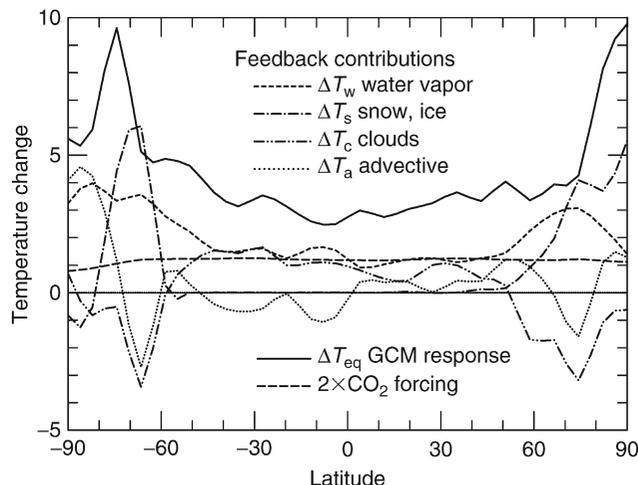

Figure A2 Annually averaged zonal-mean GCM surface temperature response for doubled CO_2 (*heavy solid line*) and temperature forcing due to doubled CO_2 (*heavy dashed line*). The other curves depict other feedback contributions as indicated.

greater than unity the feedback is positive, and if f is less than unity the feedback is negative.

The relative strengths of different climate feedback effects can be evaluated with the help of a general circulation climate model (GCM) and its radiative transfer model. The GCM is assumed to incorporate appropriate mathematical formulations for all of the necessary physical process to model the climate system, such as the evaporation, transport, and condensation of water vapor, precipitation, the freezing and melting of ice, the diurnal and seasonal changes in solar heating and thermal cooling, including the appropriate heat capacities for the ocean, land, and atmosphere. In typical GCM experiments of climate forcing, the GCM is first run to its reference equilibrium state, at which point the global distributions of water vapor, surface albedo, clouds, and temperature are recorded. A radiative perturbation, such as doubling the CO_2 amount, is then applied and the GCM is run to its new equilibrium state whereupon the changes in the distributions of water vapor, surface albedo, cloud, and temperature are again recorded and analyzed.

The principal results for a doubled CO_2 experiment are summarized in **Figure A2** by the heavy solid line which depicts the latitudinal dependence of the total annual-mean equilibrium temperature change, including albedo feedbacks which globally averaged, yields $\Delta T_{eq} = 3.9^\circ\text{C}$, and by the heavy dashed line which represents the applied forcing due to doubled CO_2 alone, which, globally averaged and expressed as a temperature change, yields $\Delta T_o = 1.2^\circ\text{C}$ (**Table A1**). The difference between the externally imposed temperature change ΔT_o , and the actual temperature change ΔT_{eq} that is realized as the model reaches its new thermal equilibrium, is the feedback contribution, which produces both a reduction of the planetary albedo of the Earth, and an enhancement of its atmospheric greenhouse strength.

Specific information regarding the relative magnitude of individual feedback contributions can be obtained by inserting the recorded cloud, water vapor, surface albedo differences between the perturbed and reference model results into the GCM one at a time, and by running the model to equilibrium with all physical process interactions turned off, except for only local

Table A1 Doubled CO₂ feedback contributions

Process	ΔT	Feedback gain	Feedback factor
2 × CO ₂ forcing	$\Delta T_o = 1.2$		
Water vapor	$\Delta T_w = 1.7$	$g_w = 0.44$	$f_w = 1.77$
Snow, ice	$\Delta T_s = 0.5$	$g_s = 0.13$	$f_s = 1.15$
Clouds	$\Delta T_c = 0.5$	$g_c = 0.13$	$f_c = 1.15$
Total	$\Delta T_{eq} = 3.9$	$g = 0.69$	$f = 3.25$

surface and atmospheric temperatures that are allowed to adjust. The resulting temperature differences define the strength of each feedback contribution relative to the total equilibrium temperature change ΔT_{eq} that may be considered as the driving force behind each feedback process. The relative strengths of different feedbacks can be readily compared when expressed as feedback gain factors ($g = \Delta T / \Delta T_{eq}$). Globally averaged, these are tabulated in [Table A1](#) for the principal feedback processes.

The surface albedo feedback, due primarily to changes in sea ice in the polar regions, and its latitudinal dependence, is shown by the heavy broken line in [Figure A2](#). The feedback effect of cloud changes is seen to be positive within low to middle latitudes, but is negative in the polar regions. About 60% of cloud feedback is the result a decrease in global albedo caused by a reduction in cloud fraction, while about 40% is attributable to greenhouse enhancement due to an increase in cloud altitude. Water vapor makes the largest individual feedback contribution with about 80% in the form of greenhouse enhancement, while 20% comes in the form of reduced planetary albedo due to increased absorption of solar radiation by water vapor. Overall, about 40% of the 2.7 °C global feedback effect in response to doubled CO₂, is the result of global albedo reduction, and about 60% is due to greenhouse enhancement. The *dotted line* in [Figure A2](#) refers to advective feedbacks that arise from changes in atmospheric circulation which act to redistribute energy latitudinally, but which, when globally averaged, must add to zero.

The feedback gain factors in [Table A1](#) combine linearly in the form $g = g_w + g_s + g_c$ to yield the total climate system feedback gain factor. Feedback factors, on the other hand, which determine the ratio by which the initial temperature perturbation will be magnified when the climate system reaches equilibrium, combine non-linearly and are evaluated as $f = (1 - g)^{-1}$. Acting alone, the snow-ice albedo feedback magnifies a given temperature perturbation by only a factor of $f_s = 1.15$. But, acting together with water vapor and cloud feedbacks, with $f_{wc} = 2.33$, it raises the combined feedback factor to $f_{wcs} = 3.25$. During the past glacial maximum when the global snow-ice cover was more extensive, the snow-ice feedback is estimated to have been about twice as strong as it is in current climate. This would have produce a combined feedback gain factor of 0.82, or a feedback factor of $f_{wcs} = 5.55$. For ice-age CO₂ amounts that were about half of those for current climate, the CO₂ radiative forcing of about $\Delta T_o = -1$ °C, would maintain a global-mean temperature 5–6 °C colder than the global-mean temperature of current climate.

Additional albedo feedback effects can arise from changes in vegetation cover. However circumstances regarding vegetation albedo feedback are more complicated than the relatively simple temperature dependence for snow and ice formation. This is because vegetation cover is more directly coupled to precipitation and drought conditions which are driven by changes in atmospheric circulation patterns rather than by changes in temperature.

Ultimately, of course, atmospheric circulation is driven by the distribution of solar heat energy, but the relationship between absorbed solar energy and vegetation albedo is somewhat indirect, making it more problematic to establish whether the vegetation albedo feedback is positive or negative. Typically, since vegetation tends to be less reflecting than the bare ground that would replace it, a decrease in vegetation cover would tend to increase the planetary albedo.

ALKENONES

Alkenones are long-chained (C₃₆-C₃₉) *di*-, *tri*- and *tetra*-unsaturated ethyl and methyl ketones synthesized by a few species of Haptophyte algae in the modern ocean (Volkman et al., 1980; Conte et al., 1994). The cosmopolitan coccolithophorid *Emiliania huxleyi* is the most important contemporary source of alkenones, followed by substantial regional contributions from *Gephyrocapsa oceanica*. Other noncalcifying Haptophytes, including *Isochrysis* spp. and *Chrysothila lamellosa*, produce alkenones but are restricted to coastal marine environments (Ziveri and Broerse, 1997). *Emiliania huxleyi* evolved in the Late Pleistocene (Thierstein et al., 1977) and *G. oceanica* in the Pliocene (Hay, 1977), however, the geological range of alkenones extends to the early Cretaceous (Farrimond et al., 1986). The distribution of alkenones in Mesozoic and Cenozoic sediments reflects, in part, their refractory nature attributed to an unusual *trans* configuration – a molecular architecture that may inhibit bacterial biodegradation (Rechka and Maxwell, 1987). Examination of older sediments containing both alkenones and nannofossils has narrowed the probable source of alkenones to microalgae within the family Noelaerhabdaceae (Volkman, 2000).

Original aspirations that alkenones represented unambiguous biomarkers for coccolithophorids were surpassed by their capacity to record sea-surface temperatures at the time of biosynthesis. A relationship between the degree of alkenone unsaturation with temperature was first observed in Haptophyte cultures (Marlowe et al., 1984). This behavior, assumed to

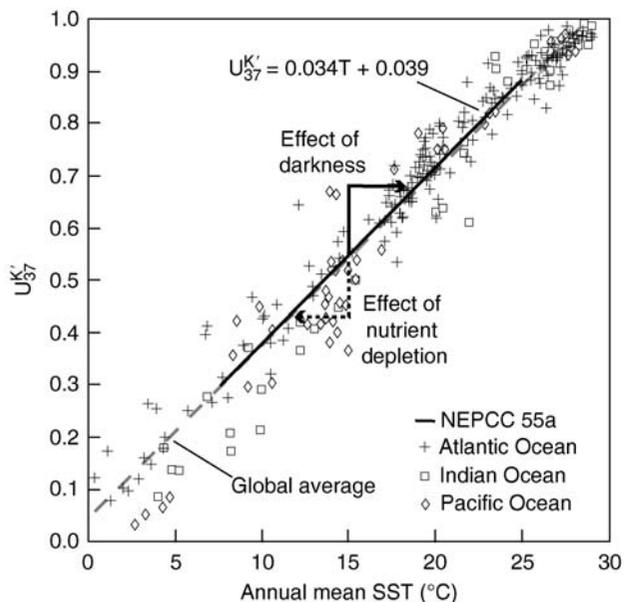

Figure A3 Relationship between U_{37}^K from surface sediments and mean annual surface temperature. Modified from Müller et al. (1998) and published in Prah1 et al. (2003).

reflect a biochemical response to maintain the integrity and permeability of its cell membrane, follows a pattern of increasing unsaturation with decreasing growth temperature. Brassell et al. (1986) pioneered the application of alkenone unsaturation in the interpretation of ancient sea surface temperatures and defined the alkenone unsaturation indices U_{37}^K and $U_{37}^{K'}$:

$$U_{37}^K = \frac{[37:2] - [37:4]}{[37:2] + [37:3] + [37:4]} \text{ and } U_{37}^{K'} = \frac{[37:2]}{[37:2] + [37:3]}$$

where [37:2], [37:3], and [37:4] represent the relative concentrations of C_{37} di-, tri-, and tetra-unsaturated alkenones respectively. Subsequent experiments using a Pacific strain of *E. huxleyi* (Prah1 and Wakeham, 1987; Prah1 et al., 1988) demonstrated a linear response of U_{37}^K and $U_{37}^{K'}$ with growth temperature between 8° and 25 °C. These critical experiments provided a calibration of $U_{37}^{K'}$ versus temperature widely applied in subsequent paleoceanographic studies. The calibration of Prah1 et al. (1988),

$$U_{37}^{K'} = 0.034T(^{\circ}\text{C}) + 0.039$$

is identical to field-based results derived from extensive surface sediment $U_{37}^{K'}$ values and mean annual sea surface temperatures at 0 m depth (Figure A3) (Müller et al., 1998). This agreement is remarkable in light of the observation that calibration differences exist between Haptophyte strains and species (Sikes and Volkman, 1993; Conte et al., 1998), as well as growth conditions (Epstein et al., 1998; Prah1 et al., 2003).

While alkenone unsaturation is useful in assessing sea surface temperatures, the stable carbon-isotope composition of these molecules contains information relevant to the concentration of dissolved carbon dioxide during algal production (Bidigare et al., 1997, 1999). Consequently, alkenone $\delta^{13}\text{C}$ values have been applied to evaluate equatorial Pacific paleoceanographic dynamics and surface-water $[\text{CO}_{2\text{aq}}]$ during the

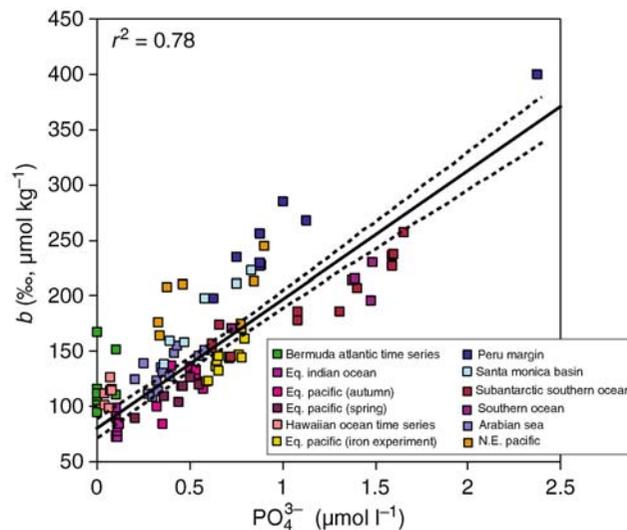

Figure A4 Compilation of “*b*” versus soluble phosphate for natural haptophyte populations (modified from Laws et al., 2001). Values for “*b*” are calculated using a value of 25‰ for ϵ_f . Solid line represents geometric mean regression. Dotted lines reflect 95% confidence intervals.

Pleistocene (Jasper et al., 1994), Late Quaternary surface-water CO_2 (Jasper and Hayes, 1990; Andersen et al., 1999), and global $p\text{CO}_2$ trends during the Miocene (Pagani et al., 1999). In addition to $[\text{CO}_2]$, other factors including cellular growth rate (Rau et al., 1992; Bidigare et al., 1997), cell geometry (Popp et al., 1998) strongly affect the stable carbon isotopic compositions of algae by influencing the magnitude of carbon isotope fractionation that occurs during carbon fixation (ϵ_p). For field-based research the expression for ϵ_p is simplified to

$$\epsilon_p = \epsilon_f - \frac{b}{C_c}$$

where ϵ_f is the carbon isotope fractionation associated with carbon fixation, C_c is the concentration of extracellular $\text{CO}_{2\text{aq}}$, and “*b*” represents the sum of physiological factors affecting the total carbon discrimination such as growth rate and cell geometry. Measurements of natural Haptophyte populations (see Laws et al., 2001) provide evidence for a robust relationship between the physiological-dependent term “*b*” and the concentration of reactive soluble phosphate (Figure A4). Although phosphate is a major limiting nutrient, it is unlikely that $[\text{PO}_4^{3-}]$ alone is responsible for the variability in growth rate inferred from variation in “*b*.” Instead, it is assumed that the availability of one or more trace element that display phosphate-like distributions in the ocean (i.e., Se, Co, Ni) influence the growth characteristics of these algae (see Bidigare et al., 1997; Laws et al., 2001 and references therein). Despite these uncertainties, the empirical relationship between the term “*b*” and $[\text{PO}_4^{3-}]$ in the modern ocean allows ϵ_p to be cast in terms of $[\text{PO}_4^{3-}]$ and $[\text{CO}_{2\text{aq}}]$, providing a proxy for evaluating paleo- $[\text{CO}_{2\text{aq}}]$ if ancient ϵ_p values are reconstructed and phosphate concentrations are constrained (Pagani et al., 1999, 2002).

ANCIENT CULTURES AND CLIMATE CHANGE

The Earth's climate warmed abruptly, starting around 11,500 years ago after the final stages of the last glaciation. The Holocene climatic amelioration following the last ice age coincided with a major transition in human history – from the hunting-gathering lifestyle of our ancestors to the onset of agriculture, permanent settlements, and the beginnings of civilization. Early populations depended on hunting, fishing, and foraging for wild plants. The abundances of these resources were strongly influenced by seasonal cycles and multi-decadal climate trends. Even after the development of agriculture, ancient societies were probably more vulnerable to the impacts of sudden climate change than modern societies, since they were predominantly agrarian and dependent on weather-sensitive crops.

The post-glacial warming trend reached its peak in the Hypsithermal during the early to mid-Holocene, between ~8,300 and 5,000 yBP. Although the Holocene has generally been regarded as a period of climate stability, relative to the sharp climate fluctuations of the Pleistocene, accumulating evidence demonstrates considerable climate variability (see *Holocene climates*). The Hypsithermal marked a time of improved climate, and also of significant population shifts and growing cultural sophistication in many parts of the world: the development of complex agricultural societies, irrigation systems, and cities, the invention of writing and metallurgy, i.e., the roots of civilization (e.g., Sandweiss et al., 1999). Stronger monsoons and a northward shift of tropical rainfall belts between ~9,000 and 7,000 yBP created a savannah-like environment in the eastern Sahara that encouraged cattle herders to settle in villages west of the Nile River, in an area that is now desert. The region was abandoned after the onset of arid conditions,

starting approximately 6,000 years ago. The migrations resulting from this dry phase may have led to the emergence of the pharaonic civilization in Egypt (Kuper and Kröpelin, 2006). Around this time, major construction of temples began in the Nile Valley. A trend toward cooler (and in some regions, drier) climates in the following millennia may have stimulated further cultural changes in many areas. Lengthy droughts in western Asia at around 8,200, 5,200, and 4,200 yBP may have triggered demographic shifts that resulted in depopulation of early settlements, relocation to more favorable areas, and re-colonization upon climatic amelioration (Staubwasser and Weiss, 2006). In China, cities grew after ~5,800 yBP and in Japan, a more complex society emerged (Sandweiss et al., 1999). The onset of a period of greater El Niño activity after 5,800 yBP, following a lull, correlated with the start of temple building along the Peruvian coast (Sandweiss et al., 2001).

Many authors have pointed out apparent relationships between the rise and fall of ancient civilizations and climate change (e.g., Ladirie, 1971; Lamb, 1977, 1995; Wigley et al., 1981; Fagan, 1999, 2004; Gill, 2000). However, changes in those societies could have also been instigated by the interaction of a number of other factors, including economic and/or political instability, diseases, human migrations, wars, cultural innovations, and environmental degradation (e.g., Kirch, 2005; Morrison, 2006), which may have been only indirectly related to climate, if at all. While it is probably an over-simplification to assume that climate change was the sole or dominant cause of sudden societal dislocations, a growing body of evidence lends support to the idea of a relationship between rapid alterations in settlement patterns, growth or abandonment of cities, with cultural discontinuities on the one hand and climate fluctuations on the other. Climate change by itself may not have been enough to initiate major population shifts or topple an otherwise stable civilization; however, it could have provided the final straw in environmentally marginal regions or in conjunction with one of the other destabilizing influences listed above. Some examples of possible connections between abrupt transitions in ancient civilizations and climate change are discussed below.

Eastern Hemisphere

The Black Sea, a freshwater lake during the last glaciation, subsequently expanded, fed by meltwater from retreating glaciers, but then dwindled to a brackish lake during the Younger Dryas, ~12,000 years ago. According to Ryan and his colleagues (Ryan et al., 1997; Ryan and Pitman, 1999), by ~7,500 yBP the global sea level had reached a point where a catastrophic flood of water from the Aegean Sea broke through the Bosphorus Strait and gushed into the Black Sea. Evidence for this event is shown by the first appearance of salt-tolerant Mediterranean mollusks. They further speculate that this event may have provided the basis for the biblical account of Noah's flood. Such a massive flood may also have triggered migration of people away from the region, west and north into Europe and south into the Middle East. Signs of a flooded settlement 95 m beneath the modern northern coast of Turkey (Ballard et al., 2000) lend further support to this hypothesis. However, this hypothesis has been challenged by Aksu et al. (2002) who instead suggest that the Black Sea, at a much lower level during the late glacial, began to rise by 11,000–10,000 yBP, fed by water from the Danube, Dniester, Dnieper, Don, southern Bug, and on occasion, Volta Rivers. A now-drowned 10–9 ka delta lobe at the southern exit of the Bosphorus Strait provides

evidence for early and strong Black Sea outflow. Sediments were deposited away from the delta across the Marmara Sea. No indication exists for erosion of these sediments by strong currents from the proposed catastrophic flood at 7,500 yBP. By ~8000 years, the sea level had risen to the point where the Marmara Sea overtopped the sills in the Bosphorus, introducing saline Mediterranean water into the Black Sea for the first time. Rather than a catastrophic flood, Aksu et al. (2002) propose instead a gradual establishment of a two-way flow in the Bosphorus. Paleo-hydrometeorological modeling of the Black Sea Basin (Georgievski and Stanev, 2006) suggests an arid period and Black Sea lowstand peaking at 11,500 yBP. Rising sea levels reached the Black Sea between 8,800 and 7,400 yBP, making a flood event possible. However, the exact timing and nature of the marine re-connection depends on several variables, such as sill depth and precipitation minus evaporation balance, which are not yet tightly constrained by the data.

The transition from hunting-gathering to agriculture in southwest Asia may have begun as early as 12,000 ago, during the Younger Dryas period, when the region became cooler and drier. The reduction in availability of wild food resources, on which Natufian groups depended, may have stimulated them to experiment with cultivation rather than depend entirely on gathering (Weiss and Bradley, 2001). During a global cold period ~8,200 yBP (see *The 8,200 ybp event*), a lengthy drought gripped the Middle East, at which time a number of early agricultural settlements appear to have been abandoned in northern and central Mesopotamia (Weiss and Bradley, 2001; Staubwasser and Weiss, 2006). This episode may have contributed to the development of irrigation agriculture in southern Mesopotamia. Another arid period ~5,200 yBP, associated with reduced Anatolian precipitation and lowered Tigris-Euphrates streamflow, may have led to the collapse of the Late Uruk culture in Mesopotamia (Staubwasser and Weiss, 2006).

Between 4,300 and 4,200 yBP, the Akkadian empire prospered in northern Mesopotamia. Yet, by ~4,200 yBP, the empire had collapsed. It has been suggested that the collapse was linked to a period of greater regional aridity and erosion in the Near East (Weiss et al., 1993; Cullen et al., 2000; deMenocal, 2001; Staubwasser and Weiss, 2006). Growing problems with salinization may have also led to declining crop yields (Roberts, 1998). A marked increase in eolian grains from a marine core in the Gulf of Oman ~4,000 years ago may be linked to the collapse. These grains were derived from adjacent terrigenous sources. A close geochemical match between volcanic shards found in the core and in a layer immediately above the Akkadian ruins suggests that Akkadian collapse and aridification were synchronous (Cullen et al., 2000). On the other hand, Tainter (2000) questions whether the extended period of drought at 4,200 yBP was the real cause of the Akkadian collapse. He points out that during an earlier period of drought, instead of a decline in population or sociopolitical complexity, the opposite had occurred – a stable state had emerged. Thus, why would adverse climate destroy a society at one time, but lead to societal advance at another?

Paleoclimate records, including geochemical data from speleothems in Israel and lacustrine sediments in Turkey and elsewhere, however, suggest that the 4,200 yBP drought was of regional extent (Cullen et al., 2000; Staubwasser and Weiss, 2006). The termination of the Harappan civilization in the Indus Valley at around 4,200 yBP may have also been related to this drought (Staubwasser et al., 2003). Dead Sea lake levels fell sharply beginning around 2,300–2,200 BC, reaching a minimum at around 1,400 BC (Enzel et al., 2003). Data from several

independent paleoclimate proxies in an Italian speleothem, interpreted as indicating an arid regime, have been accurately dated at ~4,100 yBP (Drysdale et al., 2006). This age is consistent within error limits with the timing of the southwest Asian drought. The drought may have extended as far as southern Europe, across the Middle East, northwest India and Pakistan, and into Tibet and south China (Staubwasser and Weiss, 2006).

The 10,000-year record of Dead Sea lake levels show several other fluctuations that appear to be associated with cultural transitions in the Near East (Enzel et al., 2003; Bookman et al., 2004; Migowski et al., 2006). Modern meteorological data show a high degree of correlation between rainfall in Jerusalem and many other stations in the region, including Jordan and Lebanon. Thus, variations in Dead Sea lake levels can serve as a proxy for Near East paleoprecipitation. In addition to a drop in lake level ~2,200 BC, at around the time of the collapse of the Akkadian empire mentioned above, Enzel et al. (2003) associate a drop in lake level between the late fifth and late eighth centuries with the decline of the Byzantine empire in the Near East and Arab expansion out of Saudi Arabia. Conversely, high lake levels of the second and first centuries BC and fourth century CE have been related to expansion of Roman and Byzantine presence, respectively, in the region and the Crusader period in the eleventh and twelfth century CE (Bookman et al., 2004). Examining Dead Sea lake level variations further back in time, Migowski et al. (2006) link the ~8,100–8,200 yBP drought with the decline of the earliest Jericho township. Climatic amelioration around 5,100 yBP paralleled the growth of Early Bronze Age Arad at the northeastern edge of the Negev desert. Jericho was resettled during this wetter period, but declined once more during the 4,200 yBP drought. Migowski et al. (2006) point out several other examples of growth and decline of Canaanite city-states coinciding with climatic changes.

One frequently cited example of an adverse impact of climate change is the demise of the Norse settlements in Greenland (Lamb, 1977, 1995). The failure of the settlements has also been blamed on an inability of the Vikings to adapt their agrarian economy to the hunting and fishing lifestyle of the native Inuit population as the climate grew colder, or to overgrazing and soil erosion, disease, hostilities, and declining demand for walrus ivory or furs. According to the sagas, Icelandic settlers led by Erik the Red colonized the southwest coast of Greenland c. AD 985, followed by a second settlement on the west coast. However, by around AD 1,450, the colonies had been abandoned. Foraminifera and lithologic proxies from marine cores in Nansen Fjord, eastern Greenland, as well as oxygen isotope data from Greenland ice cores suggest that warmer conditions prevailed from AD 700 to around AD 1,300, corresponding to the Medieval Warm Period (Ogilvie et al., 2000). The lithologic data, in particular, point to less sea ice and more open water, which would have been favorable for seafaring. The 1,300s were marked instead by more frequent occurrences of sea ice and colder temperatures. As the climate deteriorated, the Norse settlers relied less on cattle and increased their dietary intake of seafood (Arneborg et al., 2002). While seal, walrus, caribou, and wild birds had always been part of the Norse Greenlanders' diet, McGovern (2000) suggests that their inability to develop Inuit-style harpooning technology may have prevented them from hunting seals in winter, at times when other food resources were especially scarce. However, archeological remains do not show evidence for sudden disease, starvation, or warfare (although one medieval record blames the demise of the Western Settlement in the 1,360s on the "skraelings" [a derogatory term for native people]).

Trade with Norway and Iceland declined over time, as increased sea ice and storminess in the fourteenth century made ocean voyages riskier, with a greater likelihood of ships lost at sea. Although largely self-sufficient, the Norse Greenland economy would have declined as exports of luxury goods, such as walrus ivory and fur, and imports of metal tools and other non-locally produced goods would have ceased. Climatic cooling was undeniably an important factor in the decline of the Viking settlements in Greenland, yet a full explanation for their disappearance remains enigmatic. The Western Settlement was abandoned by ~1,360, followed by the Eastern Settlement ~1,450. It is still uncertain whether the last inhabitants emigrated to Iceland or died in Greenland.

Western hemisphere

The collapse of the Classic Maya civilization c. AD 750–950 is another example where the fall has been attributed to lengthy drought. Paleoclimate records inferred from lake sediments in central Yucatan, Mexico point to periods of peak aridity centered around AD 800 and AD 1,020 (Hodell et al., 1995, 2001). High-resolution geochemical data from a marine core in the Cariaco Basin off northern Venezuela provide additional evidence of regional drought (Haug et al., 2003). Bulk titanium content has been used as a proxy for terrigenous sediment flux into the Cariaco Basin during the regional rainy season (summer-fall), when the Intertropical Convergence Zone (ITCZ) is at its northernmost position in the southern Caribbean, including Central America and southern Mexico. The higher the rainfall, the greater the deposition of Ti-bearing terrigenous sediments, and vice-versa (i.e., low rainfall = low Ti content). Variations in titanium concentrations parallel periods of late Holocene climate change. For example, Ti levels were low ~200–500 yBP, corresponding to the Little Ice Age, but higher between 1,070 and 850 yBP during the Medieval Warm Period. Other dry periods lasted from 1,750 to 1,650 years ago and again between 1,300 and 1,100 years ago (Haug et al., 2003). This latter period was marked by several severe multi-year droughts, during which time many densely populated Mayan cities were completely abandoned, leading to the end of the Classic Maya civilization. Haug et al. (2003) suggest that the Maya population had expanded rapidly in preceding, wetter years until reaching the carrying capacity of the land, which left the society vulnerable to extreme climate events. For example, soil erosion and nutrient depletion, resulting from deforestation and land clearance, (Roberts, 1998) may have contributed to crop declines. However, the dry conditions affecting the Yucatan Peninsula may have been regional in scope, possibly extending into western South America (see below).

The Tiwanaku civilization on the Bolivian-Peruvian altiplano surrounding Lake Titicaca emerged around 400 BC and lasted until ~AD 1,100, when Tiwanaku was abandoned. Sediment cores from the Rio Catari Basin near Lake Titicaca and Quelccaya (Peru) ice core data reveal a long history of regional climate variation (Binford et al., 1997). The onset of agriculture and complex societies began during a more humid phase starting around 1,500 BC. Several dry episodes occurred subsequently, although lake levels remained relatively high for several centuries prior to the abandonment of Tiwanaku and dropped abruptly at AD 1,100. Snow accumulation in the Quelccaya ice core decreased, starting around AD 950, which was roughly contemporaneous with the Classic Mayan drought. Dust levels in the Quelccaya ice core peaked slightly earlier, at around AD 900. While there had been several earlier dry periods, the

impacts of the AD 1,100 drought were probably greater, since the population had become dependent on raised-field agriculture that required an abundant supply of water. On the other hand, major ENSO-related flood events at AD 690 and AD 1,300 on the Rio Moquegua, southwest of Lake Titicaca in southern Peru, did not lead to valley abandonment (Magilligan and Goldstein, 2001). However, evidence for severe drought at AD ~1,100 is absent from the river records. While negative consequences of prolonged drought cannot be ruled out, Magilligan and Goldstein believe instead that non-climatic factors, such as social instability, were the main drivers of the Tiwanaku collapse.

The Mochica civilization, noted for its exquisite pottery, refined metallurgy, and monumental architecture, developed along the northern coastline of Peru, between AD 300 and 500. Moche, the capital, and nearby coastal cities, were abruptly abandoned around AD 600, and resettlement took place farther inland at the foothills of the Andes, where river runoff was more reliable, between AD 600 and 750 (deMenocal, 2001). Agricultural fields and irrigation systems were overlain by desert dunes at the time of the abandonment. The Quelccaya ice core shows low ice accumulation rates and increased eolian dust in the period from AD 563 to 594. Other population shifts between coastal and highland cultures in Peru and Ecuador have also been associated with climate change. Much earlier, the start of temple construction along the Peruvian coast after 5,800 yBP coincided with the onset of El Niño events, following a period of low activity. However, regional abandonment of major temples after 3.2–2.8 yBP correlates with an increase in El Niño frequency (Sandweiss et al., 2001; *Paleo-El Niño-Southern Oscillation (ENSO) records*).

Climate reconstructions based on long-term tree-ring chronologies show that the American Southwest has experienced a number of extensive droughts (Cook et al., 2004; Benson et al., 2006a, b). A 400-year long dry spell persisted between AD 900 to 1,300, during which period particularly severe drought episodes were centered in AD 1,034, ~1,090, 1,150, 1,253, and 1,280. A number of independent proxies of long-term aridity changes from surrounding states bolster the tree-ring records. The 1,150 and 1,280 droughts affected much of the western U.S. (Benson et al., 2006a, b). The decline and abandonment of Chaco Canyon, Anasazi settlements in northern New Mexico, between AD 1,130 and 1,180, may have been related to the 1,150s drought. The abandonment of Mesa Verde, Colorado may have been spurred by the late thirteenth century droughts. In a marginal environment such as the Four Corners area of the U.S. Southwest, even the sophisticated water catchment systems developed by the Anasazi would have been insufficient to cope with minor precipitation shortfalls or changes in seasonal rainfall patterns. Skeptics argue that other causes, such as social disintegration, incursion by hostile tribes, deforestation, or disease may have contributed to the population decline. A major volcanic eruption in AD 1,258, the largest during the Holocene in terms of aerosol loading, may have caused temporary global cooling and a shortened growing season, perhaps reinforcing the effects of the drought (see *Volcanic eruptions and climate change*). Cook et al. (2004) speculate that higher temperatures, coinciding with the Medieval Warm Period, may have contributed to the more frequent and persistent droughts. Benson et al. (2006a, b) find that the 1,150 and 1,280 droughts appear to have been associated with minima in the Pacific Decadal Oscillation and a positive phase of the Atlantic Multidecadal Oscillation (see *Teleconnections*, Encyclopedia of World Climatology).

The cases outlined above illustrate examples of apparent correlations between episodes of abrupt cultural change and

documented climate fluctuations. While cultural and climatic events may closely match in time, this in itself does not prove causality. Minor climatic perturbations could have provided the last straw to societies already stressed to the brink by socio-economic and political instability, or environmental degradation. A careful analysis of archeological and paleoclimatological records, along with written documents wherever feasible, is necessary to determine the actual causes of major cultural transitions.

ANIMAL PROXIES – INVERTEBRATES

Invertebrates are the most common constituents of the metazoan fossil record, and since they are abundant in Phanerozoic marine sedimentary rocks worldwide, they are of great utility in reconstructing ancient climates and environments. Here, we review two aspects of this record. First, we discuss the utility of invertebrate marine fossil assemblages in interpreting ancient climates and environments, and second, we explore the ways in which shell chemistry may be used to further address these issues.

Interpreting ancient climates

In modern environments, marine diversity is greatest at equatorial latitudes, and declines towards higher latitudes. In general, data from the fossil record is in accord with this observation, showing a similar pattern throughout the Phanerozoic (Hallam, 1994; Parrish, 1998). Although the primary factor governing this pattern is a subject of some debate, many environmental factors other than temperature are clearly important. These include availability of nutrients, decreased environmental stability at high latitudes (increasing seasonality with latitude) (Sanders, 1968), dominance of r-selected trophic generalists in resource-limited high latitude regions as opposed to high niche partitioning observed in resource-rich low latitude regions, possibly resulting from the effects of seasonality (Valentine, 1973), and variation in light incidence across latitudinal gradients (Ziegler et al., 1984). Additionally hypersalinity in restricted environments and brackish water (hyposalinity) in estuarine or deltaic environments significantly limit diversity of marine organisms (Heckel, 1972).

Two types of approaches have been used in understanding the relationship of fossil assemblages to ancient climates. The first utilizes the distributions of extant species and/or genera, and interprets the paleoclimatological settings of fossil assemblages that contain some of the same taxa. This approach carries the underlying assumption that organisms maintain a consistent climate range throughout their history. This approach is limited in temporal scope, but has been successfully applied to Tertiary and Quaternary deposits. The second approach incorporates paleogeographic data (typically paleomagnetic data, which provides an estimate of paleolatitude) in faunal assemblage analysis, permitting examination of ancient climate zones and latitudinal diversity patterns. Examples of each type of approach are discussed below.

One of the most influential examples of the first approach is Addicott's (1969) classic analysis of shallow water Tertiary molluscan faunas of the northeastern Pacific. In this study, Addicott used water temperature affinities of extant bivalves and gastropods along the western coast of Mexico and the United States to erect a latitudinal zonation of tropical (Panamic), subtropical (Surian), and warm-temperate (Californian) molluscan provinces. Through analysis of the distributions of selected warm-water genera across the Tertiary fossil record of this region, Addicott demonstrated a southerly retreat of warm-water genera from the Oligocene to Pleistocene, indicating an overall cooling trend across the Tertiary. The data, however, showed a pronounced northward migration of warm water taxa during the Miocene, indicating that tropical water conditions extended as far north as Washington, and revealing a striking Miocene warming event. Following this warming

event, a gradual southerly migration of warm water taxa from the Late Miocene through the Pleistocene was observed, indicating a re-establishment of the cooling trend following this thermal maximum.

This type of approach may also be used at a finer scale to identify either localized or shorter-term fluctuations in climate or ocean temperature, or shifts in paleoceanographic conditions. Roy et al. (1996) reviewed the response of the Pleistocene molluscan fauna of the eastern Pacific to recently discovered millennial-scale climate perturbations. Since species response to climate change is individualistic, high-amplitude climatic variations were found to produce short-lived, novel associations of species, unlike modern assemblages. Some such associations were interpreted as the result of time averaging in the fossil record, as the temporal scale of climate change closely approaches the limit of stratigraphic resolution; however, some novel assemblages clearly represent community associations resulting from rapid climate change. Nakashima (2002) analyzed the spatio-temporal distribution of the Miocene–Pliocene bivalve *Fortipecten* in the northwestern Pacific to identify a potential short term and/or localized cooling event in the Mid-Pliocene. Gladenkov et al. (2002) timed the opening of the Bering Strait at 5.32 Ma using the incursion of a North Atlantic molluscan fauna into the Northern Pacific. The increasing use of these types of localized studies will certainly yield an enhanced integrated perspective of Cenozoic climate change and the response of marine communities.

Studies of ancient paleoclimates using fossil assemblages are generally hindered by the paucity of extant genera in the fossil record. Additionally, many unique paleoclimatological problems are posed by past conditions such as the ice-free greenhouse world of the Cretaceous, or the existence of a single super-continent throughout much of the Mesozoic. Due to the lack of available comparisons with living taxa, interpretations of ancient climates typically rely much more on incontrovertible climate indicators, such as reef faunas, which occur under exclusively tropical conditions, or faunas associated with glacial deposits. Importantly, independent estimates of paleolatitude (from paleomagnetic data) are available for many ages and localities, facilitating study of latitudinal trends in biodiversity for ancient assemblages.

Brachiopods are a particularly useful group for Paleozoic strata, as they were abundant members of most marine communities across this era, and exhibit a relatively high degree of provincialism. In general, times of global cooling result in high latitudinal temperature gradients and are marked by the presence of several distinguishable latitudinal assemblages. In contrast, warmer eras exhibit a lower pole-equator temperature gradient, and, in the Paleozoic, tend to be characterized by cosmopolitan brachiopod faunas at low and mid latitudes, which are distinct from low-diversity, high latitude faunas (Harper and Sandy, 2001). For example, during the cool climate of the late Ordovician, at least three latitudinally controlled brachiopod assemblages are recognized, whereas only two are present in the warmer Silurian. A low-diversity (at times monospecific) brachiopod fauna, dominated by the genus *Clarkeia*, characterized high-latitude nearshore marine assemblages of the Silurian, while a higher-diversity cosmopolitan fauna existed at low and mid latitudes (Cocks and Fortey, 1990). Later in the Paleozoic, during the Carboniferous, northward shifts of northern range boundaries of many brachiopod genera in the late Viséan stage has been interpreted to represent warming at high latitudes. In the subsequent early Namurian stage,

a southward shift in northern range boundary of many genera is coincident with a northward shift of many southern range boundaries. Together, these trends were interpreted as indicative of high latitude cooling accompanied by equatorial warming (Raymond et al., 1989; Kelley et al., 1990).

The end of the Paleozoic Era is punctuated by the end-Permian mass extinction and the coincident shift in dominance of marine invertebrate assemblages from brachiopods to mollusks. Thus, bivalves and gastropods are of greatest use to biogeographic/paleoclimatologic studies in the Mesozoic and Cenozoic. In general, bivalve thickness and size is inversely correlated with latitude, as is ornamentation of gastropod shells (Vermeij, 1978). Additionally, bivalves (primarily rudistids, but also lithiotids), were the primary framework builders of Mesozoic reefs, which were confined to tropical seas and are thus of utility as paleoclimate indicators.

Fossil assemblages as paleoenvironmental indicators

While global-scale fossil assemblage data are needed to interpret paleoclimates or latitudinal gradients, on a local or regional scale, these assemblages provide excellent indicators of paleoenvironmental conditions, including attributes of paleobathymetry and paleo-oxygen levels. For a given latitude, the distribution of marine organisms from nearshore habitats to basinal ones is controlled largely by physical factors, such as current energy, substrate type and consistency, light and/or nutrient availability, etc. Thus, faunal assemblages show strong associations with sedimentary regimes, facilitating the recognition of biofacies (consistent associations of fossil assemblages and physical sedimentological properties).

In lower Paleozoic strata, trilobite assemblages are abundant and show a pronounced onshore-offshore gradient. Fortey (1975) demonstrated that, during part of the Ordovician period, each part of the shelf environment was dominated by different taxonomic groups of trilobites: inner shelf assemblages were dominated by ilaenids and cheirurids, the middle shelf by nileids, and the outer shelf by olenids. Fortey also noted that outer shelf trilobites tended to be cosmopolitan in distribution, while inner shelf trilobites showed a high degree of endemism. An implication of both of these studies is that open water forms were able to cross some ocean basins, while shallow water forms were not. Cook and Taylor (1975) found that Cambro-Ordovician trilobite assemblages the western United States and southern China shared deep-water trilobite faunas, but contained unique shelfal faunas. Through comparison with modern arthropod distributions, these authors concluded that a pronounced thermocline prevented migration of shelfal faunas, whereas deep-water trilobites lived in sub-thermocline habitats and were thus able to migrate. Biofacies models have been utilized throughout the Phanerozoic (e.g., Patzkowsky, 1995: Ordovician brachiopods; Webber, 2002: Ordovician whole-faunas; Johnson, 1974: Devonian brachiopods; Harper and Jeffrey, 1996: Carboniferous brachiopods; Sandy, 1995: Triassic–Jurassic brachiopods; Sageman and Bina, 1997: Cretaceous whole-faunas).

The marine trace-fossil record, overwhelmingly the product of invertebrate bioturbation, is of great utility in interpreting ancient benthic oxygen levels. An oxygen-deficient marine biofacies model, developed through actualistic study in modern environments, correlates trace fossils and depth and extent of bioturbation to the amount of dissolved oxygen present in bottom waters (Savrda et al., 1984). This model can be used to

infer relative degree of bottom water oxygenation in marine strata across much of the Phanerozoic. Using this model, Savrda and Bottjer (1987) identified a new marine biofacies, termed the exaerobic zone, which occurs at the boundary between anoxic and dysoxic bottom waters. In the rock record, exaerobic environments are characterized by high-density occurrences of a single species through narrow stratigraphic intervals, at the transition from unbioturbated to weakly bioturbated strata. Exaerobic taxa include some species of brachiopods and some “flat-clam”-type bivalves which apparently derived energy from sulfur-oxidizing chemolithoautotrophic bacteria, instead of from a phototrophic-based food web (Savrda and Bottjer, 1987). Trophic decoupling of whole ecosystems from photosynthetic primary productivity occurs also at hydrothermal vents and hydrocarbon seeps: vent and seep assemblages are also recognizable in the fossil record.

Shell chemistry as a proxy for paleoclimate

Whereas species presence/absence, assemblage content, diversity and distribution may be used to address the types of paleoclimatological questions outlined above, specific chemical signals contained within the shells or skeletons of invertebrates can provide highly sensitive proxies for paleotemperature and related climatic or environmental parameters. Of primary use to geochemical studies are mollusks, brachiopods and corals, all of which secrete calcareous skeletons and, importantly, possess a diagnostic original microstructure. As carbonate minerals are easily altered or recrystallized during post-burial diagenesis, care must be taken to sample only specimens which retain the original microstructure in order to assure that the geochemical signals attained are representative of the organism’s living environment, and not the diagenetic environment.

Stable isotope ratios of oxygen ($\delta^{18}\text{O}$ – $^{18}\text{O}/^{16}\text{O}$) and, to a lesser extent, carbon ($\delta^{13}\text{C}$ – $^{13}\text{C}/^{12}\text{C}$) from invertebrate shells and skeletons have proven particularly valuable for paleoclimate reconstructions. In general, cool waters are enriched in ^{18}O and warm waters are relatively depleted. For any given time in the past, however, the average $\delta^{18}\text{O}$ value of the ocean reservoir is determined primarily by planetary ice volume, as light isotopes are preferentially removed from the ocean by evaporation and stored in ice, leaving the ocean reservoir isotopically heavy. The carbon cycle is driven by biologic productivity; organisms selectively take up the light isotope, leaving productive surface waters isotopically heavy, and bottom waters isotopically light with respect to $\delta^{13}\text{C}$. Both carbon and oxygen in seawater are incorporated into the carbonate shells and skeletons of marine animals. Brachiopods and mollusks secrete their shells in isotopic equilibrium with seawater, but corals typically do not (Hudson and Anderson, 1989). While brachiopods secrete stable calcite shells, most mollusks secrete shells composed of aragonite, which is geologically less stable, and tends to re-crystallize to calcite, thereby acquiring the isotopic signal of the diagenetic environment. Therefore isotopic studies of mollusks, by far the most common carbonate-secreting members of fossil marine assemblages since the Mesozoic, must focus on rare original aragonitic shell material which has survived, or on mollusks which secrete an originally calcitic shell or portion of the shell, such as oysters, rudist and inoceramid bivalves, or belemnites (Hudson and Anderson, 1989).

Isotopic studies using marine invertebrates have focused on two primary goals. One objective has been to understand global trends in $\delta^{18}\text{O}$ and/or $\delta^{13}\text{C}$ of the marine reservoir as a whole

through a specific time interval of interest, in order to interpret climate, global ice volume and glacial history or changes in primary productivity, particularly those associated with biotic radiations or crises. The second approach involves more localized, fine scale isotopic study of marine assemblages in order to interpret local or regional paleoclimate or paleoceanographic conditions.

Hudson and Anderson (1989) compiled a data set of Paleozoic $\delta^{18}\text{O}$ values from brachiopods, marine cements, and other fossil organisms to interpret large-scale climate trends across that era, using $\delta^{18}\text{O}$ as a proxy for sea temperature. These authors found an overall decline in sea temperature across the Paleozoic, punctuated by significant highs in the Middle Ordovician and Late Devonian-Early Carboniferous, and lows in the Late Ordovician and Middle Carboniferous.

Lowenstam (1964) assessed latitudinal paleotemperature gradients for multiple stages of the Cretaceous period. Lowenstam collected $\delta^{18}\text{O}$ data from mollusks from multiple paleolatitudes across several discrete intervals of Cretaceous time, which, when plotted for each period, show greatest high-low latitude temperature gradients in the Maestrichtian and Albian stages, and also indicate that significantly greater temperature gradients existed in all stages of the Cretaceous than in the recent. The results of this study, conducted nearly four decades ago, are still significant today (Parrish, 1998).

At a more localized scale, stable isotope studies have revealed new insights into paleoceanographic conditions. By extracting $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ signals from mollusks of the Jurassic Oxford Clay (United Kingdom), Anderson et al. (1994) were able to assess temperature gradients and degree of mixing within the water column. These authors used animals which inhabited different parts of the water column including benthic bivalves and nektonic cephalopods, and found a pronounced $\delta^{18}\text{O}$ gradient, indicating a significant ($\sim 5^\circ\text{C}$) difference between bottom water temperature (cooler) and upper water column temperature (warmer). The authors found no significant differences in $\delta^{13}\text{C}$ composition among the groups studied, however, a finding that they interpreted to indicate a well-mixed water column. Allmon et al. (1996) used isotopic evidence to support the interpretation that upwelling conditions occurred on the west coast of Florida during the Pliocene. Using microsampling techniques, Allmon et al. (1996) captured seasonal variations in isotopic composition across individual bivalve and gastropod shells, and interpreted this signal as the result of seasonally strengthened upwelling, which would have brought nutrient-rich (low $\delta^{13}\text{C}$) cool waters (high $\delta^{18}\text{O}$) to the shallow shelf. The ready availability of mass spectrometers (used to conduct isotopic analysis) and the development of new techniques requiring ever-smaller quantities of sample will continue to stimulate higher-resolution isotopic investigations in the future.

Nearest living relative

The most obvious way to make inferences about the paleoenvironment and paleoclimate using vertebrate fossils is to note the modern environments and climate associated with their nearest living relatives. The presence in the fossil record of one or a few specimens of a single genus or species has been used in this way. Based on such evidence, Vucetich and Verzi (2002) asserted that during the Pleistocene there were warm pulses that enabled tropical forms now known only from Brazil to extend their ranges more than 1,200 km south to the area of Buenos Aires.

Instead of considering only one taxon, it is a more common practice to compare the paleoenvironmental and paleoclimatic preferences for the nearest living relatives of all taxa represented in a fossil assemblage. Using this method with modern small mammals, Antoñanzas and Bescós (2002) inferred that during the Early to Middle Pleistocene at Atapuerca, Burgos, Spain there were several cycles of fluctuation between glacial conditions when the environment was steppe-like and interglacials, which were warmer. During transitions between these conditions, the fauna of small mammals was more species-rich, having elements of both extremes. It is rarely, if ever, the case that an extensive faunal list from a fossil site, even a Late Quaternary one, is identical to a living mammalian community. These disharmonious associations where taxa are found together as fossils but exist in separate modern communities or *visa versa*, such as the United States Late Quaternary mammal faunas as compared with those of Late Holocene and modern faunas, are thought to have been caused by a change from a more patchy environment in the Late Quaternary to a more uniform one in the Holocene (FAUNMAP Working Group, 1996). Thus, experience has shown that it is unlikely that an exact modern analog to a fossil vertebrate assemblage will be found except in sediments deposited during the last 4,000 years.

An inverse correlation between the number of modern species of arvicolid rodents in a fauna and mean annual temperature was established empirically by Montuire et al. (1997). This was done by determining the number of species of these rodents in 253 modern faunas, each covering an area between 100 and 10,000 km², and noting the mean annual temperature for the area. The mean annual temperature range for any one particular species in a fauna was found to be about 12 °C. This relationship was then applied to two Late Pleistocene fossil assemblages, with one giving a result that seemed plausible to the authors and the second less satisfactory owing to uncertainty in the correlation between various sites regarded as part of the same fossil assemblage.

Use of the nearest living relative of fossil vertebrates for making paleoenvironmental and paleoclimatic inferences is not restricted to the late Cenozoic. A mean annual temperature of 14 °C for Axel Heiberg Island during the Late Cretaceous,

then, as now, in the High Arctic, was based on the presence of champsosaurs. The temperature estimate was inferred from the tolerances of their nearest living relatives and analogs (crocodilians and large lizards; Tarduno et al., 1998).

Taphonomy

Taphonomy is the study of the processes by which an organism becomes a fossil. It is particularly focused on attempts to reconstruct otherwise missing data about organisms and the ecosystem of which they were a part. In carrying out such studies, reconstruction of the paleoenvironment is a vital part of the process. In a taphonomic analysis of a Late Cretaceous accumulation of small vertebrates at Naskal in India, Khajuria and Prasad (1998) reconstructed the environment of deposition of the fossils as, "... a distal flood plain, which served as a natural death trap, on whose banks terrestrial and other animals might have gathered in search of food and water during a prolonged drought and perished subsequently due to the desiccation of the lake." This interpretation was based both on the nature of the fossils, particularly the corroded surface of many of the specimens, and a detailed geological analysis of the site.

Analysis of a fossil assemblage may provide environmental information about the area that surrounded the site where the specimens accumulated independently of any other evidence. However, sometimes the data may yield ambiguous or contradictory results. For example, Alberdi et al. (2001) analyzed three Plio-Pleistocene mammal assemblages from the Guadix-Baza Basin, Spain. On the basis of the geology, they inferred that the immediate environment where the fossils were found in each case was a lake margin. However, solely considering the composition of the different assemblages, they reconstructed the paleoenvironments surrounding these ancient lakes in two quite different ways. The presence of a great diversity of artiodactyls, particularly browsers, at one site was regarded as, "... indicative of wooded or bushy areas. . .," while nearby, "... a high diversity of sub-aquatic forms and a smaller variety of artiodactyls species. . .," was interpreted as indicative of, "... an open, sparsely forested environment susceptible to seasonal drought."

The distribution of fossil vertebrates within a deposit can provide paleoclimatic information. The complete excavation of the sediment accumulated in what during the Plio-Pleistocene was a lake about 1 ha in area, yielded approximately 40 skeletons of three species of kangaroos near Morwell, Victoria, Australia. The specimens were at different stratigraphic levels, indicating that the fossils accumulated over a significant period of time rather than as a consequence of a single catastrophic event. In similar lakes today when a kangaroo drowns, its body first sinks, then bloats and floats to the surface. Eventually the body cavity containing the gas ruptures and the body sinks permanently to the bottom of the lake. While on the surface, a corpse is most often found near the lee margin of the lake. In the Morwell Plio-Pleistocene lake deposit, most of the specimens occurred in the southeast part of the paleolake, indicating that the prevailing direction of the wind was then from the northwest (T. Rich, personal observation).

Functional analysis

Corroboration of paleoenvironmental and paleoclimatic hypotheses based on other evidence can be found in the functional interpretation of fossil vertebrates. *Leaellynasaura amicagraphica*, a small ornithischian dinosaur, has been hypothesized

to be active all year around in a frigid polar setting in what is now southeastern Australia (Constantine et al., 1998). This was based on two independent lines of evidence. Taken together, the consequences of the evidence are to be expected in an animal that lived in such a manner under those conditions. Enlarged optic lobes were visible on the dorsal surface of the brain, which suggested the animal had enhanced ability to see under the low light conditions of a polar winter (Rich and Rich, 1989). Histological cross-sections of the bone of this same animal showed that it lacked lines of arrested growth (LAGs), which would be expected if for any reason, such as hibernation, its level of metabolic activity had decreased markedly during its lifetime. However, another dinosaur, an ornithomimosaur from the same site as *L. amicagraphica*, had LAGs (Chinsamy et al., 1998).

Stable isotopes

Chemists studying modern animals have been able to relate stable isotope ratios of the same element to a number of environmental factors. The variation in isotopic ratios is due to the fact that physical and chemical processes proceed more slowly for molecules that weigh more. For example, the rate of evaporation for a molecule of water with an oxygen atom with two additional neutrons, ^{18}O , is less than that of a molecule of water with the more common oxygen isotope, ^{16}O . As the temperature of the water increases, the difference in the rate of evaporation increases, leaving liquid water with proportionately heavier water molecules left behind. An animal that ingests that liquid water at a particular temperature will form molecules of body tissue with a ratio of ^{18}O to ^{16}O reflecting that temperature. However, the ratio incorporated in the body of the animal will not be exactly the same as that of the water it ingested. This is because fractionation, or a further segregation, of the two oxygen isotopes takes place during metabolic processes that occur within the animal as it deposits oxygen in bone, dentine, or enamel, for example. The correlation between the two isotopes deposited in the animal's tissue and the temperature of the water ingested has to be established empirically. Other factors affecting the ratio of the two isotopes come into play as well, such as the humidity of the environment. Thus, it is not always straightforward even in the case of modern animals to determine "environmental proxies" from isotopic ratio studies.

Because of the success of isotopic ratio investigations in modern animals, applying similar techniques to fossil vertebrates in order to try to determine past climatic and environmental factors has been underway for the past few decades. A major point of contention in isotopic research is whether the fossil material retains the isotopic ratios of the once living organism or if there is significant post-mortem chemical alteration (Kohn and Cerling, 2002). While there is considerable doubt about how long the isotopic integrity of a fossil bone remains, there is less reason to question the chemical stability of enamel. This is in part because enamel is more dense, has lower organic content, forms larger crystals than is the case in bone or dentine, and when it is chemically altered from hydroxyapatite, it changes to fluorapatite, which can be detected. For these reasons, much of the recent stable isotope work on fossil vertebrates has focused on tooth enamel.

The area where isotopic techniques has been applied most successfully are investigations of the ratio of the carbon isotopes ^{13}C and ^{12}C . This ratio is different in C_3 and C_4 plants. C_3 plants are, "... most leafy, woody, and other soft plants

(browse) and cool growing season or aquatic grasses, whereas C_4 plants include most tropical and temperate grasses” (MacFadden et al., 1999). The difference in the ratios of ^{13}C to ^{12}C in these two categories of plants is related to the fact that they have different photosynthetic pathways. C_3 plants, which use the Calvin Cycle as their photosynthetic pathway, concentrate less ^{13}C relative to ^{12}C than is the case with C_4 plants, which use the Hatch-Slack photosynthetic pathway.

In mammalian herbivores, there is a consistent difference in the ^{13}C to ^{12}C ratio of the tooth enamel between those that primarily feed on C_3 plants (browsers) and those that primarily feed on C_4 plants (grazers). Those that are mixed feeders have intermediate ratios. However, the values measured in the tooth enamel are not exactly the same as in the plants themselves. Rather, it has been established empirically that in all cases the tooth enamel is enriched in ^{13}C relative to the plants on which the animal feeds. The degree of this enrichment appears to be size dependent, with mouse-sized animals having one fractionation value and larger animals having a different, larger fractionation value. However, despite this variation, modern herbivores that feed exclusively on C_3 plants can be distinguished from those animals that feed solely on C_4 plants by analyzing their $^{13}C/^{12}C$ ratio in tooth enamel. Mixed feeders range in between the C_3 and C_4 endpoints. Making the assumption that this difference was also the case with fossil mammalian herbivores is the basis for interpreting diets of the extinct forms.

Using carbon isotope data together with wear facet analysis from the teeth of six different 5 million year old horses from Bone Valley Florida, MacFadden et al. (1999) were able to reconstruct their dietary preferences; ranging from browsers to mixed feeders to grazers. Wear facet analysis corroborated the isotopic results. This was surprising because on the basis of the high crowned nature of the horse teeth alone, they all would have been considered grazers. This result is concordant with paleoenvironmental, “. . .reconstructions of central Florida at 5 Ma [which] indicate low-elevation floodplain and estuarine environments with a mosaic of local close-canopy forests, woodlands, and open-country grasslands” (MacFadden et al., 1999). In this instance, isotopic ratios of vertebrate fossils were utilized to corroborate a paleoenvironmental reconstruction made from other lines of evidence and to caution against the use of a single indicator of dietary preference, such as crown height.

The other most common isotope system to be investigated in fossil vertebrates is that of oxygen, despite the complicating factors mentioned above. The ratio of ^{18}O to ^{16}O in vertebrates is sensitive to temperature, humidity and diet (Kohn and Cerling, 2002). In one recent study using fossil taxa, measurements of the oxygen isotope ratio in both terrestrial mammals and gar in the Big Horn Basin of Wyoming were interpreted as indicating that a rapid increase in mean annual temperature occurred at the end of the Paleocene and beginning of the Eocene (Fricke et al., 1998). This study circumvented the problem of variation in diet affecting the oxygen isotope ratio by sampling the same genera through the period of time under investigation.

Because mammalian molars generally grow from the tip of the cusps to the base of the roots, by measuring the ratio of ^{18}O to ^{16}O at different heights of the enamel of a horse molar it was possible for Bryant et al. (1996) to observe the $^{18}O/^{16}O$ ratio through the time that the tooth formed instead of taking an average for the entire tooth. The changes they observed were regarded as due to seasonal temperature changes through that period. Because molars develop consecutively, with the first molar forming, then the second, and finally

the third molar, it was possible for Bryant et al. (1996) to correlate between molars and estimate the seasonal fluctuations in temperature over the entire period that formation of the molars took place. An excellent, more technical summary of this topic is summarized in Parrish (1998, pp. 84–88 and 154–161).

ANTARCTIC BOTTOM WATER AND CLIMATE CHANGE

Background

The production and spreading of Antarctic Bottom Water (AABW) in the modern ocean is understood in general terms, if not in detail. Abyssal regions of the global ocean are filled by cold, dense bottom waters that originate in the Southern Ocean and saltier, less-dense deep water (NADW) formed in the North Atlantic. From the distribution of thermohaline properties near the sea floor, it has long been known that AABW influence extends everywhere except the northernmost Atlantic and Arctic Ocean (Mantyla and Reid, 1983). Production uncertainties result from a variety of formation scenarios, mixing recipes, source regions, bottom water definitions, and inferences from local expeditions extrapolated over wider regions. AABW properties vary spatially from the coldest, freshest waters on the Antarctic continental slope to trace amounts of Antarctic origin in the northern oceans. A brief outline of bottom water formation mechanisms and a discussion of formation regions and rates are presented here. A note about ongoing efforts to redefine AABW is followed by consideration of temporal variability over recent decades and implications for AABW generation during glacial periods. A review of present-day bottom water formation, with additional figures and references, appears in Jacobs (2004).

AABW formation mechanisms

Bottom waters are produced where cooling, salinization, and uptake of atmospheric gases “ventilate” and provide negative buoyancy to surface and shelf waters, enabling them to mix with “older” Circumpolar Deep Waters (CDW) along the Antarctic continental margin. Gill (1973) demonstrated that bottom water properties in the Weddell Sea appeared to be accounted for by a mixture of cold, salty shelf water and warmer, fresher water above the deep water salinity and temperature maxima over the continental slope (Figure A5). The shelf water results from sea ice formation and export from the continental shelf, but is denser and mostly located well south of the continental shelf break. Gill also showed a V-shaped double-sided frontal region over the continental slope, marking the convergence of a variety of shelf, surface and deep waters (Figure A6). A fresh, westward-flowing “river” imbedded in the center of this Antarctic Slope Front (ASF; Jacobs, 1991; Whitworth et al., 1998) has properties that reflect upstream melting, freezing and mixing processes. Sinking along the ASF is enhanced by non-linearities in the seawater equation of state, which introduce isopycnal curvatures that can increase seawater density during mixing (Figure A7). Density is also enhanced by thermobaricity, the pressure dependence of the thermal compressibility of seawater. Regionally higher tidal energy near the shelf break facilitates mixing and reduces local sea ice concentrations. Melting icebergs entrained into the rapid slope current increase vertical convection and create openings in the sea ice field that amplify the impacts of winter atmospheric forcing.

Another factor in modern AABW formation is the “ice shelf water” that results from melting and freezing in the large, deep sub-ice shelf cavities (Jacobs et al., 1970; Foldvik et al., 1985). While positively buoyant relative to the denser shelf waters from which it forms, and for which it provides another sink, the very

cold ice shelf water can augment thermobaric effects over the continental slope in the Weddell and Ross Seas (Figure A8). With salinities that are intermediate between shelf and surface waters, ice shelf water is also well positioned to mix isopycnally with CDW (Figure A5). The amount of AABW produced directly from ice shelf water is probably limited to ~ 3 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$), since more of the circumpolar ice shelf and iceberg meltwater, some resulting from CDW sources, upwells into the near-surface layers. A portion of that lighter product will be incorporated into the fresh slope current that eventually contributes to AABW.

Some AABW in the global ocean starts out as deep water that is ventilated by mixing and interleaving along the continental margin (Carmack and Killworth, 1978) or by “open ocean” deep convection. An example of the latter is the remnant “chimney” structure observed downstream from a prominent rise in the sea floor, in conjunction with the large Weddell Polynya of 1974–1976, showing that $>3,000$ m of the water column had been perturbed by winter air-sea interaction (Figure A9). The number, frequency and geographic limits of such features is unknown, but the accompanying polynya has not reappeared in the same form, and the associated deep water formation rate may again have been no greater than ~ 3 Sv. With limited spatial resolution, most global scale general circulation models have until recently formed AABW from this type of deep convection. Deep convective eddies may also develop along the continental margin and move seaward, resulting in similar relict features. Another process that can produce AABW is simple advection off the continental shelf, as evidenced by the properties of waters along the Weddell-Scotia Confluence, and trapped within the deep basins of the Bransfield Strait.

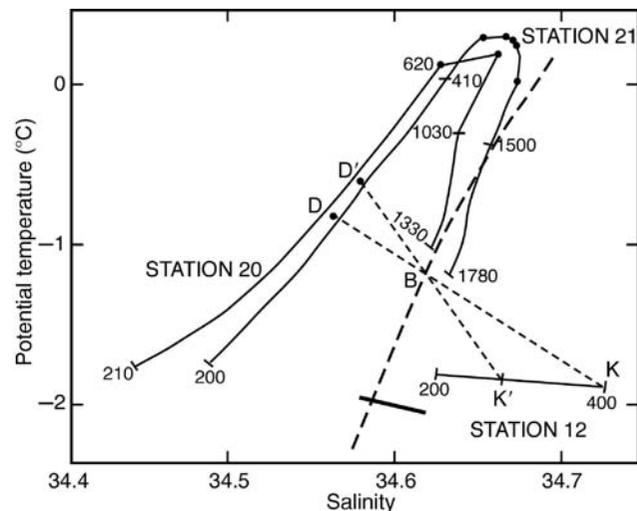

Figure A5 A “T/S diagram” of vertical profiles on the southern Weddell Sea continental shelf (12) and slope (20 and 21), with measurement depths in meters. Modified from Gill (1973), who observed that the properties of bottom water at B appeared to be a mixture of K–K’ shelf water and D–D’ slope water. The *short solid line* is the range of ice shelf water properties near the mouth of Filchner Trough, from Foldvik et al. (1985), and the *heavy dashed line* is an isopycnal (line of constant density). These additions show that bottom water can form more readily from ice shelf water and slope water below the salinity maximum.

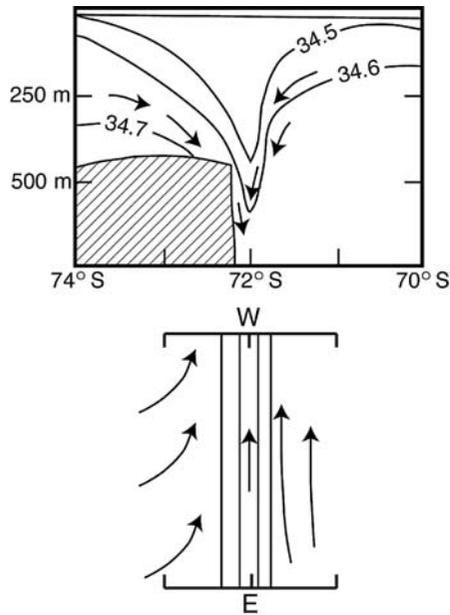

Figure A6 Suggested vertical and horizontal (400 m) circulation patterns near the continental shelf break at 50° W, 72° S in the Weddell Sea, modified from Gill (1973). The upper panel shows isohaline contours from several 1968 stations, including two of the three in Figure A5.

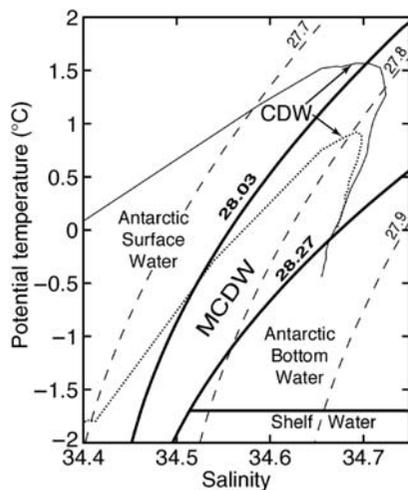

Figure A7 The T/S relationship of water masses near the Antarctic continental margin, modified from Whitworth et al. (1998). The solid curves labeled 28.27 and 28.03 are neutral density surfaces and the dashed curves from 27.7 to 27.9 are potential density. Dotted lines are from two reference stations, with arrows to the CDW temperature maxima. MCDW is modified Circumpolar Deep Water (CDW).

AABW formation regions

It is still widely believed that most AABW is produced in the Weddell Sea, where each of the formation mechanisms outlined above were initially identified. Most of those processes are not site specific, however, and other regions have similar water

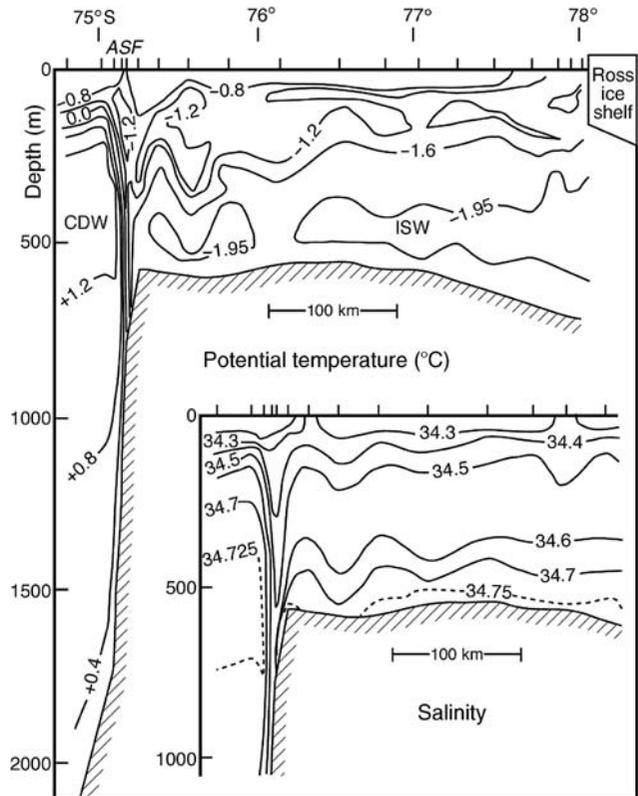

Figure A8 Vertical temperature and salinity (inset) sections across the continental shelf near 175° W in the Ross Sea, from February 1984 measurements at the indicated locations. Ice shelf water (ISW), with temperatures colder than the sea surface freezing point ($\sim -1.9^\circ\text{C}$) that formed from net melting into higher salinity water under the ice shelf, mixes with warmer Circumpolar Deep Water (CDW) and fresher waters along the Antarctic Slope Front (ASF) to form AABW.

masses, persistent winter coastal polynyas and sea ice export, ice shelves and an ASF. An historical focus on thermohaline properties in the Weddell sector influenced AABW definitions, which have typically been based on potential temperature. That is the temperature that would be reached by seawater raised adiabatically to the sea surface. For seawater with a salinity near 35 parts per thousand, a potential temperature of 0.0°C , the common upper boundary for AABW, represents a cooling of $\sim 0.2^\circ\text{C}$ for a 3,000 m decompression.

The Ross Sea physical regime is very similar to that of the Weddell Sea, and serves to illustrate the arbitrary nature of the $<0.0^\circ\text{C}$ and related definitions of AABW. CDW over the continental slope in the Ross is roughly a degree warmer than its counterpart in the Weddell. Since bottom water is a mixture of near-surface, shelf and deep waters, warmer varieties of bottom water can be produced in the Ross Sea, as shown by temperatures near the sea floor in the Southeast Pacific Basin (Obers et al., 1992, plate 54). The salinity range of newly formed AABW in the Ross Sea (Jacobs et al., 1970) is also wider than the high salinity type usually portrayed in volumetric analyses. In addition, some of the bottom water produced in the Ross Sea flows into the Australian Antarctic Basin (Gordon and Tchernia, 1972), and its properties will vary over time, e.g., in response to changing shelf water salinity (Jacobs, 2004).

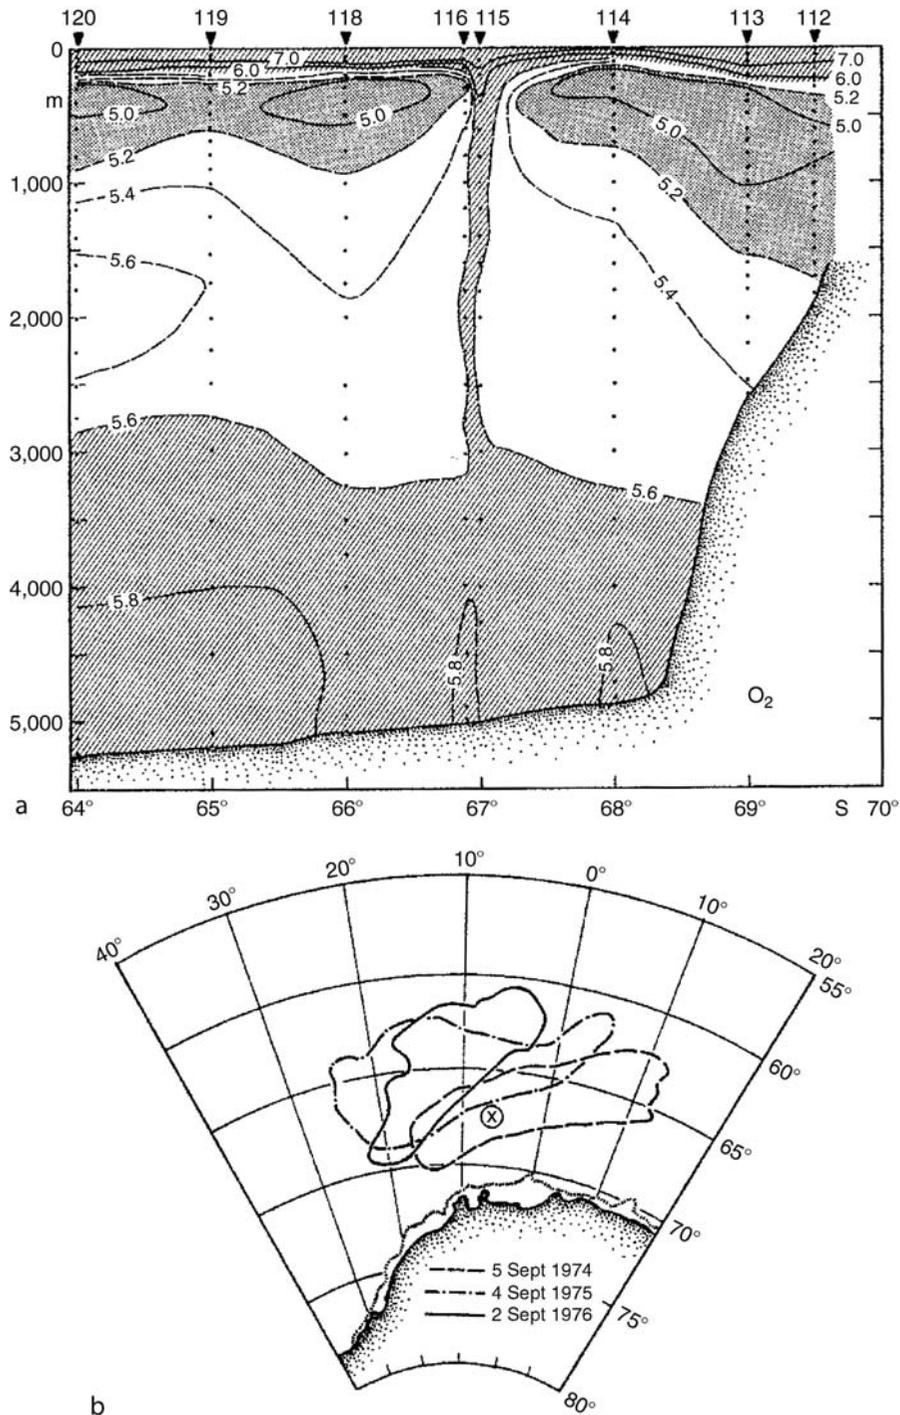

Figure A9 (a) Dissolved oxygen along a February 1977 NW–SE section near 8° W in the Weddell Sea displays a relict structure that resulted from an “open ocean” deep convection event, most likely associated with (b) the Weddell Polynya of 1974–1976, with its late winter limits defined by satellite-derived sea ice concentration maps. After Gordon (1978), where perturbations of the temperature, salinity and density field are also displayed. AMS copyright.

Neither thermohaline properties nor measurement location can thus be relied on to determine bottom water provenance.

The idea that all AABW of consequence to the deep ocean circulation is produced in the Weddell Sea was based mainly on early

temperature and dissolved oxygen measurements (Deacon, 1937; Stommel and Arons, 1960). More recent assessments show a substantially smaller Weddell sector contribution (Figure A10). The Ross Sea/Pacific percentage has increased to ~20% in those

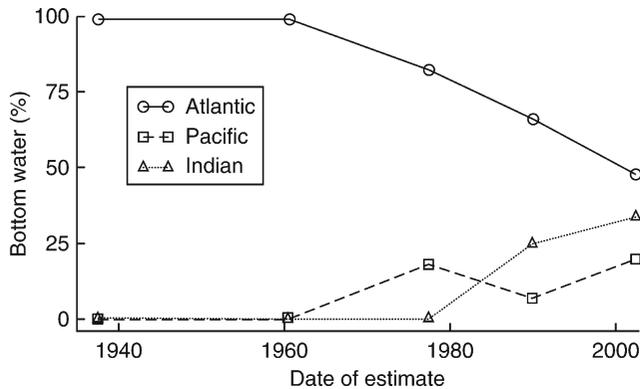

Figure A10 Changing estimates of bottom water source regions around Antarctica, with Atlantic representing the Weddell Sea, Pacific the Ross Sea and Indian typically only George V Coast (details and references in Jacobs, 2004).

analyses, not including its contribution to the Indian sector, where estimates have risen above 30%. While there are good reasons to doubt many of the estimates of origin, models are now able to resolve smaller-scale processes along the continental margin, and observations show substantial AABW production in the Pacific and Indian Ocean regions (Jacobs, 2004). Some of that production enters the Enderby Basin and diffuse eastern end of the Weddell Gyre from the east, evolving into deep and bottom water before being exported from the Weddell Sea.

AABW formation rates

Most investigations of the rate of AABW formation have also targeted the Weddell Sea, where the majority of estimates fall between 2 and 5 Sv (Figure A11). Values are for sustained annual production, although most observations have been made during the summer, and both rates and properties vary seasonally. Circumpolar rates cover a much wider range, but in both cases the high variability results in part from different definitions and study areas, along with different techniques, including boundary current transports, heat, salt, mass and geochemical budgets, numerical and inverse models. Global ocean circulation models typically call for about 20 Sv of new AABW production, and recent calculations tend to hover around this enduring estimate.

Whitworth et al. (1998) and Orsi et al. (1999, 2002) have utilized neutral density surfaces and the anthropogenic chloro-fluorocarbon (CFC) tracer to redefine bottom water and better constrain its present-day formation rate. Taking pure AABW to be heavier than the deepest isopycnal in the Drake Passage, and mapping the distribution of neutral density near the sea floor throughout the global ocean (Figure A12) revealed spreading patterns consistent with earlier work (e.g., Mantyla and Reid, 1983). Integrating the concentrations of CFC-11 within broader density bands along six N–S transects in the Atlantic, Pacific and Indian sectors indicated that the deep global ocean is currently being renewed from southern sources at a rate of ~ 17.5 Sv. This preliminary estimate of new production is comprised of $\sim 60\%$ partially ventilated near surface and shelf waters, and $\sim 40\%$ much older lower CDW. Analyses of additional CFC data sets may resolve questions about representative sections, water mass mixing and normalization, as the CFC source function and seawater saturation levels have varied over the

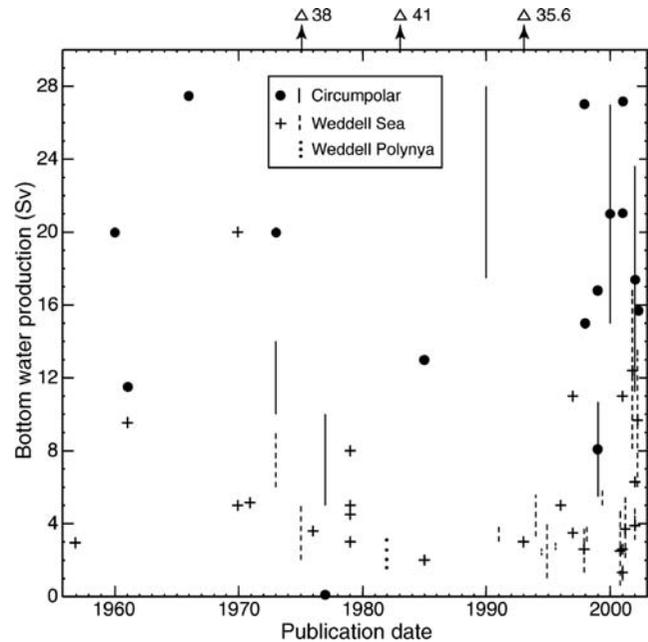

Figure A11 More than four decades of bottom water production estimates for the Weddell Sea and circumpolar Southern Ocean. 1 Sv = 1 Sverdrup = $10^6 \text{ m}^3 \text{ s}^{-1}$ (Jacobs, 2004).

measurement period. However, the revised definitions and CFC findings are consistent with inverse modeling of the World Ocean Circulation Experiment data set (Ganachaud and Wunsch, 2000), and with the venerable concept that AABW and NADW formation rates are roughly equal in the modern ocean.

AABW property variability

Interannual to multidecadal variability in AABW temperatures has been reported for many years, largest near the Antarctic continental margin. Moorings and repeat ocean stations seaward of the Filchner Trough and in the northwest Weddell Sea have displayed fluctuations and short term trends in temperature and salinity, consistent with changes in the overlying deep water (Fahrbach et al., 2004). Weddell deep water has warmed by $\sim 0.1^\circ \text{C}$ per decade since the early 1970s, due to changes in CDW inflow, processes within the Weddell Gyre or on the adjacent continental shelf (Robertson et al., 2002). Farther north, decadal temperature variability has been observed in and near the Vema Channel, although locations of restricted flow between basins are subject to strong mixing and countercurrents that complicate “choke point” monitoring and transport estimates.

Changes in salinity and other bottom water properties have also been reported at longer than seasonal time scales, and in other regions of the Southern Ocean (e.g., Foster and Middleton, 1979; Jacobs, 2004). The importance of salinity variability where bottom waters are formed is that a decrease of 0.01‰ lowers the density more than twice that of a warming of 0.10°C . Also, near-surface temperatures remain near the freezing point for much of the year in the polar oceans, whereas salinity ranges more widely, reflecting changes in precipitation, melting and sea ice volume, all elements of the hydrological cycle that are sensitive to climate change. Some salinity decreases observed over recent decades in the Southern

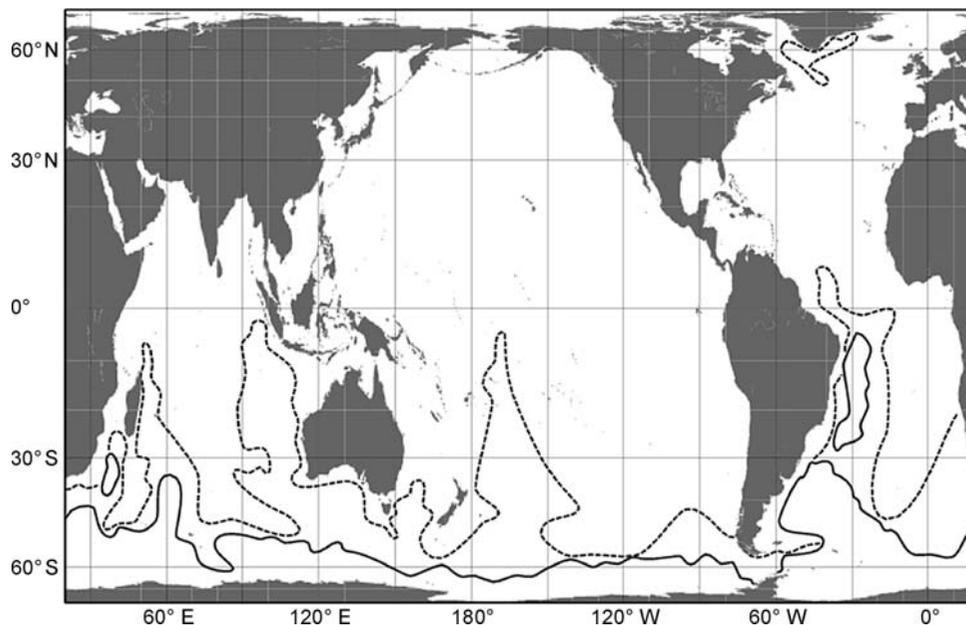

Figure A12 Distribution of neutral density near bottom in the world ocean, adapted from Orsi et al. (1999). The densest water lies south of the solid line, and an intermediate density class is limited by the dashed line.

Ocean are comparable to the “Great Salinity Anomaly” of the North Atlantic (Jacobs, 2004), albeit much less than models often require to significantly damp the strength of the thermohaline circulation.

AABW and past climate change

Analyses of the deep ocean circulation during glacial periods such as the Last Glacial Maximum (LGM) often indicate that AABW production increased as NADW formation waned (Boyle and Keigwin, 1987; Duplessy et al., 1988). Complete shutdown of the meridional ocean circulation cell that includes NADW is thought to require a very large perturbation of the hydrological cycle, such as the massive and rapid runoff of glacial meltwater. Models and observations show short term and less extreme sensitivity of the thermohaline circulation to smaller forcing changes that may apply in the Antarctic where vertical stability is low, but most work has been concentrated in the North Atlantic (Andrews, 2001; Clark et al., 2002). One attempt to consider a possible response of deep and bottom water formation to millennial scale climate change focused on the low production rates in the Weddell Sea (Figure A11). Along with its reputation as the primary source, this led to a hypothesis that the formation rate had recently slowed in the Southern Ocean (Broecker et al., 1999). However, the large rate uncertainties at present preclude reliable inferences about temporal variability, and that idea could not be reconciled with available evidence on water properties, mixing between young and old components, and other documented source regions.

Some models suggest more than one mode of stability in the thermohaline circulation, with sensitivity to winds and sea ice extent in addition to freshwater (e.g., Keeling, 2002). It is also possible that a shift in deep water formation sites may accompany changing climatic conditions without major modifications in the interior abyssal circulation. Depending on the associated property changes, this could be consistent with some chemical evidence,

and with early ocean circulation theory that focused on the main ocean thermocline but suggested deep water source locations are more or less a “climatological accident” (Stommel and Arons, 1960). In any case, glacial AABW would have been saltier than modern AABW by up to 1.5 psu, in proportion to the volume of freshwater residing in larger grounded ice sheets at that time. Its temperatures would have been lower in response to less or colder NADW inflow to the Southern Ocean, if not more extensive fields of sea ice. Such changes would have produced denser AABW than at present, but shallower waters were probably also denser at the LGM.

Several aspects of modern bottom water theory present problems for continued or enhanced AABW production at the LGM, or vice versa. These include the generation of high salinity shelf water, wide continental shelves for its accumulation and storage, and large ice shelves beneath which its properties are modified. With the Antarctic continental shelf largely filled with grounded glacial ice at the LGM (Denton and Hughes, 1981), most of the shelf area now accessible to the ocean, along with its ice shelves and their associated basal melting would have been eliminated. Kellogg (1987) postulated that AABW production could have been maintained at the LGM by a shift to the “open ocean” deep convection mode. Speculation at the time that open ocean deep convection might now be the dominant mode of deep and bottom water formation, and a suggestion that the Weddell Polynya existed during the LGM, encouraged the idea. However, thicker sea ice and colder CDW at that time would have made it more difficult to maintain sensible heat polynyas over the “open ocean,” although deep-reaching eddies might have occurred near the continental margin, or farther north if the sea ice edge were then near the Polar Front.

From the formation mechanisms outlined above, it can be inferred that a large continental shelf region, high salinity shelf water and ice shelves are helpful but not essential to AABW

generation. Nonetheless, the glacial ocean may have had access to the winter atmosphere in a region of strong sea ice formation, at or near a location where deep convection can take place. Since LGM grounded ice did not reach the shelf break in the Ross Sea (Conway et al., 1999), AABW production could have continued wherever similar conditions prevailed over the continental slope, and would have been strengthened by the more severe climate at that time (Figure A13). A larger ice sheet grounded on the outer continental shelf would have had steeper surface slopes, increasing the velocity of katabatic winds that now maintain coastal polynyas at various sites along the Antarctic coastline. If the coastline was then much closer to or directly above the continental slope, and less “warm” NADW was available, the stronger forcing would have injected more brine directly into colder

CDW. Lacking enough meltwater to provide vertical stability, a circumpolar band combining an ice front, winter polynyas and a continental slope could have experienced nearly continuous deep convection. More and colder AABW could thus have formed at the LGM, and during millennial scale coolings, along presently active and inactive portions of the continental margin. For considerations of the AABW response to climatic variability on longer time scales, see Hay (2001) and references therein.

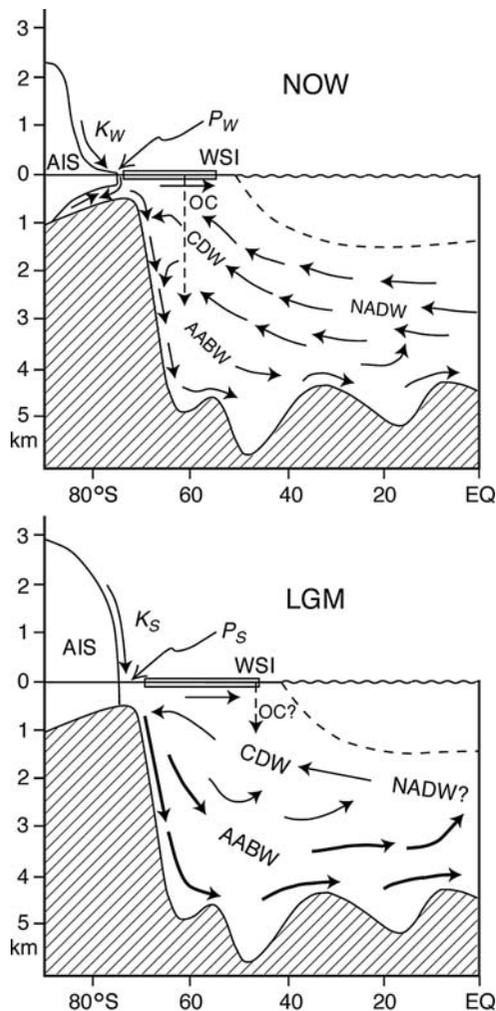

Figure A13 A schematic illustration of deep (NADW, CDW) and bottom (AABW) water circulation in the Atlantic sector of the Southern Hemisphere now and at the LGM, modified from Kellogg (1987). The Antarctic Ice Sheet currently supports ice shelves with net basal melting, along with weak katabatic winds and coastal polynyas (K_w and P_w). Grounded near the shelf break during glacial periods, the larger ice sheet could have supported stronger winds and polynyas (K_s and P_s) and more intense AABW formation. Intermittent open ocean convection (OC) at present may have occurred near the more northern winter sea ice edge (WSI) at the LGM. Weaker NADW or a shallower “glacial intermediate water” may also have prevailed at that time (Andrews, 2001).

ANTARCTIC COLD REVERSAL

The Antarctic Cold Reversal (ACR) is an event seen in Antarctic ice core proxy climate records in which the warming that occurred between 20,000 and 10,000 years ago, as the Earth emerged from the last glacial period into the present Holocene interglacial, was interrupted by a temporary cooling lasting about 1,500 years between 14,500 and 13,000 yBP.

The transition between the last glacial period and the Holocene is the most recent of a series of major changes in climate that have occurred throughout the Quaternary as the Earth cycled between glacial and interglacial conditions. These cycles, often referred to as Milankovitch cycles after Milutin Milankovitch, the Serbian mathematician who first showed that climate cycles are synchronized with cycles in the Earth's orbit, are characterized by a sawtooth pattern in which temperature decreases to a minimum over a period of about 90,000 years and then rises to warm or interglacial values within about 10,000 years. Milankovitch cycles are the Earth's response to variations in the distribution of the solar radiation that reaches its surface. The radiation varies in a complicated but regular manner due to variations in the Earth's elliptical orbit and to changes in the inclination of the Earth's spin axis.

The climate change that occurred in the transition between the last glacial episode and the Holocene was very large compared with changes that have occurred since then in the Holocene. Global temperatures rose by as much as 10 °C in some places and sea level increased by 120 m, principally as a result of the melting of the Laurentide and Fennoscandian

Ice Sheets that covered large parts of North America and northern Europe, respectively, throughout the glacial period. Proxy records of climatic temperature from sources such as marine sediments and ice cores show differing patterns of warming in different places, but the main contrast appears between records from the Northern and Southern Hemispheres. In Northern Hemisphere records, particularly those from around the North Atlantic Ocean, a slow warming starting at about 20,000 BP is followed by a large jump in temperature at 14,500 BP known as the Bølling Transition (or Interstadial). After the Bølling Transition there is a slow then more rapid cooling, ending with temperatures nearly as cold as those at the glacial maximum. This cold period, known as the Younger Dryas because it was first identified by the pollen of a flower, *Dryas Octopetala*, which grows in cold climates, starts at 12,700 BP and ends with another large jump at 11,600 BP to temperatures almost as warm as those of today (Figure A14).

Antarctic records also show a period when warming reverses, but the shape of the southern record is different from that in the north. In the south, the cooling period is considerably smaller in amplitude than the Younger Dryas and shows no rapid jumps. When the Antarctic cooling was first observed in ice core records, dating was uncertain, and it was seen as a possible Southern Hemisphere expression of the Younger Dryas. Later work, however, showed that the Antarctic cooling, first referred to as the Antarctic Cold Reversal (ACR) by Jouzel and others in 1995, preceded the Younger Dryas by at least 1,000 years.

Milankovitch cycles account for the long-term cycles of climatic change. However, the radiation variations are too small to account for the large temperature changes, and the forcing at the 100,000-year principal period of climate change (corresponding to the eccentricity period) is considerably weaker than that at the precession period (23,000 years) or the obliquity period (41,000 years). The magnitude of the climate change between glacials and interglacials, the dominance of the 100,000-year cycle in the long-term record, and the existence of rapid temperature jumps and reversals in the transitions all point to powerful feedbacks and thresholds in the Earth's climate system. One of the most important of these is ocean circulation. Ocean currents transport large amounts of heat and thus have large effects on regional climate. The best known is the Atlantic conveyor, which transports warm water from the tropics and the Southern Ocean to the North Atlantic, where it heats the atmosphere and ameliorates the climate of North America and Europe. The Atlantic circulation is maintained by evaporation and cooling in the north, which increases the salinity and density of the water, causing it to sink (thermohaline circulation). This only happens in the northern Atlantic Ocean because the northern part of the Pacific Ocean, although cold, is not saline enough to sink and the absence of any blocking land mass in the Southern Hemisphere results in flow around Antarctica and minimal North-South heat transport.

Computer model experiments suggest that the ocean circulation is sensitive to changes in evaporation and injections of fresh water. In today's interglacial climate, ice volume (and climate) is stable; however, during the glacial and transition periods, ice sheet fluctuations injected large quantities of fresh water into the oceans, resulting in large changes in circulation. Model simulations indicate that Atlantic Ocean circulation can take three general forms: an interglacial mode, such as exists today, in which warm water flow extends to the north of the shallow sill between Scotland and Iceland before sinking (the

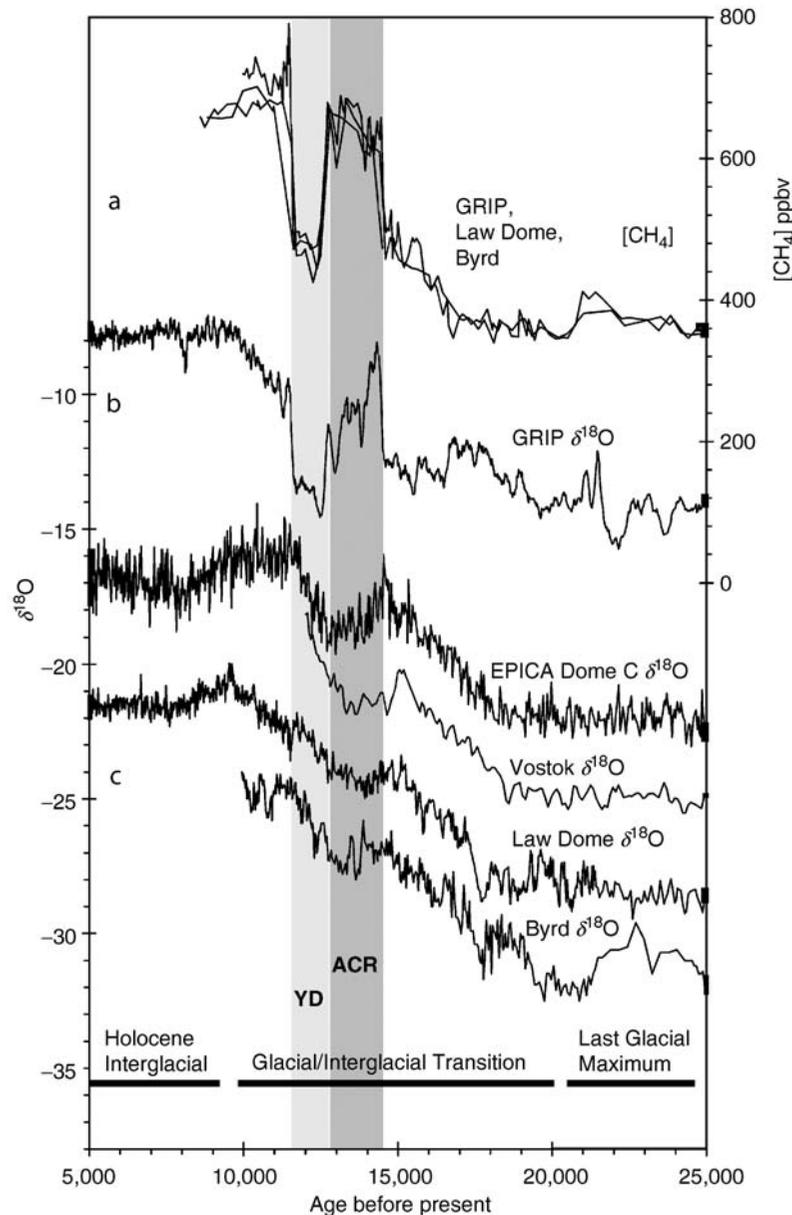

Figure A14 Ice core records showing principal features of the global warming through the glacial-interglacial transition. The period of the Antarctic Cold Reversal (ACR) is shaded. YD stands for Younger Dryas. (a) The overlaid plots are of atmospheric methane concentrations obtained from trapped air in the GRIP, Law Dome and Byrd cores. The large and rapid changes associated with the Bølling Transition and the Younger Dryas are used to synchronize the timing of the ice core records. (b) The stable isotope ratio ($\delta^{18}\text{O}$) record from the GRIP (Greenland Icecore Project) core. $\delta^{18}\text{O}$ is a proxy for climatic temperature. The record shows the characteristic Northern Hemisphere pattern of a rapid rise at the Bølling transition, a decline into the Younger Dryas, a rapid jump out of the YD and a subsequent rise to Holocene temperature. (c) Antarctic ice core records: EPICA and Dome C in inland East Antarctica, Vostok in central East Antarctica, Law Dome in coastal East Antarctic site, and Byrd in West Antarctica. GRIP, Byrd and Vostok data, including original references, are available at IGBP PAGES/World Data Center-A for Paleoclimatology, NOAA/NGDC Paleoclimatology Program, Boulder CO, USA. <http://www.ngdc.noaa.gov/paleo/icecore.html>

Atlantic Conveyor); a glacial mode, where the flow sinks to the south of the sill; and a third mode in which the flow is essentially cut off (see *North Atlantic Deep Water and climate change; Thermohaline Circulation*). These three modes are reasonably successful in describing two types of rapid change climate events seen in records from around the North Atlantic Ocean: Dansgaard-Oeschger events (named after the ice core

paleoclimatologists Willi Dansgaard and Hans Oeschger) and Heinrich events (named after the German paleoceanographer Hartmut Heinrich). In Dansgaard-Oeschger events, cold glacial conditions are interrupted by an abrupt (10–100 year) warming, which is followed by a slow cooling back to glacial conditions over some 1,000 years. It is surmised that the glacial mode of circulation, in which warm water sinks before

reaching very far north, is abruptly enhanced, leading to an interglacial mode of circulation and hence warmer climate in the far north. Under glacial conditions, however, this mode is not stable, so it gradually reverts to the glacial mode. Dansgaard-Oeschger events produce warming in the North and, because of the enhanced transport of heat; cooling in the south (the Atlantic Conveyor does not just carry warm tropical water north but also water from the Southern Ocean). Heinrich events operate in the opposite manner and enhance cooling in northern mid-latitudes. Heinrich events presumably occur when surges of the Laurentide Ice Sheet inject low-density freshwater into the North Atlantic, reducing circulation from glacial levels to the cutoff state. Heinrich events lead to the coldest conditions in the northern records, but the Heinrich mode in which Atlantic circulation is switched off is also unstable and circulation reverts to a normal glacial mode after a few centuries. Dansgaard-Oeschger and Heinrich events are observed throughout the late glacial and the glacial/Holocene transition, but not in the Holocene. The Bølling Transition in the Northern Hemisphere, the start of the Antarctic Cold Reversal at around 14,500 BP, and the end of the Younger Dryas at 11,500 BP are the second to last and last Dansgaard-Oeschger events before the warmer Holocene conditions led to the present-day stable interglacial ocean circulation pattern.

A significant advance in our understanding of the climate system came when air trapped in ice cores was used to synchronize records from Greenland (representing the Northern Hemisphere) and Antarctica (in the Southern Hemisphere). The ice-core trapped-air synchronization method relies on the fact that the atmosphere is well mixed on timescales of more than a few years so that changes in the atmosphere can serve as global time markers. The method is complicated, however, because the air is not sampled when the snow is deposited on the ice sheet surface, but is gradually trapped at a depth of about 70 m when pores in between snow crystals are closed by the weight of overlying snow. This produces two effects. The first is that the trapped air is younger than the surrounding ice (the ice that provides the proxy climate record) and the second is that the trapped air does not represent a sample taken at a single point in time. Typically, the age of the air is a few hundred years younger in the Holocene and up to several thousand years younger in glacial periods when snow accumulation rates were much lower. The corresponding errors in the age are likely to be around 100 and 1,000 years. Sites with higher accumulation rates, where the ice is younger at depth, have correspondingly smaller age uncertainties.

Using trapped air, Blunier and Brook (2001) showed that the large millennial scale Dansgaard-Oeschger fluctuations seen in Greenland records were synchronized with Antarctic records in a distinct pattern; Antarctic temperature varied smoothly, warming for a few thousand years and then cooling for a similar period. Greenland temperatures showed no increase while Antarctica warmed, but exhibited a large temperature jump around the time when the Antarctic went from warming to cooling (Figure A14). A similar pattern occurs throughout the glacial period and ends with the two events in the glacial-Holocene transition: the Bølling Transition and the jump at the end of the Younger Dryas (see *Bølling-Allerød Interstadial*; *Younger Dryas*).

Although the idea of one hemisphere driving the other in climate has now largely been discarded in favor of the concept of a coupled feedback system, the timing and order of events is important in determining cause and effect. Trapped air synchronization using a high accumulation record from Law Dome

on the coast of East Antarctica has shown that, in the transition, the start of the ACR is not exactly synchronous with the Bølling Transition but leads it by about 200 years (Figure A14 shows the sequence of events). Two hundred years is a relatively short time and this figure is still subject to some uncertainty, but the fact that the ACR occurs before the Northern Hemisphere cooling makes it difficult to ascribe a simple Northern Hemisphere driver. A possible mechanism that might explain the observed events comes from model simulations by Weaver and others (2003). They find that injection of a large amount of freshwater into the Southern Ocean by a surge of the Antarctic Ice Sheet would enhance the flow of the Atlantic Conveyor. The effect is similar but opposite in effect to the surges of the Laurentide Ice Sheet that result in Heinrich events. Just as a surge of the Laurentide Ice Sheet can slow or stop the Atlantic conveyor, a large amount of freshwater injected into the Southern Ocean enhances the conveyor flow and hence the transport of heat from the south to the north. The effect on climate would be a cooling in the south at the same time or slightly preceding a warming in the north.

ANTARCTIC GLACIATION HISTORY

The continent of Antarctica is currently 98% covered by two connected continental-scale ice sheets plus smaller ice caps and glaciers of the Antarctic Peninsula. The history and behavior of the two large ice sheets, the East Antarctic Ice Sheet (EAIS) and the West Antarctic Ice Sheet (WAIS) (Figure A15) have had a major influence on Earth's past climate. The waxing and waning of Antarctica's ice sheets are strongly tied to global sea levels and climate change, ocean circulation patterns, Earth's albedo and life on the planet.

Antarctica's glaciation history is partially a function of its sub-ice topography. Underlying the EAIS are cratonic rocks and mountain ranges that would be exposed subaerially if the ice sheet

was removed (Figure A16) and that served as a foundation for ice sheet inception. Exceptions include the Wilkes, Pensacola and Aurora Subglacial Basins and the Amery Basin, which all lie below sea level. In contrast, much of the bed beneath the WAIS lies below sea level (Figure A16), reaching depths $>2,000$ m in the Byrd Subglacial Basin and Bentley Subglacial Trench. The WAIS occupies a rift-related basin that is bounded by the Transantarctic Mountains (TAM) to the south and the mountain ranges of Marie

Byrd Land, Ellsworth Land and the Antarctic Peninsula to the north. These mountain ranges have influenced regional atmospheric circulation and also served as nucleation points for glaciation. In these tectonically active regions, the isostatic changes to the crust associated with ice sheet evolution is complicated by the complex tectonic history. The uplift of the Transantarctic Mountains, which reached their present height by ~ 34 Ma, played a particularly important role in ice sheet development. Overall, the fundamental differences in bed elevation between the EAIS and WAIS translate into different histories and ice flow characteristics.

Another major factor that affected ice sheet development was the opening of gateways, such as the Drake Passage and the Tasmanian Seaway, which allowed thermal isolation of the Antarctic continent after the breakup of Gondwana. Antarctica moved into a polar position in the Cretaceous; however, the complete opening of these rift-related gateways did not occur until the early Cenozoic. Both gateways appear to have opened near the Eocene-Oligocene boundary (34 Ma) (e.g., Lawver et al., 1992; Shipboard Scientific Party, 2000; Latimer and Filippelli, 2002). These openings allowed the development of the Antarctic Circumpolar Current (ACC), which prevents the delivery of warm surface water to the Antarctic continent. The details of the timing and influence of ACC onset on the development of continental scale Antarctic ice are not well constrained (Barker and Thomas, 2003). Alternatively, DeConto and Pollard (2003) argued that the opening of gateways was secondary to falling atmospheric CO_2 levels in causing Antarctic ice sheet development. From model simulations, they suggest that snowline lowering associated with falling CO_2 permitted glacier growth.

Proxy records of ice volume changes can be derived from the oxygen isotopic composition of deep-sea benthic foraminifera.

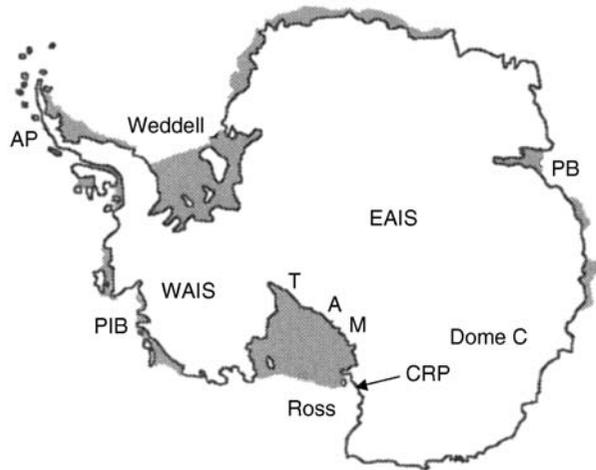

Figure A15 Antarctic place names along with ice shelves shown in gray. WAIS, West Antarctic Ice Sheet; EAIS, East Antarctic Ice Sheet; AP, Antarctic Peninsula; PB, Prydz Bay; TAM, Transantarctic Mountains; CRP, Cape Roberts Project site; PIB, Pine Island Bay.

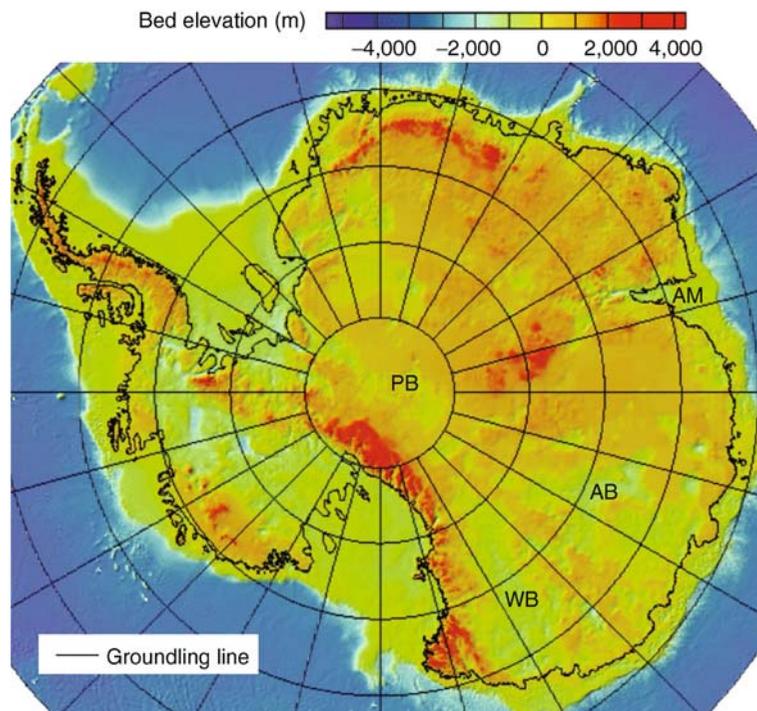

Figure A16 Antarctic sub-ice topography and bathymetry. WB, Wilkes Basin; AB, Aurora Basin; PB, Pensacola Basin; AM, Amery Basin. (Modified from Lythe et al., 2000.)

Positive $\delta^{18}\text{O}$ isotopic excursions can be interpreted as ice volume increases and/or bottom water temperature decreases (Figure A17). Assuming that the temperature effect on $\delta^{18}\text{O}$ is accurately accounted for, the benthic foram oxygen isotopic data indicate Antarctic ice sheet development at the Eocene-Oligocene boundary (34 Ma) (Shackleton and Kennett, 1975; Zachos et al., 2001). The isotopic data also indicate persistence of this ice until about 26 Ma when the $\delta^{18}\text{O}$ decreased $>1\%$. Zachos et al. (2001) interpreted part of this decrease as a reduction in Antarctic ice volume. The mid-Miocene increase in $\delta^{18}\text{O}$ is interpreted to represent the regrowth of the EAIS, followed several million years later by development of the WAIS (Figure A17). The lag in WAIS development is attributed to the bed elevation differences between East and West Antarctica. Since much of the bed beneath the WAIS is well below sea level (>700 m) (Figure A16), the ice had to become thick enough to overcome buoyancy effects in order to ground on the seafloor.

Southern Ocean records of ice-rafted debris (IRD) provide some of the earliest sedimentological evidence of Antarctic glaciation. Deep Sea Drilling Project (DSDP) and Ocean Drilling Program (ODP) sites in the Southern Ocean show a wide variety of dates for onset of ice rafting and range from the latest Cretaceous to the Pliocene (Anderson, 1999). Minor occurrences of IRD are found at several sites around the continent

in the late Eocene and early Oligocene, and the majority of sites show either minor or significant IRD content during the Miocene. One limitation of IRD records is that ice sheet volume cannot be determined; IRD only indicates that glaciers were calving from Antarctica and the icebergs reached the Southern Ocean.

Ice sheet evolution studies from the Antarctic continental margin draw upon marine seismic surveys, drill cores, and gravity cores. A number of DSDP and ODP cores have been collected around the Antarctic margin as well as the Southern Ocean, yielding volumes of data. Continental shelf sites that have targeted Cenozoic records of Antarctic glaciation include DSDP sites 270–273 in the Ross Sea, ODP sites 739–742 and 1,166 in Prydz Bay, and sites 1,098–1,100, 1,102 and 1,103 from the western Antarctic Peninsula. Few cores have been drilled on the continental shelves, in part because of the poor recovery that is common from these sites. For instance, ODP sites 1,100, 1,102 and 1,003 on the outer continental shelf averaged $<14\%$ recovery when trying to core through diamict (Shipboard Scientific Party, 1999).

The eastern Ross Sea DSDP sites contain Mid-Late Eocene to Early Oligocene glacial and glacial marine sediment (Hayes and Frakes, 1975; Hambrey, 1993). In these cores, a clear glacial sedimentary signal appears in the late Oligocene to early

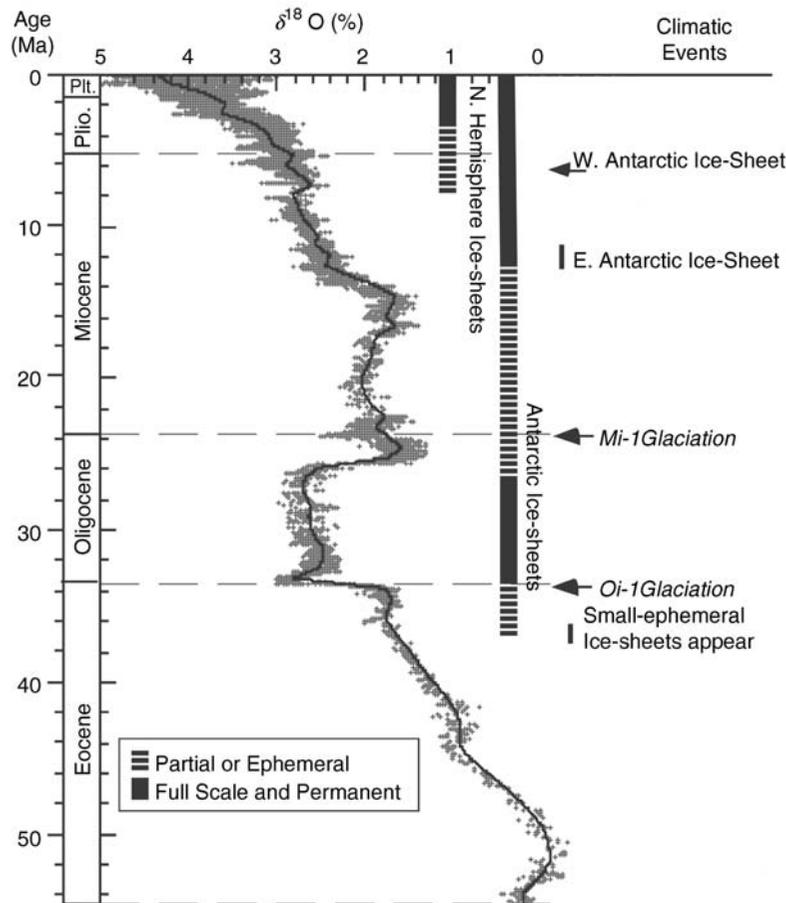

Figure A17 Composite oxygen isotopic curve from benthic foraminifera showing interpretation of Antarctic ice sheet evolution. (Modified from Zachos et al., 2001.)

Miocene with extensive ice throughout the early Miocene. More recently, cores drilled in the western Ross Sea for the Cape Roberts Project (Figure A15) contain a nearly complete record of Antarctic history from about 34 to 17 Ma and provide an excellent regional record of ice sheet evolution. The cores were drilled from a sea ice platform and around 1,500 m of Cenozoic sediments were recovered from three closely spaced sites. As in the eastern Ross Sea, these Oligocene sediments on the flanks of the Transantarctic Mountains record a glacial marine setting from 34 to 24 Ma, indicated by the presence of ice-rafted debris. From 24 to 17 Ma, grounded ice became more extensive under a cooler climate (Cape Roberts Science Team, 1999). In total, the Cape Roberts cores provide evidence of at least 22 cycles of glacial advance and retreat in the Oligocene and early Miocene.

In the Leg 188 synthesis of Prydz Bay cores, Cooper and O'Brien (2004) reported that glacial sediments first appeared on the continental shelf near the Eocene-Oligocene boundary, similar to the Ross Sea records. Prydz Bay Miocene sediments record a transition from a meltwater-rich setting to an IRD-dominated setting, reflecting a temperate to cold climate transition and buildup of ice in East Antarctica. Uplifted Miocene glacial marine sediments of the Pagodroma Group are exposed in the Prince Charles Mountains south of Prydz Bay (Hambrey and McKelvey, 2000). These strata support observations from the marine record, although the exact timing of the transition from temperate to polar conditions is not well constrained.

Marine seismic surveys provide a regional context for core data and are therefore valuable records of past ice sheet fluctuations. Major ice sheet advances are indicated by widespread erosional events, which produce strong seismic reflections that truncate underlying strata and that have a distinctive progradational geometry. The number of such erosional surfaces on a continental shelf represents a minimum number of ice sheet advances because evidence for some advances may be erased by subsequent ice sheet erosion of the shelf. Because of limited core recovery on the shelves, many seismic records lack age control on the glacial unconformities. The age of nearshore unconformities has been linked to Southern Ocean IRD records; however, increases in IRD abundance have been ascribed to both ice sheet maxima and minima (Anderson, 1999), thus clouding the issue of the timing of glacial fluctuations. Even considering these limitations, marine seismic records provide clear evidence of numerous major ice sheet fluctuations across the continental shelf since the Oligocene.

The Ross Sea has been extensively characterized by seismic surveys and a recent compilation of eastern Ross Sea seismic data is interpreted to show the presence of localized West Antarctic ice caps in the Early Oligocene (De Santis et al., 1995). Bart (2003) reported at least two episodes of Ross Sea glaciation to the outer continental shelf during the early mid-Miocene and suggested that it was a WAIS-dominated expansion. This reconstruction requires the WAIS expansion to precede the major EAIS regrowth after 14 Ma (Figure A17). Bart (2003) discussed the contradictions with $\delta^{18}\text{O}$ Antarctic ice sheet evolution, which suggest full WAIS development in the late Miocene (Zachos et al., 2001). Bart (2003) argued that possibly the bed of the WAIS was above sea level or that ocean and atmospheric temperatures in West Antarctica were cooler than previously thought. Marine seismic records around the East Antarctic perimeter also show major erosional events beginning in the Oligocene and continuing throughout the Miocene (Anderson, 1999).

The Pliocene ice sheet configuration has been the subject of vigorous debate and two contradictory reconstructions have been proposed. One model suggests that the EAIS has remained a stable continental-scale ice sheet since the Miocene whereas the other reconstruction suggests that the size of the EAIS was dramatically reduced from the late Miocene to mid-Pliocene, allowing marine incursion into the Wilkes-Pensacola Basins (Figure A16). Part of the debate stems from alternative explanations for the presence of marine diatoms in Sirius Formation glacial deposits that outcrop in the TAM at elevations from 1,750 to 2,500 m. Webb et al. (1984) suggested that these marine diatoms reflect airborne transport and subsequent deposition, and movement of sediment by glacial ice following a major deglaciation of East Antarctica. Others have suggested that the marine diatoms were transported to the Sirius Formation directly by eolian processes (e.g., Sugden et al., 1993). Additionally, Sugden et al. (1995) reported the presence of Miocene-age glacial ice in the East Antarctic Dry Valleys, indicating stable polar conditions for at least the past 8 million years. However, cosmogenic ^3He isotope data from depth profiles of till deposits in the region indicate high ablation rates, which is inconsistent with the presence of Miocene ice (Ng et al., 2005). The Pliocene climatic conditions and ice sheet configuration remain unresolved.

The marine evidence for Pliocene ice sheet fluctuations is less controversial but does not necessarily resolve the disparate terrestrial reconstructions. Combining DSDP and ODP core data with seismic data from the eastern Ross Sea, Antarctic Peninsula, and Prydz Bay, Bart (2001) estimated that all regions of Antarctica experienced one major ice sheet advance during the early Pliocene (5–3.5 Ma) and that the Antarctic Peninsula dataset shows at least six glacial erosional unconformities during this time. Using ice volume estimates from Southern Ocean $\delta^{18}\text{O}$ records and the seismic data, Bart (2001) suggested that, at times, the Pliocene ice sheet volume might have exceeded the Last Glacial Maximum (LGM) ice volume.

Pleistocene ice sheet reconstructions benefit from the data obtained from numerous ice cores that have been drilled in East and West Antarctica. These cores provide a nearly continuous record of environmental conditions both in the ice sheet interior and near the margin. All long ice core records show clear glacial-interglacial cycles, but details vary by site. For instance, the Siple Dome core shows an abrupt 6 °C increase in temperature at 22 ka (Taylor et al., 2004). This rapid warming has not been observed in other Antarctic ice cores. Climate records from the Dome C ice core now extend back over 700,000 years (Figure A18) (EPICA community members, 2004) and provide vital information about Earth's past greenhouse gas levels, as well as local paleotemperature estimates. Preliminary isotopic data from this record indicate that the variability in EAIS surface elevation since the mid-Pleistocene is similar to the variability over the past 40 kyr (EPICA community members, 2004).

Pre-LGM ice core records and glacial geological records cannot yet be unambiguously linked because of problems with chronology and lack of sediment cores that recover pre-LGM deposits. There is some evidence of a smaller Pleistocene WAIS in the Ross Sea. Scherer et al. (1998) reported evidence for major WAIS size reduction based on the presence of Quaternary diatoms in till collected from beneath Ice Stream B (Whillans Ice Stream) in the Ross Sea sector of the WAIS.

The evolution of the Antarctic Ice Sheet during and since the LGM has been studied extensively. The marine records

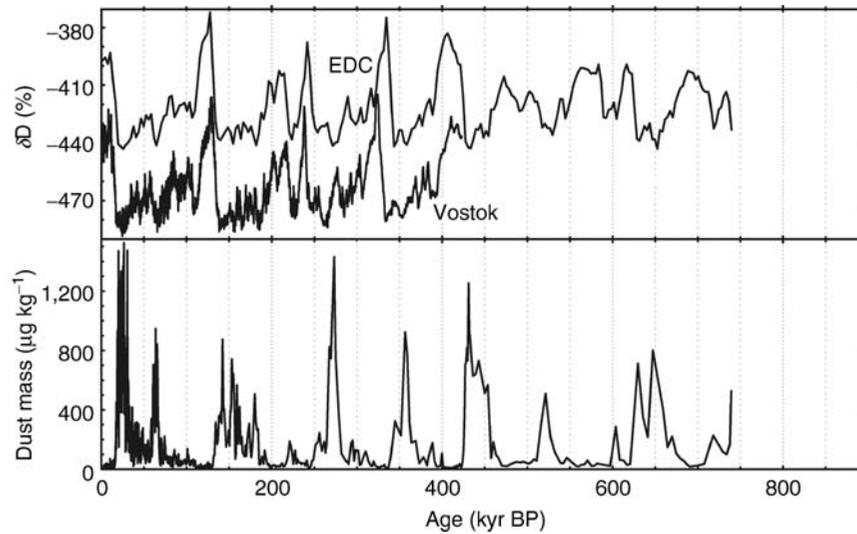

Figure A18 Dome C ice core data. δD is a temperature proxy and the Dome C data (EDC) show strong similarity to the shorter Vostok record. (Modified from EPICA community members, 2004.)

of the late Pleistocene have been accessed through piston coring, high-resolution seismic surveys and swath bathymetric surveys of the seafloor. On land, raised beaches, lacustrine sediments and moraines also provide important constraints on ice sheet history. The detailed LGM ice sheet reconstructions provide important limits for modeling exercises whose ultimate goal is predicting the fate of Antarctic ice under various climatic conditions. The chronological resolution of most continental margin records is limited by challenges with radiocarbon dating and is substantially lower than the equivalent deposits of the Northern Hemisphere. The ocean reservoir correction is well-known for carbonates (1,200–1,300 years) (Gordon and Harkness, 1992; Berkman and Forman, 1996); however, little carbonate material is preserved in the shelf sediments. The alternative of dating the acid-insoluble bulk organic fraction of marine sediments produces ages older than expected. Andrews et al. (1999) discussed strategies to correct these dates.

The timing of ice sheet advance around the continent is not well constrained for the LGM and therefore cannot provide information on the synchronicity of the behavior of the WAIS and EAIS. In the Ross Embayment, the LGM ice sheet grounded in McMurdo Sound (south of Cape Roberts) and blocked the mouths of the Dry Valleys after 26.9 ^{14}C ka and remained in that position until 12.7 ^{14}C ka (Denton and Marchant, 2000). Radiocarbon dates from central Ross Sea till show a somewhat later advance in this region, with ice reaching its maximum position as late as ~ 14 ^{14}C ka (Licht and Andrews, 2002). These data, however, do not provide the spatial resolution needed to characterize the WAIS and EAIS advances separately. The timing of ice advance across the Antarctic Peninsula, Weddell Sea and East Antarctic continental shelves is effectively unknown.

Ice-sheet size reconstructions for the LGM are constrained by terrestrial and marine geological records, which show that the WAIS and EAIS did not achieve an equilibrium thickness or position. Supporting evidence includes the observation that grounded ice did not reach the continental shelf break in many places around the perimeter, that ice of the East Antarctic interior

did not thicken substantially (Denton et al., 1989), and that ice may have only remained at its furthest extent for 2–3 kyr. Numerical models confirm that this is not an equilibrium position (e.g., Steig et al., 2001). Summaries of Antarctica's LGM ice extent and deglaciation can be found in Ingólfsson et al. (1998) and Bentley (1999) for terrestrial records, and Anderson et al. (2002) for marine records. The largest area with sparse data on ice extent and chronology is the Weddell Sea.

The characteristics of the LGM ice sheet, such as velocity, thickness and flow directions, provide important information on ice sheet dynamics. Marine geophysical studies of seafloor morphology and geometry of the strata around the Antarctic margin have been used to identify the signature of paleo ice streams. Evidence of past ice streams typically includes glacial lineations developed in deformable till (Figure A19). These features range in age from Miocene to LGM and have been reported for Prydz Bay (e.g., O'Brien and Harris, 1996), the Ross Sea (e.g., Shipp et al., 1999) and the Antarctic Peninsula (e.g., Canals et al., 2000). Past ice flow paths have been constrained for the Ross Embayment using till provenance. Recent studies have shown that till from TAM outlet glaciers and from beneath West Antarctic ice streams have unique isotopic and sand petrographic signatures that can be identified in Ross Sea till (Farmer et al., 2006; Licht et al., 2005). The central Ross Sea was identified as the zone of convergent flow from the EAIS and WAIS, which requires substantial reorganization of the West Antarctic ice streams between the LGM and today.

The timing of deglaciation from the maximum grounded ice extent was, in most places around the Antarctic margin, later than the eustatic sea level minimum at 18 ^{14}C ka, as reported by Fairbanks (1989) and subsequently confirmed at additional sites. Most records from Prydz Bay and the adjacent East Antarctic margin show evidence of initial deglaciation between 11 and 10 ^{14}C ka (summarized in Ingólfsson et al., 1998). Similarly, initial ice sheet retreat from the Antarctic Peninsula LGM positions occurred ~ 12 –11 ^{14}C ka (e.g., Domack et al., 1991; Pudsey et al., 1994). The oldest dates on raised marine deposits along the

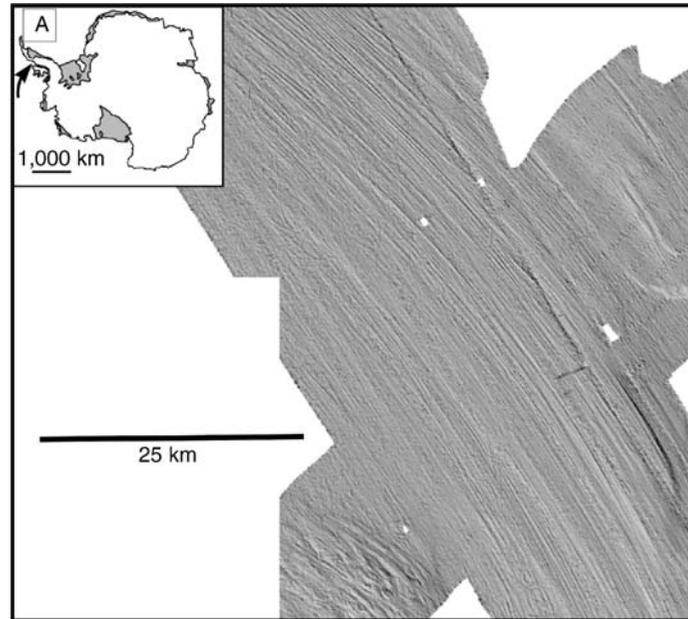

Figure A19 Glacial lineations in Marguerite Bay imaged with swath bathymetry. (Modified from Dowdeswell et al., 2004.)

Antarctic Peninsula, which indicate ice retreat onshore, range from 8.4 to 6 ^{14}C ka (Ingólfsson et al., 1998). The timing of ice sheet retreat is well constrained for the western Ross Sea, but more uncertain for the central and eastern Ross Sea (e.g., Licht and Andrews, 2002). Ice sheet retreat from the western Ross Sea began at ~ 12 ka (Domack et al., 1999), reached the Drygalski Trough at ~ 9 ka, and Ross Island at ~ 7 ka (Licht et al., 1996). The timing of ice sheet retreat from the western Ross Embayment was also estimated from a postglacial rebound curve created for the Scott Coast (west of Ross Island) (Hall and Denton, 1999). Unloading of the crust from ice sheet retreat led to coastal uplift of 8–31 m. Rapid uplift began at about 6.5 ^{14}C ka, indicating that ice sheet retreated shortly before this time. The timing of ice sheet retreat inferred from these coastal deposits agrees closely with the marine record of ice sheet retreat from the McMurdo Sound region (Licht et al., 1996). The Ross Embayment retreat chronology provides no evidence of rapid or catastrophic deglaciation (e.g., Conway et al., 1999). It is unclear whether the ice in the Weddell Sea sector of the continent behaved in lockstep with Ross Embayment ice because the deglaciation chronology is effectively unknown (Anderson et al., 2002).

The sources of rapid rises in sea level ($2\text{--}5\text{ cm yr}^{-1}$) during the latest Pleistocene, called meltwater pulse (mwp) 1A and 1B (Fairbanks, 1989), have been controversial and Antarctica has been implicated as a primary source for mwp-1A at ~ 12.5 ^{14}C ka (Clark et al., 1996). However, Antarctic deglaciation chronologies show that much of the ice retreat occurred after mwp-1A and that the ice volume reduction was too small to account for the observed rise (Licht, 2004).

More recently an increase in mean annual surface air temperature of $2.5\text{ }^{\circ}\text{C}$ has been measured at Faraday Station on the Antarctic Peninsula since 1945. This warming, plus an increase in ocean temperatures has been blamed for the recent disintegration of ice shelves on the eastern side of the Antarctic Peninsula (Rott et al., 1996) and in Pine Island Bay (Rignot, 1998). However, most of the continent is not warming and

if remains uncertain how Antarctic ice will respond to future global change and rising sea level.

ANTARCTIC SEA ICE HISTORY, LATE QUATERNARY

Introduction

Sea ice results from the freezing of surface sea water. In the Southern Ocean, sea ice surrounds the Antarctic continent and it today covers 20×10^6 km² in winter and only 4×10^6 km² in summer (Gloersen et al., 1992). This pronounced seasonal cycle strongly affects the climate of the Southern Hemisphere through its impacts on the energy and gas budget, atmospheric circulation, the hydrological cycle, and biological productivity (Figure A20). Sea ice also modulates the climate of remote places through its impact on deep and intermediate oceanic circulations. More details about sea ice formation, its seasonal cycle and its importance in the climate and ocean systems can be found in the entry on *Arctic sea ice*, this volume.

Sea ice is a very reactive component of the cryosphere. It has experienced drastic changes through time. Whaling ship records (de la Mare, 1997), satellite measurements (Cavalieri et al., 2003), and ice core data (Curran et al., 2003) indicate that Antarctic sea ice underwent a dramatic decrease in maximum extent since the 1950s. Such a reduction may accelerate in the near future because of global warming, and this will in turn have important feedbacks on future climate. However, sea ice is still not well-computed in climate models because of its complicated relationship with climate change over a large range of timescales. One way to ameliorate our understanding of such relationship is to reconstruct sea ice extent over long time periods and certain key periods for which the global climate is reasonably well-known. These reconstructions, which started in the early 1980s, are still very sparse in numbers and coverage because of the scarcity of good sediment sequences in the Southern Ocean.

Three long records from the Atlantic and Indian sectors of the Southern Ocean are presented here to give an idea of sea ice dynamics over the last two climatic cycles. A map of winter and summer sea ice extent at the Last Glacial Maximum (LGM) is also shown to illustrate sea ice distribution under a very different climatic state from the present.

Long records

Long records of sea ice extent result almost exclusively from the investigation of fossil diatom assemblages preserved in deep-sea sediments. Diatoms are the most abundant photosynthetic micro-algae in Southern Ocean surface waters. The cell is surrounded by a test of biogenic silica that is generally well preserved in sediments subsequent to the organism's death. Some diatom species thriving in Antarctic waters present a strong affinity to sea ice (Horner, 1985) and are therefore most useful to estimate sea ice cover in the past.

Fossil sea ice diatoms can be used qualitatively to estimate past seasonal sea ice extent. Abundances greater than 3% of *Fragilariopsis curta* and *F. cylindrus* denote a recurrent presence of seasonal winter sea ice while abundance greater than 3% of *F. obliquicostata* marks the returning presence of summer sea ice at the core location (Gersonde and Zielinski, 2000). Increasing abundances of these taxa indicate greater sea ice cover. Fossil diatoms can also be used quantitatively, based on a statistical treatment of 30 diatom species including sea ice taxa and open ocean taxa (Crosta et al., 1998a). In this statistical method, called the Modern Analog Technique or MAT, open ocean taxa are essential in constraining the seasonal sea ice edge. The MAT compares the fossil diatom assemblages to a set of core-top diatom assemblages with known modern surface conditions that are subsequently used to attribute an estimate of sea ice duration in number of months per year to the fossil sample.

Long records of Antarctic sea ice extent are very rare and are restricted to the Atlantic and Indian sectors to date. Three records from the east Indian sector (core SO136-111, *black curve* in Figure A21), and the Atlantic sector (core TNO57-13PC4, *dark blue curve* in Figure A21; and core PS1768-8, *light blue curve* in Figure A21) are shown. Sea ice conditions at the first two core locations were estimated by MAT (Hodell et al., 2000; Shemesh et al., 2002; Crosta et al., 2004), while winter sea ice conditions at the third core site were documented by relative abundances of *F. curta* + *cylindrus* (Gersonde and Zielinski, 2000).

The three records give a very coherent picture of sea ice advance and retreat around Antarctica during the Late

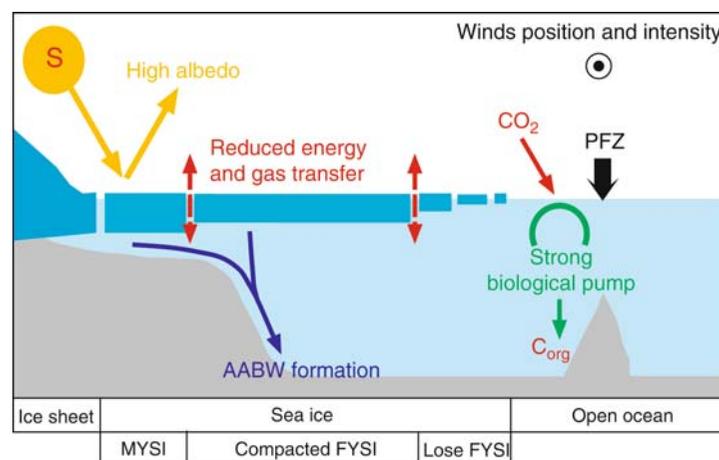

Figure A20 Schematic illustration of sea ice impacts on the Southern Hemisphere climatic system. AABW: Antarctic Bottom Water; MYSI: Multi-Year Sea Ice; FYSI: First-Year Sea Ice that freezes and melts every year. FYSI can be separated in consolidated ice (concentration above 40%) and unconsolidated ice (concentration below 40%).

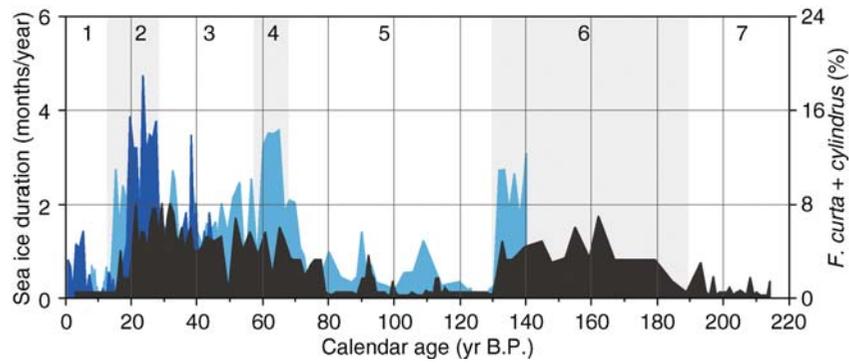

Figure A21 Sea ice history over the last 220 kyr BP. Sea ice duration was estimated by MAT in core SO136-111 from the east Indian sector of the Southern Ocean (black curve) and in core TNO57-13PC4 from the Atlantic Sector of the Southern Ocean (dark blue curve). Sea ice duration is compared to relative abundances of *F. curta* + *cylindrus* proxy of sea ice presence in core PS1768-8 (light blue curve). Core SO136-111 covers the last 220 kyr BP, core TNO57-13PC4 covers the last 40 kyr BP, and core PS1768-8 covers the last 140 kyr BP. Odd numbers and white areas represent interglacial stages while even numbers and shaded areas represent glacial stages.

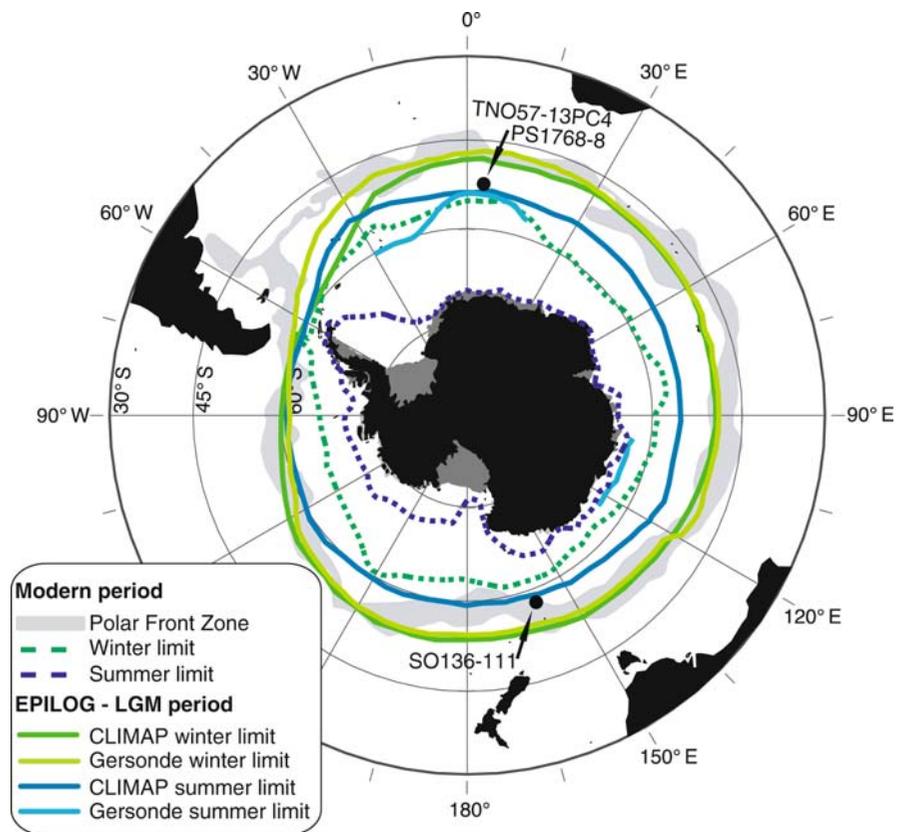

Figure A22 Comparison of LGM winter and summer sea ice edge reconstructions by CLIMAP (1981) and Gersonde et al. (2005) with modern winter and summer sea ice edges (Schweitzer, 1995).

Quaternary, although the amplitude of sea ice changes are more important in the Atlantic sector (Figure A21) in relation to the presence of the Weddell Gyre promoting northward ice transport. Today the cores are a few degrees latitude northward of the winter sea ice edge (Figure A22), and were similarly ice

free during other warm periods such as Marine Isotopic Stages 5 and 7 (MIS 5 and MIS 7 respectively). Winter sea ice extent during these periods was certainly very comparable to that of today. At interglacial-glacial transitions, sea ice advanced very rapidly to reach its full glacial extent within a few thousand

years (Figure A21). The two longest records indicate that sea ice conditions were certainly comparable during every glacial stage of the last 220 kyr. During glacial-interglacial transitions, sea ice retreats back very rapidly to its modern position within a few thousand years.

Sea ice advance and retreat are initiated by atmospheric and oceanic temperature changes but, due to the very reactive nature of sea ice, it reaches full glacial or full interglacial condition before the completion of the temperature change (Bianchi and Gersonde, 2002). Conversely, variations in sea ice cover during full glacial conditions are linked to feedback processes of wind stress and atmospheric temperatures.

Last glacial maximum

In the early 1980s, a tremendous effort was applied to reconstruct global conditions of the Earth at the Last Glacial Maximum (LGM), (CLIMAP, 1981). For the Southern Ocean, the reconstruction was based on estimates of sea-surface temperatures via a radiolarian-based transfer function and winter and summer sea ice limits via a combination of micropaleontological and lithological tracers. According to CLIMAP (1981), winter sea ice edge was 5–10° latitude northward of its modern position, overlying the modern Antarctic Polar Front (Figure A22), due to colder air and sea-surface temperatures and more intense winds. The winter sea ice cover at the LGM was therefore twice that of the modern surface. Similarly, the LGM summer sea ice edge was projected northward of its modern position, overlying the modern winter sea ice margin (Figure A22). The summer sea ice cover was thus 5–6 times greater than its modern counterpart is. A permanently covered area of around 20×10^6 km² was estimated, strongly affecting the Southern Hemisphere climate. For example, paleoclimatic models attribute a 70 ppm impact on atmospheric CO₂ to the Southern Ocean, out of the 80 ppm drop observed on the glacial-interglacial timescale when CLIMAP sea ice limits are introduced as boundary conditions (Stephens and Keeling, 2000).

Soon after the CLIMAP (1981) report, summer sea ice extent was found to actually represent spring sea ice extent (Burckle et al., 1982). However, no proxy was calibrated to document summer sea ice cover until the development of diatom-based transfer functions in the late 1990s that crystallized the relationships between diatoms and surface conditions (Zielinski and Gersonde, 1997; Crosta et al., 1998a). Diatom assemblages confirm a doubling of the winter sea ice cover at the LGM mainly due to the progression of the compacted sea ice (Burckle and Mortlock, 1998; Crosta et al., 1998b). Conversely, diatom assemblages argue for a more restricted summer sea ice cover than previously estimated (Figure A22). In the Atlantic sector, off the Weddell Sea, the glacial summer sea ice margin was certainly displaced northward to overlie the modern Antarctic Polar Front (Armand and Leventer, 2003). A similar situation probably prevailed in the western Pacific off the Ross Sea. In the Indian and the eastern Pacific, however, glacial summer sea ice cover was more comparable to modern conditions prevailing in these sectors. In the Northern Hemisphere, similarly, LGM winter sea ice cover was greatly expanded, while summer sea ice cover was comparable to today (de Vernal and Hillaire-Marcel, 2000). Paleoclimatic models estimate a 5–30 ppm impact of Antarctic sea ice cover on the glacial atmospheric CO₂ drop when sea ice extent and concentration data in agreement with diatom-based reconstructions are used as boundary conditions (Morales-Maqueda and Rahmstorf,

2002; Bopp et al., 2003). Although Antarctic sea ice, and more globally the Southern Ocean, is certainly a key component in regulating atmospheric CO₂ variations through albedo feedback, and therefore climate changes, it alone cannot explain glacial-interglacial changes in pCO₂ that are dependant upon feedbacks involving several components of the internal climate system.

Conclusion

Despite its importance in global climate change, Antarctic sea ice extent during the Late Quaternary has been weakly documented, in part because few proxies have been developed that can document past sea ice conditions and, in part, because of the lack of good sediment records. Early reconstructions of sea ice extent focused on the Last Glacial Maximum. Such reconstructions were still recently used in modeling. However, the evolution of paleoclimate models requires long records of sea ice cover to confront its dynamic response to climate changes. Very few such records exist, but they all argue for very rapid waxing and waning at climate transitions, leading to Antarctic sea ice cover doubling or halving in a few thousand years. Such variations in ice cover have deep impacts on the global climate through the albedo, the hydrological and wind systems, the deep and intermediate oceanic circulations, the transfer of gas and energy at the ocean-atmosphere interface, and the biological pump.

ARCHEAN ENVIRONMENTS

A primary research objective in the study of Archean rocks (>2.5 Ga) has been to determine conditions on the surface of the Earth during the first two billion years of its history. Recent advances in isotope geochemistry and geochemical microanalysis have allowed new insights into the earliest few hundred million years of Earth's history, and have pushed back the time at which the first life could have emerged.

The earliest subdivision of the Archean Eon beginning with Earth's accretion at 4.56 Ga and extending to ca. 4.0–3.8 Ga, has been called both the Priscoan (“previous time”) Era and Hadean (“Hell-like”) Era. These divisions of geologic time are based on the inherent bias of the rock record, making

distinctions in part based on whether or not rocks have survived. The term “Hadean” is also based on the preconception that Earth was so hot from formation and bombardment by meteorites that the atmosphere was dominated by steam and rock debris, and solid material would have been pulverized or melted (Cloud, 1972). Detrital zircon crystals (ZrSiO₄) from this period challenge this preconception (Compston and Pidgeon, 1986; Mojzsis et al., 2001; Peck et al., 2001; Wilde et al., 2001; Valley et al., 2002; Cavosie et al., 2004, 2005), and provide evidence for proto-continental crust and low temperatures at the surface of the Earth during the period 4.4–4.0 Ga.

4.57 to 4.45 Ga: the hot early earth

The most widely-cited age of the Earth is ca. 4.55 Ga as determined by Claire Patterson from lead isotopes in primitive meteorites and terrestrial sediments (Patterson, 1956). This is the age of condensation of solid material from the solar nebula (since revised to 4.56–4.57 Ga), and dates the origin of the material from which Earth began to accrete.

There are no recognized terrestrial samples from the first 150 Myr of Earth's history, thus constraints on surface conditions are inferred from isotopic data and the geologic history of the Moon. The currently accepted model of Moon formation calls for impact of the Earth with a planet-sized bolide, causing separation of the Moon from Earth's mantle (Canup and Righter, 2000). This model explains the orbit of the Moon and its geochemical similarity to Earth. The oldest Moon rocks have ages ca. 4.49 Ga, constraining the age of the catastrophic impact (Canup and Righter, 2000) and in agreement with W isotopes, which suggest formation of the Moon within 30 Myr of the Earth's accretion (Halliday, 2000).

Heat from meteorite impacts, residual heat from the Earth's accretion and core formation, and high heat production from radioactive elements likely made the surface unsuitable for the formation of oceans and continents during the beginning of Earth's history. For example, estimates of heat production from the early Earth's store of radioactive elements are on the order of 3–6 times that of today (Pollock, 1997). Conditions on the surface may have been extreme enough to form magma oceans until the waning of large impacts and the dissipation of heat into space (cf. Jones and Palme, 2000). Dissipation of heat could have resulted in rapid and turbulent mantle convection well into the Archean (Pollock, 1997). The last large terrestrial impact could have caused the resetting (and presumably planet-scale mixing) of xenon and other isotope systems at 4.45 ± 0.05 Ga (Zhang, 2002). It is possible that a slightly older impact formed the Moon. No terrestrial materials appear to have survived this last catastrophic event.

The cool early earth: evidence from 4.40 to 4.00 Ga detrital zircons

In the early 1980s newly developed ion microprobe technology was used to identify individual zircon crystals older than 4.0 Ga (Froude et al., 1983; Compston and Pidgeon, 1986). These crystals were eroded from their original host rocks, transported by water ca. 3 Ga, and are now found in metasedimentary rocks of the Narryer Gneiss Complex (Western Australia). The original ≥4.0 Ga igneous rocks are not known to have survived erosion and recycling. These Zircon crystals provide the only direct evidence for conditions at the surface of the Earth ≥4.0 Ga, as no other samples of solid material are known from this time period.

Recently, a crystal dated at 4.4 Ga was discovered (Wilde et al., 2001), providing a glimpse of conditions within 160 Myr of the Earth's accretion.

Zircons from Western Australia are evidence for 4.4–4.0 Ga rocks similar to modern continental crust. Mineral inclusions in the 4.4 Ga zircon include SiO_2 (Peck et al., 2001; Wilde et al., 2001; Cavosie et al., 2004), indicating crystallization from an evolved, silica-saturated magma. Similar conditions have been inferred for other Archean magmas based on inclusions from other 4.2–4.0 Ga zircons (Maas et al., 1992). Trace element compositions (including rare earth elements) of these zircons are also elevated relative to the mantle, consistent with crystallization from an evolved magma (Maas et al., 1992; Peck et al., 2001). All of these lines of evidence suggest the existence of igneous rocks similar to those of modern continental crust.

Isotopic analysis of these 4.4–4.0 Ga crystals has provided new constraints on surface conditions of the Earth (Peck et al., 2000, 2001; Mojzsis et al., 2001; Wilde et al., 2001; Cavosie et al., 2005). Oxygen isotope ratios ($^{18}\text{O}/^{16}\text{O}$) of these crystals are elevated relative to the primitive ratios of the Earth's mantle and the Moon (Valley, 2003). Elevated oxygen isotope ratios in terrestrial materials are most typically caused by low-temperature interaction between rocks and water at the surface of the Earth (i.e., hydrothermal alteration or low-temperature mineral formation). Magmas with elevated oxygen isotope ratios are formed by melting or assimilation of this material. The possible presence of liquid water calls into question some widely assumed conditions of the “hell-like” nature of the early Earth (Valley et al., 2002).

Emergence of continental crust

The first igneous rocks on Earth were most likely basaltic or komatiitic, with similarities to modern oceanic crust (e.g., Taylor, 1992). Lack of preservation of this crust may be due to melting and recycling back into the mantle. The timing and development of *continental* crust is a fundamental question as to surface conditions of the early Earth. The oldest recognized continental crust is 4.03 Ga granitic gneiss preserved in the Acasta Gneiss Complex, Northwest Territories, Canada. These strongly deformed rocks constitute $<20 \text{ km}^2$ of the 4.0–2.6 Ga Slave Craton. Other remnants of early (≥ 3.8 Ga) crust are limited to a few thousand square kilometers in the Uivak gneisses of Labrador, the Qianxi and Anshan Complexes in China, the Napier Complex of Antarctica, and the Isaq Gneiss Complex and Aasivik Terrane of southwestern Greenland (Figure A23). Sedimentary rocks ca. 3.5–3.0 Ga in age contain some of the oldest recognized terrestrial material: 4.4–3.2 Ga detrital zircons in the Narryer Gneiss Complex, detrital zircons as old as 4.0 Ga from the Wyoming Province, USA, and detrital zircons as old as 3.85 Ga from metasediments in the Qianxi complex (see Nutman et al., 2001). The Archean rock record is more complete for rocks ca. 3.5 Ga and younger.

The small amount of early Archean crust can either be interpreted as the surviving pieces of once extensive continental crust *or* as a reflection of the low rate of continental crust production in the early Archean. This dichotomy is reflected in different crustal growth models developed over the last 30 years: some propose rapid generation of Archean crust (most of which would be recycled), while others call for initially slow growth. Studies of middle Archean sediments support this latter view (e.g., Nutman et al., 2001), as recycled early Archean rocks constitute a minor component. This contrasts with geochemical signatures from the Acasta Gneiss, the Isaq

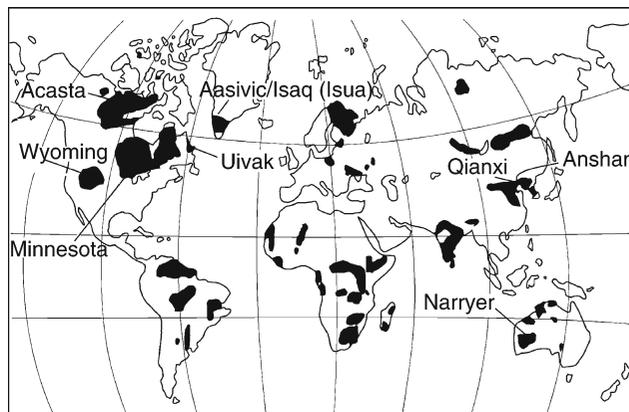

Figure A23 Preserved Archean crust (≥ 2.5 Ga), (after Bowring and Housh, 1995) and localities >3.8 , mentioned in text.

Gneiss Complex, and ≥ 4.0 Ga detrital zircons that show derivation from a mantle which had already produced crust earlier in its history (≥ 4.3 Ga; see Jacobsen, 2003 and references therein). Taken with the continental affinities of the Jack Hills detrital zircons, there is now ample evidence for continental crust between 4.4 and 4.0 Ga. Most of this original crust was eroded and/or recycled back into the mantle, perhaps aided by meteorite bombardment of the early Earth.

Timing of meteorite bombardment

Meteorite bombardment of the Earth during the period 4.4–3.8 Ga is known from the cratering record of other bodies in the inner solar system, but the terrestrial record has been erased by plate tectonics and erosion. On the Moon (where impact events have been dated) the time-integrated flux of impacts is estimated through crater density, addition of material to lunar crust, and the extent of impact stirring (Arrhenius and Lepland, 2000; Hartmann et al., 2000).

The terrestrial meteorite flux over time is controversial and has not been uniquely determined. Presumably meteorite bombardment would have been at its peak early in the Solar System's history, during and preceding extraction of the moon at ca. 4.5 Ga. The waning of impacts is not well constrained, although many lunar samples of impact glass yield a grouping of ~ 3.9 Ga ages called the “late heavy bombardment” (e.g., Cohen et al., 2000). If the rate of impacts has decreased steadily through time, then the high rate of impacting at 3.9 Ga suggests even more impacts earlier.

However, recent dating of lunar impact glasses supports an alternate hypothesis: that the cluster of 3.9 Ga ages represents a renewal of impact intensity caused by deflection of materials from the outer Solar System (Cohen et al., 2000). If the Earth was subjected to a spike of meteorite bombardment ca. 3.9 Ga, then the 4.4–4.0 Ga interval might have been relatively tranquil, consistent with cooler surface temperatures inferred from zircons crystallized during this period (see Valley et al., 2002).

The terrestrial record of bombardment is equivocal. There are no reported descriptions of shock features in 4.4–3.8 Ga zircons or rocks, as would be expected if they had been involved in large impacts. Metasedimentary rocks from southwestern Greenland (3.8–3.7 Ga) do not contain impact-related sedimentary structures (i.e., surge deposits, see Arrhenius and Lepland, 2000), nor has measurable extraterrestrial iridium

been found. However, evidence has been presented for an elevated extraterrestrial tungsten isotope signature in Isua metasediments of Greenland (Schoenberg et al., 2002), similar to evidence for extraterrestrial chromium isotopes associated with ~3.2 Ga South African beds of impact glass (Kyte et al., 2003).

The timing of the early bombardment of Earth is poorly constrained and limited by the rocks available for study. However, indirect geologic and geochemical evidence for liquid water during this period argues for at least transient periods of quiescence during bombardment. It is possible that tranquil periods allowed the precipitation of oceans between ~4.4 (the first evidence for continental crust) and 3.9 Ga (the late heavy bombardment).

Oceans

A critical parameter for evaluating surface conditions on Earth is whether or not liquid water is a stable phase, a function of both temperature and vapor pressure of the atmosphere. Supracrustal rocks in the Itsaq Gneiss Complex (the Isua and Akilia Island localities) are the earliest known rocks deposited in water: 3.8–3.7 Ga pillow lavas and chemical sediments (Myers and Crowley, 2000). The age and ultimate origin of rocks of the Akilia Island locality are controversial, but the Isua lithologies are widely accepted as having formed under submarine conditions (below wave base according to Fedo et al., 2001). The next oldest unequivocal evidence for submarine deposition, although indirect, is the abundance of metasediments ≤ 3.5 Ga worldwide. Volcanogenic massive sulfide deposits are also common in rocks ≤ 3.4 Ga and could have formed at a variety of ocean depths (including deep water $>1,000$ m; Rasmussen, 2000).

There are critical gaps in the rock record from ≥ 3.8 Ga and between 3.7 and 3.5 Ga, a period during which life is believed to have originated. A proxy for the presence of water is the geochemical signature of water-rock interaction associated with Archean detrital zircons (Peck et al., 2001; Mojzsis et al., 2001; Wilde et al., 2001; Valley et al., 2002; Cavosie et al., 2005). The elevated oxygen isotope ratios in these 4.4–4.0 Ga zircons are consistent with low-temperature exchange between rocks and water. On the modern seafloor, hydrothermal alteration \leq ca. 250 °C produces similar oxygen isotope ratios, but there is more uncertainty as to the conditions of water-rock interaction during the Archean. Lower temperature estimates are plausible if: (a) oxygen isotope ratios of the oceans have slowly risen over time (e.g., Perry, 1967), (b) meteoric waters instead of seawater were involved in Archean water-rock interaction, or (c) hydrothermal alteration was less efficient than today (Valley et al., 2002). Steam and liquid water could have coexisted at temperatures ≤ 250 °C, especially given the likelihood of periodic meteorite impacts. However, steam alone is an inefficient mechanism for exchange between water and rocks and a steam atmosphere the size of modern oceans would require temperatures outside of the oxygen isotope constraints from the detrital zircons (Valley et al., 2002).

The oxygen isotope record from zircons records the compositions of magmas from 4.4 Ga to the present (Figure A24). This record includes 4.4–4.0 and 3.6–3.2 Ga detrital zircons, and zircons in igneous rocks from ≤ 3.6 Ga. The Archean zircons came from igneous rocks that had oxygen isotope ratios ranging from mantle-like to elevated values, similar to Phanerozoic rocks but with a more limited spread (Valley, 2003). These similarities would not be expected if older rocks had formed in the absence of water and only younger ones had interacted with water (see also Campbell and Taylor, 1983).

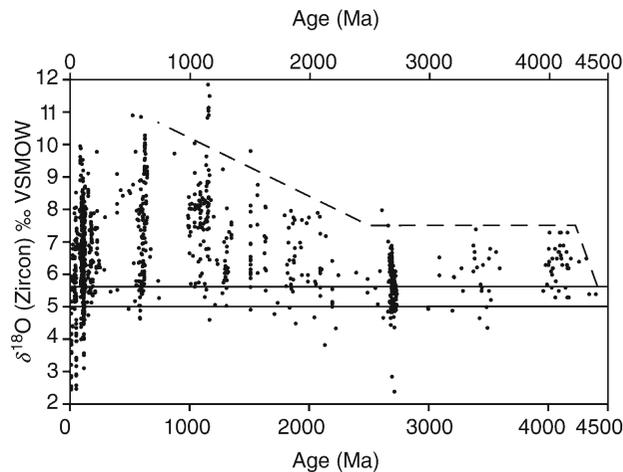

Figure A24 Oxygen isotope ratio of zircon through time (after Valley et al., 2005). Oxygen isotope ratios $\geq 6\%$ are indicative of interaction between liquid water and rocks at the surface of the Earth. Note that the signature of a liquid hydrosphere extends to samples as old as 4.4 Ga.

The constancy of isotope ratios suggests that surface temperatures from 4.4 to 4.0 Ga were similar to those of the later Archean. The increase in values starting at the Archean-Proterozoic boundary marks an increased involvement of mature supracrustal rocks (with a water-rock interaction signature) in the genesis of igneous rocks, but it is not certain if this indicates increased rates of recycling or more highly evolved compositions (Peck et al., 2000).

The temperature of Archean oceans has been controversial because 3.8–2.5 Ga chemical sediments have low oxygen isotope ratios compared to younger rocks (see Perry, 1967; Perry and Lefticaru, 2003). This has been taken to indicate any (and all combinations) of the following factors: (a) Archean ocean water temperatures of up to 80 °C, (b) lower oxygen isotope ratios of Archean ocean water, and (c) later alteration of original isotope ratios in ancient samples. The oxygen isotope ratio of the ocean seems to have been buffered at or near present levels since at least 3.6 Ga, as predicted by models and observed in hydrothermally altered rocks (see Muehlenbachs, 1998). In addition, careful sampling in ~3.5 Ga rocks has constrained the influence of post-depositional alteration. Although the oxygen isotope ratio of the ocean has certainly fluctuated within a relatively small range and some chemical sediments may have been altered, the overall evidence points towards ocean temperatures up to ca. 40 °C higher than those today as late as ~3.5 Ga (Knauth and Lowe, 2003; Perry and Lefticaru, 2003).

What was the thermal history of the hydrosphere during the Archean? During the period of accretion and heaviest bombardment of the Earth (≥ 4.5 Ga) all water must have been vapor or dissolved in silicate melts. Oxygen isotope evidence from 4.2 to 4.0 Ga zircons indicates a liquid or liquid-steam hydrosphere ≤ 250 °C. This is consistent with predictions of rapid cooling of the surface of the Earth (1–10 Myr) shortly after accretion and during waning bombardment (Pollack, 1997; Zahnle et al., 1988; Sleep et al., 2001). Late heavy bombardment of Earth at ~3.9 Ga could have vaporized Earth's oceans, but beginning at 3.6–3.8 Ga there is good geological evidence for a stable hydrosphere. It has been suggested that in order for oceans to remain liquid rather than freezing, the lower luminosity of the Sun during the Archean may have been offset by high levels

of greenhouse gases (Sagan and Chyba, 1997), or that oceans may have been partially covered by ice and warmed by submarine volcanism and periodic impacts (Bada et al., 1994).

Evidence and controversy for early life

The need to understand the timing of and conditions for the origin of life is one of the principle motivations for assessing the early Archean environment. The primary requirements for evolution of life are organic molecules, a source of energy, and liquid water. Organic molecules could have been delivered to Earth by carbonaceous meteorites and comets, and energy was available from the Sun and terrestrial volcanism. The precipitation of liquid water from an early steam-rich atmosphere was thus the final ingredient for an environment where life could have evolved during the period 4.4–4.0 Ga, perhaps to be extinguished by large bolide impacts or during the late heavy bombardment at 3.9 Ga. Theoretical limits of the habitability of the early Earth are thoroughly discussed elsewhere (see Nisbet and Sleep, 2001), but here we focus on evidence for early life from the rock record.

The earliest evidence for life is a distinctive carbon isotope signature from metamorphosed sedimentary rocks of southwestern Greenland. Low carbon isotope ratios ($^{13}\text{C}/^{12}\text{C}$) in reduced sedimentary carbon are commonly the result of isotope fractionation by biological pathways, and thus are taken as a “fingerprint” of ancient life even in the absence of preserved fossils (Schidlowski, 2001). While some studies have been controversial, the best evidence for early life comes from southwest Greenland: low carbon isotope ratios of graphite particles in clastic sedimentary rocks from 3.8 to 3.7 Ga rocks at Isua (Rosing, 1999). These rocks are preserved in low-strain zones, were clearly waterlain, and the graphite may represent original organic detritus.

The earliest fossil evidence for life are ~ 3.5 Ga microscopic structures in the Apex chert of Australia as well as numerous occurrences of stromatolites (mounds produced by photosynthetic microbes). These microstructures are interpreted as being the remains of various Archean microbes (Schopf, 1993). This claim of diversity of life has been challenged by Brasier et al. (2002), based on morphology of the features as well as a hydrothermal origin of the host-rock. However, the kero-gen-like Raman spectra and low carbon isotope ratios are strong evidence of biologic activity (Schopf et al., 2002). Furthermore, abundant stromatolites are found in associated rocks. The association of microfossils with seafloor hydrothermal systems has been recognized in rocks as old as 3.5 Ga (Van Kranendonk, 2001), supporting the hypothesis that life originally evolved near submarine vents or springs in early Archean oceans (e.g., Nisbet and Sleep, 2001).

ARCTIC SEA ICE

Introduction

Sea ice occupies a large part of the world ocean (about 7%) and covers most of the Arctic Ocean (Figure A25), where it averages about three meters in thickness. Sea ice undergoes very large seasonal variations in its areal extent in response to changes in solar insolation. In circumpolar regions of the Northern Hemisphere, its coverage rises from approximately 7 to 15 million km² from summer to winter (see Figure A26). Sea ice is an extremely important component of the climate

system because its reflectivity plays a role in the energy budget at the Earth's surface and because it forms a barrier between the atmosphere and the ocean, thus reducing the exchange of heat, moisture and gases. Moreover, a portion of the Arctic sea ice is exported to the North Atlantic Ocean, where it becomes a source of freshwater that can interfere with deep water formation and thus with the thermohaline circulation pattern. Recent data on Arctic sea ice derived from direct observations and satellite imagery indicate large interannual variations and suggest a decreasing trend in both area and thickness during the last decades of the twentieth century. Longer-term data on a time scale ranging from 10² to 10⁶ years available from historical archives and from deep-sea sedimentary records reveal large fluctuations in the average extent of sea ice during the Quaternary, from more reduced to much more extended covers than at present, generally as a result of hemispheric-scale climate changes. For example, historical information indicates that sea ice expanded in the subpolar North Atlantic from the Medieval Warm Period to the Little Ice Age. At another time scale, biological and sedimentary tracers of sea ice demonstrate that it was significantly more widespread than at present in both the North Atlantic and North Pacific during the Last Glacial Maximum, whereas the middle Holocene warm episode seems to have been marked by reduced sea ice cover in the Arctic Ocean and circumpolar seas. The age of initial formation of the sea ice cover in the Northern Hemisphere during the late Cenozoic remains an open question, but the development of quasi-permanent pack ice in the Arctic Ocean probably occurred during the late Miocene.

Sea ice formation

Sea ice is a general term that comprises several types of ice originating from the freezing of marine waters, which occurs at a water temperature of about -1.8°C , depending upon salt content. The term “sea ice” excludes icebergs, which are massive pieces of floating freshwater ice that were calved from the front of continental glaciers. The freezing process of marine water differs from that of freshwater because it involves downward migration of brines resulting from the segregation of sea salts and ice crystals composed of almost pure water. It is a relatively complex process from a thermodynamic viewpoint since ice crystal formation induces an increase in the salt content of the surrounding seawater, thus increasing the density and decreasing the freezing point of this water.

Sea ice formation is a consequence of the cooling of marine water in response to low air temperatures. It also depends upon the structure of the water masses, since the vertical density gradient actually determines the depth of the mixed surface layer, which must cool before the surface can reach the freezing point (e.g., Barry et al., 1993). A shallow stratification in the upper water column and the presence of a low-salinity (thus, density) surface water layer are important parameters for the formation of sea ice. In the Arctic Ocean, a mixed layer with salinities often below 30‰ at the surface, overlies a generally warmer and more saline (>34.5‰) water layer originating from the Atlantic. The low salinity of the mixed layer in the Arctic Ocean results from freshwater inputs, notably from Eurasian rivers (Yenessei, Ob, Lena, Kolyma; $\sim 1,700 \text{ km}^3 \text{ yr}^{-1}$) and the Mackenzie River ($\sim 260 \text{ km}^3 \text{ yr}^{-1}$) (Carmack, 1998).

In the Arctic Ocean, a large part of the sea ice formation occurs over shallow continental shelves surrounding the basin (Figure A25), notably in the Siberian and Laptev Seas, where the shelf is particularly wide and sea surface salinity is

Figure A25 Map of the Arctic Ocean and adjacent subpolar seas. The bathymetry is indicated by 200 and 1000 meter isolines. The Arctic Ocean represents an area of approximately 9.5×10^6 km². About one third consists of shallow shelves that are roughly delimited by the 200-m isobath. A large part of sea ice formation takes place on the shelves, notably in the East Siberian and Laptev Seas.

relatively low because of large freshwater discharges from Eurasian rivers. South of the Arctic Circle, in subarctic seas and even in some mid-latitude epicontinental seas such as the Gulf of St. Lawrence in Eastern Canada, sea ice also develops seasonally at the result of a low saline, shallow (30–50 m depth) mixed layer, which fosters low thermal inertia and rapid cooling in winter.

New ice versus multiyear pack ice

When surface water reaches the freezing point, it first forms frazil ice (floating needle-shaped ice crystals) that is transformed gradually into grease ice (a slushy mixture of seawater and frazil ice) and then into floating ice. Floating ice may consist of small, circular meter-large pieces called pancake ice. It may also develop into more or less continuous fields known as pack ice, which can form a meter-thick layer of frozen ice solidly.

Sea ice develops annually, during winter. A large part of it melts during summer, but a large portion remains frozen. Sea ice that survives at least one melt season is called multiyear ice, and is distinguished from the new ice (annual sea ice and first year ice). Multiyear pack ice is typically 3–5 m thick, whereas annual ice rarely exceeds 2 m in thickness.

In general, the minimum extent of marine ice within the annual cycle corresponds to the multiyear pack ice distribution, and occurs in September. Annual ice that develops in winter

leads to a maximum coverage of about 15.0×10^6 km² in March (Figure A26), when sea ice extends southward along the East Coast of Canada and Eurasia.

The Arctic ice cap, summer pack ice, and ice motion

In the central Arctic Ocean, about 6 million km² are occupied by multiyear pack ice that remains frozen all year long. This massive Arctic pack ice is also known as the Arctic or polar ice cap and slowly rotates as a unit. Surrounding the polar ice cap, broken pieces of multiyear ice are separated by leads, which are linear fields of open water or thin ice. These pieces of multiyear ice form the summer pack ice, which never completely melts. In the Northern Hemisphere in summer, multiyear sea ice, including both the Arctic pack ice and the summer pack ice, covers a surface area of approximately 7.5×10^6 km² (see Figure A26).

A large part of the multiyear pack ice in the central Arctic originates from sea ice production over the Eurasian Shelf; from there it spreads northward toward the central Arctic Ocean to contribute to the multiyear pack ice. Depending upon the winds and surface currents, sea ice is in constant motion within the Arctic basin, and is eventually exported into the North Atlantic. The two main paths for pack ice drift are: (a) the Beaufort Gyre, which is a clockwise movement centered in the Canadian Basin, and (b) the Trans Polar Drift, which deflects ice away from the Siberian coasts across the Arctic

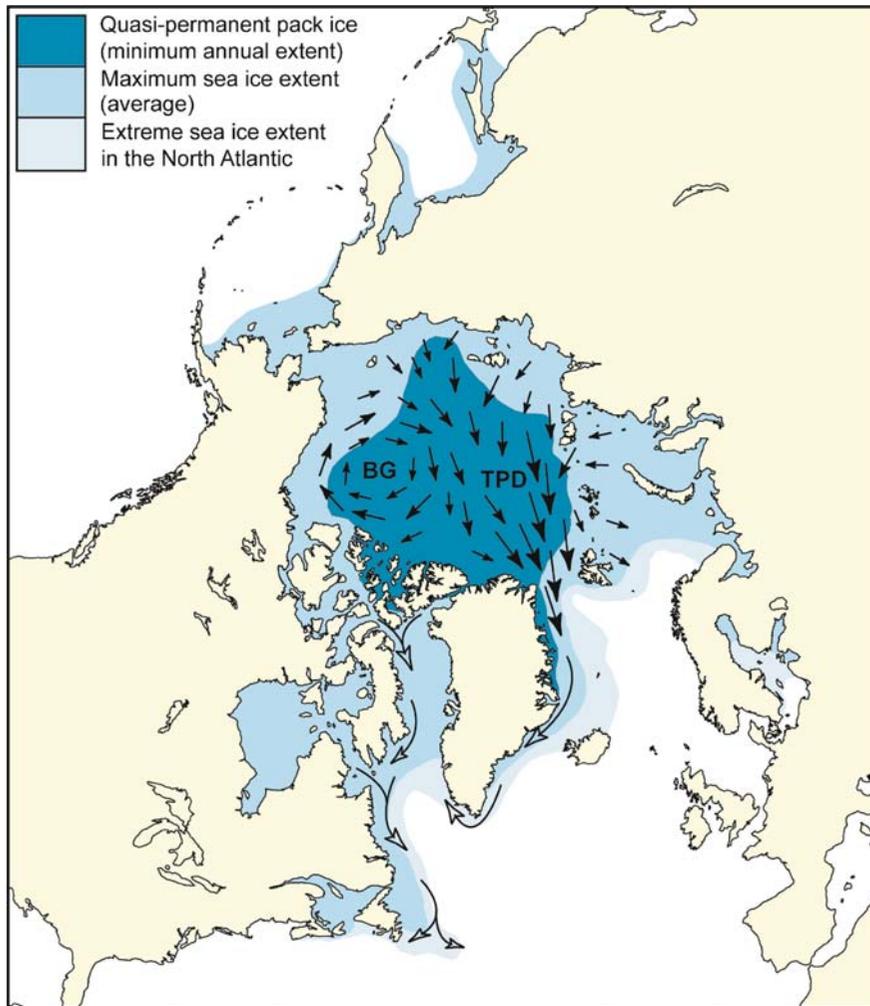

Figure A26 Map of maximum (March) and minimum (September) sea ice extent over the Northern Hemisphere. The main paths of sea ice drift, the Beaufort Gyre (*BG*) and the Trans Polar Drift (*TPD*) are schematically shown by *black arrows*. The main surface currents carrying Arctic sea ice melt waters toward the North Atlantic are illustrated by *open-end arrows*.

and toward the Atlantic Ocean (see Figure A26). The ice drift velocity ranges generally from 1 to 10 cm s^{-1} , with lower values in the Beaufort Gyre and higher values at the outlet of the Trans Polar Drift in Fram Strait. The times required for ice to make a revolution in the Beaufort Gyre and to traverse the Trans Polar Drift have been estimated to be 5–10 years, and about 3 years, respectively (e.g., Barry et al., 1993).

Biogenic productivity associated with sea ice and polynyas

Sea ice itself is a habitat for a specific food web that includes bacteria, viruses, and unicellular algae (notably diatoms) that form filaments and colonies as well as small invertebrates circulating within the brine network. The biomass in the pack ice, however, is very sparse, and the planktonic productivity below the permanent Arctic ice cap is extremely low because of much-reduced light penetration restricting photosynthetic activity and thus primary production. Higher production occurs along ice-marginal zones, which include mostly the annual sea ice that melts seasonally and also the summer ice pack. Many

unicellular algae species live within or beneath sea ice and reach a very high productivity in the ice-marginal zones. Other unicellular organisms adapted to complete their life cycle during a short ice-free season also appear to have high productivity in the ice-marginal zones, which can sustain large populations of zooplankton and animals.

Within the ice-marginal zones, areas of open water surrounded by sea ice, called polynyas, are maintained free of ice for at least several months a year through several processes, including currents, upwelling and winds. Polynyas are often characterized by a huge biological production, with fishes, mammals (seals, whales, polar bears, etc.) and birds. In the Arctic, there are several polynyas ranging from several km^2 to 50,000 km^2 .

The importance of Arctic sea ice in the climate and ocean systems

Sea ice and air temperature

Sea ice is a major component of the climate system, especially because of its high albedo or reflectance (up to about 80%), which reduces the fraction of incoming solar radiations

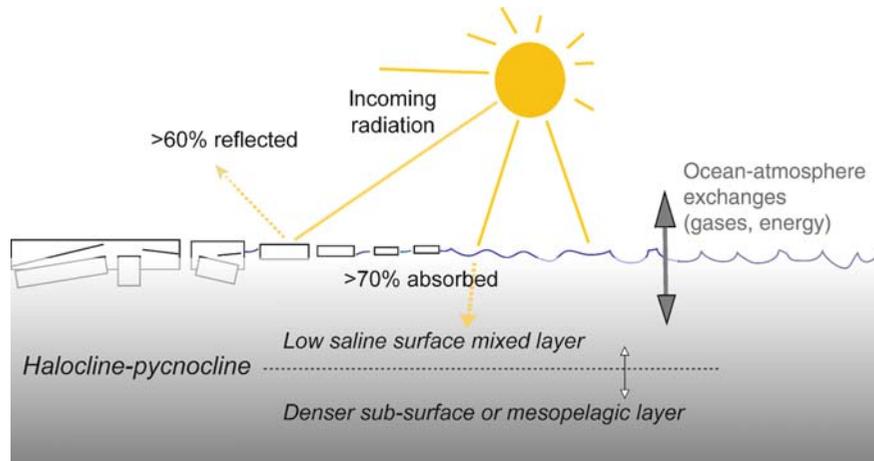

Figure A27 Schematic illustration of the role of sea ice in the climate system.

absorbed at the ocean's surface (Figure A27). The presence of sea ice therefore has an intrinsic cooling effect and its large coverage in high latitudes of both hemispheres modulates the energy budget at the Earth's surface.

Sea ice also plays a role in climate since it constitutes a barrier that restricts the heat and gas exchanges between the ocean and the atmosphere. As a consequence of sea ice, heat gain in the ocean during summer is suppressed, and heat release from the ocean to the atmosphere is also suppressed, thus further contributing to the cooling of the air during winter. In the last few decades, instrumental measurements in the Arctic indeed show an inverse correlation between sea ice cover and surface temperatures, with a spatial scope in temperature anomalies usually extending beyond sea ice boundaries (Comiso, 2002).

Beyond its cooling feedback effect, sea ice no doubt plays a role in large-scale climate conditions and atmospheric circulation pattern since it determines the surface pressure gradients.

Sea ice and thermohaline characteristics of marine waters

Freeze and thaw processes accompanying the development of seasonal sea ice determine the sea surface salinity, and therefore play a determinant role in the density and stratification of water masses. When freezing, at the bottom of the newly formed ice, seawater releases salt and brines, which sink and increase the density of underlying waters. Sea ice itself consists of almost fresh water and has a salinity ranging from 0 to 6‰. Arctic sea ice therefore is a low saline water reservoir, corresponding to a mean freshwater volume of about 17,300 km³ (Carmack, 2000). Annual sea ice melting in summer results in a low-saline buoyant surface water layer overlying a much denser water mass. As a consequence, the occurrence of seasonal sea ice is generally accompanied by the development of a strong stratification of water masses with a sharp gradient of salinity and density between a shallow surface or mixed layer and the sub-surface layer (or mesopelagic) layer.

Arctic sea ice and thermohaline circulation

A significant portion of Arctic sea ice drifts to be exported southward into the North Atlantic Ocean. The main routes for southward sea ice drift are determined by surface ocean

currents and follow the Trans Polar Drift and the eastern continental margins of Greenland and eastern Canada (Figure A26). The amount of fresh water exported from the Arctic Ocean to the North Atlantic Ocean as a result of melting of annual or summer multiyear sea ice is considerable, with a volume of approximately 3,500 and 900 km³ per year through Fram Strait and the Canadian Arctic Archipelago, respectively (Aagaard and Carmack, 1989). As a consequence, freshwater fluxes from the Arctic sea ice reservoir may play a significant role in the density of surface water in the northern North Atlantic Ocean, and thus in stratification in its water column. Because the main centers of convection and deep water formation in the North Atlantic Ocean are located in the Greenland and Labrador seas, the routes and intensity of Arctic sea ice export might prove to be critical parameters for determining the strength and pattern of the North Atlantic thermohaline circulation (e.g., Haak et al., 2003).

The instrumental record of Arctic sea ice variations

Instrumental data on Arctic sea ice have existed only for a few decades. From the nineteenth century to the middle part of the twentieth century, climatological archives and shipboard observations provide some indications on sea ice cover. After about 1953, an increasing volume of ship data, coupled with aircraft observations permitted the development of regional charts of sea ice extent and concentration. These charts combined with satellite observations starting in 1972, were used to produce comprehensive records of sea ice in the Northern Hemisphere for the last century on multidecadal time scales.

The composite instrumental record established by Walsh and Chapman (2000) suggests approximately constant year-to-year sea ice conditions during the first half of the twentieth century. It also indicates a decrease in the summer minimum sea ice cover extent starting from the mid-century, whereas winter sea ice remained unchanged until the 1970s, when the winter maximum extent started to diminish. According to Walsh and Chapman (2001), the observed decrease in both multiyear and annual sea ice covers recorded accounts for about 10% of the total coverage recorded by the beginning of the twentieth century. Other estimates also suggest that the decline in Arctic sea ice has been particularly significant during the last two decades of the twentieth century, with regard to both its extent (up to

14% according to Johannessen et al., 1999) and its thickness (up to 1–2 m locally; Rothrock et al., 2000).

Recent changes in the coverage of Arctic sea ice seem to be beyond dispute. However, the actual rate of decline in sea ice cover is difficult to evaluate quantitatively because of interannual-to-interdecadal variations (e.g., Mysak and Power, 1992; Yi et al., 1999; Comiso, 2002; Moritz et al., 2002) that obscure the longer-term trend. Moreover, the changes in ice cover extent have not been spatially uniform through space from one region to another. According to recent compilations, the largest decrease in sea ice cover has been recorded in the Western Arctic, notably in the Chukchi and East Siberian Seas (Comiso, 2002), whereas sea ice cover seems to be more extensive in the western Labrador Sea (Hill, 1998).

The linkages between Arctic sea ice and climate oscillations

Recent studies based on modeling or observations tend to illustrate linkages between high-frequency variations in Arctic sea ice and the dominant Northern Hemisphere climate oscillations, known as the Arctic (AO) and North Atlantic (NAO) oscillations (Thompson and Wallace, 1998; Greatbatch, 2000). These linkages are particularly apparent because the positive AO and NAO patterns correlate together, especially in winter (Rogers and McHugh, 2002), and correspond to intensified storm tracks through the Nordic seas, enhanced latitudinal and moisture heat fluxes toward high latitudes, and thus higher surface temperatures and a lesser extent of sea ice in the Eurasian Arctic (Dickson et al., 2000; Moritz et al., 2002). The positive AO-NAO situation also appears to be associated with an enhanced Trans Polar Drift resulting in a higher rate of Arctic sea ice export through Fram Strait toward the North Atlantic (Dickson et al., 2000; Moritz et al., 2002). Based on the record of the last 20 years of the twentieth century, the AO is considered to account to a large extent for the recent warming of the Eurasian Arctic together with a cooling over Labrador (Moritz et al., 2002).

In addition to linkages with AO-NAO, a coupling of sea ice with the thermohaline circulation in the North Atlantic may be cited. For example, particularly large freshwater outflow from the Arctic through Fram Strait in the 1960s was the source of a “great salinity anomaly” in the northern North Atlantic that apparently caused disruption of North Atlantic deep water formation through the early 1980s (Dickson et al., 1988).

The historical record of Arctic sea ice

Past records of sea ice extent in the northwestern North Atlantic are available from the accounts of voyages by Irish

monk-explorers in remote waters and Vikings who established settlements in Iceland and in southwest Greenland before the end of the first millennium (Lamb, 1977). Until AD 1200, sea ice was only occasionally reported to have caused difficulty in sailing, and all historical data suggest minimum sea ice extent around Iceland and off Greenland during the medieval warm episode, which was characterized by conditions favorable for navigation across the North Atlantic and the development of remote human settlements. Navigation reports and other historical archives show that the spread of seasonal sea ice became more and more extensive in the northern North Atlantic after AD 1250 (Figure A28). During the decade from AD 1340 to 1350, the increasing spread of Arctic sea ice around Greenland even led to the abandonment of the old sailing routes along the 65° N parallel, which caused the decline of the Viking settlements in southern Greenland.

Sedimentary tracers of sea ice changes

Remains related directly or indirectly to sea ice are found in marine sediments, permitting the reconstruction of past variations in the extent of sea ice cover or drift patterns.

Some of the proxies for sea ice are directly related to sedimentary processes. These include grain size. The coarse material (coarse silt and fine sand fractions) can be incorporated into sea ice during formation on the shelf, and thus provide indirect evidence for sea ice presence (e.g., Pfirman et al., 1990). The coarse material is entrained and transported by sea ice before it is released through melting at the sea ice margin (e.g., Hebbeln and Wefer, 1991). They also include mineralogical or geochemical analyses that permit the identification of source rocks for the detrital particles incorporated into the ice on the shallow shelves, thus allowing interpretations in terms of ice drift patterns (e.g., Bischof and Darby, 1997; Darby, 2003).

Most other sea ice proxies currently used in paleoceanography are related to biological activity, especially planktonic production in the photic zone, which is severely constrained by sea ice. Sea ice is indeed a determinant component of the ecosystem inasmuch as it influences light penetration and photosynthesis. Thus, close relationships exist between the sea ice cover and the phytoplanktonic populations. Sediments accumulated below the permanent multiyear pack ice are often devoid of biological remains whereas the sediments accumulated below the ice-marginal zone may contain abundant microfossils.

Amongst the microfossils used as sea ice proxy, diatoms are most useful because they include species specific to the ice-marginal zone. Many studies conducted in the Arctic and subarctic use diatom assemblages, which led to qualitative reconstruction of changes in sea ice cover extent during the late

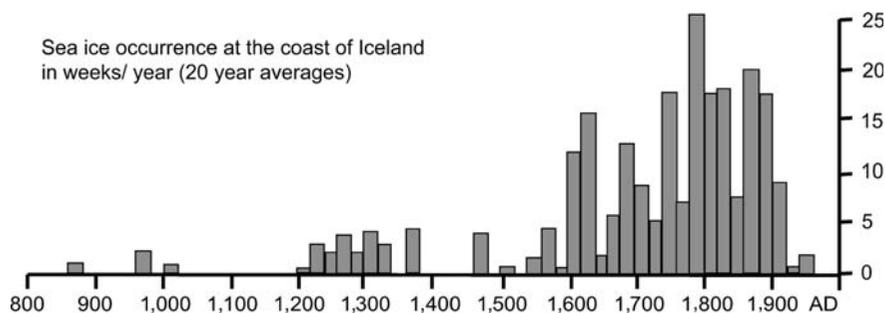

Figure A28 Historical record of sea ice occurrence around Iceland (modified from Lamb, 1977).

Quaternary in the northernmost Pacific (e.g., Sancetta, 1981, 1983), the Nordic seas (Koç et al., 1993), and the Russian Arctic seas (e.g., Bauch and Polyakova, 2000). However, because diatoms are composed of opal, which is susceptible to dissolution in marine waters unsaturated in dissolved silica, their preservation in sediment is often very poor. Other proxies of sea ice include the cysts of dinoflagellates, which yield relatively diversified and abundant organic-walled microfossils in the sea ice-marginal zone. The distribution of dinoflagellate cysts appears to depend upon the duration of the ice-free season during which the life cycle, including sexual reproduction and cyst formation, must be completed. It permitted the development of transfer functions for the quantitative reconstruction of changes in sea ice cover as expressed in number of months per year with sea ice cover (e.g., de Vernal and Hillaire-Marcel, 2000). In addition to diatoms and dinoflagellate cysts, the occurrence of a number of biological indicators, including coccoliths and foraminifera, can be used as proxies for sea ice-free conditions, at least seasonally. Biomarkers such as alkenones are also occasionally used as indicators for ice-free conditions since they rely on biogenic production of coccoliths.

Another indicator of past sea ice can be found in the continental ice cores, which may contain marine brine compounds as a result of sea ice free conditions. For example, sea salt variations in ice cores from Devon Island and Greenland have been interpreted as indices of sea ice cover changes in the adjacent marine environment (e.g., Mayewski and White, 2002).

The late Quaternary record of Arctic sea ice changes

Based on the above-mentioned proxies, there are time series that report sea ice cover variations, qualitatively (presence or absence) or quantitatively (e.g., in number of months per year; Figure A29). However, these time series have a regional value, and only very few data sets are available to develop scientifically reliable scenarios of Arctic sea ice cover during the geological past.

The interval that has been the most studied from this point of view is the Last Glacial Maximum, dated around 21,000 yBP. Maps of sea ice extent were developed at the scales of the World Ocean (CLIMAP, 1981), the circum-Antarctic oceans (Crosta et al., 1998), and the North Atlantic (de Vernal et al., 2000). These reconstructions of the LGM sea ice cover indicate that it was much more extensive than at present, in both the southern and northern hemispheres (see Figure A30). Climate modeling experiments of the LGM tend to demonstrate that such an extensive sea ice cover played a role as an important mechanism or feedback loop in the cooling recorded globally during the ice ages (e.g., Gildor and Tziperman, 2000; Hewitt et al., 2001).

Another interval in the recent geological past that has received much attention with respect to Arctic sea ice is the thermal optimum of the early- and mid-Holocene. Regional data sets illustrate reduced extent of sea ice cover as compared to present in the Nordic seas notably (Figure A31; Koç et al., 1993). In the case of the early Holocene, climate modeling also suggests that reduced sea ice may have played an amplifier role in the Northern Hemisphere warming due to high insolation (Smith et al., 2003).

The Cenozoic development of Arctic sea ice

The timing and processes at the origin of the sea ice cover in the Arctic Ocean are not accurately known or perfectly

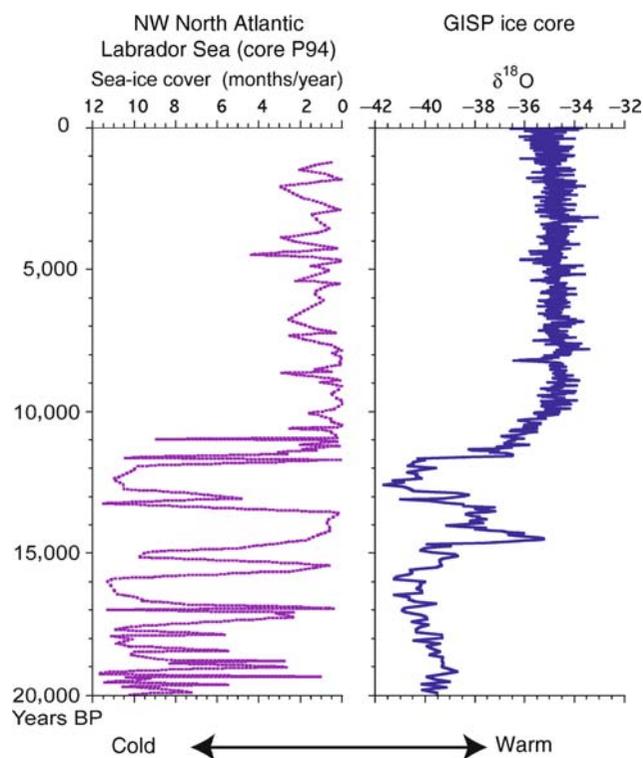

Figure A29 Example of reconstructed sea ice cover records for the last 20 kyr. The sea ice estimates (left) from a core collected in the Labrador Sea are based on dinocyst assemblages (de Vernal et al. 2000). They are compared to the GISP 2 isotopic record (right; cf. Grootes and Stuiver, 1997) on Greenland, which provides an independent record of climate.

understood. Nevertheless, the overall geological record suggests that pack ice developed during the mid-Cenozoic, after the Arctic Ocean had reached its polar, isolated position, and a bipolar glacial mode was established in the climate system (e.g., Clark, 1982; Bleil and Thiede, 1990).

During the Cretaceous and Paleocene, temperate conditions prevailed in the Arctic regions, where an ice-free ocean no doubt played a determinant role in poleward heat fluxes and the relatively uniform climates from low to high latitudes. The Arctic Ocean ice cover probably developed during the mid-Cenozoic, concomitantly with the general decrease in ocean temperatures, which is recorded worldwide on the basis of isotopic or micropaleontological data. In the Arctic Ocean, sea ice formation was likely fostered by salinity stratification due to freshwater river flows from the Eurasian continent combined with the isolation of the western Arctic from the Pacific, thus restricting exchange with oceanic waters (e.g., Clark, 1982).

The oldest sedimentary or micropaleontological indications of Arctic pack ice are Miocene in age. The development of a permanent ice cover over the Arctic Ocean may possibly date from the Late Miocene, but open ocean conditions have prevailed episodically during the Pliocene and Pleistocene according to microfossil data from Arctic cores (e.g., Clark, 1990).

In addition to sea ice cover in its strict sense, a floating ice sheet of about 1 km in thickness may have covered vast areas

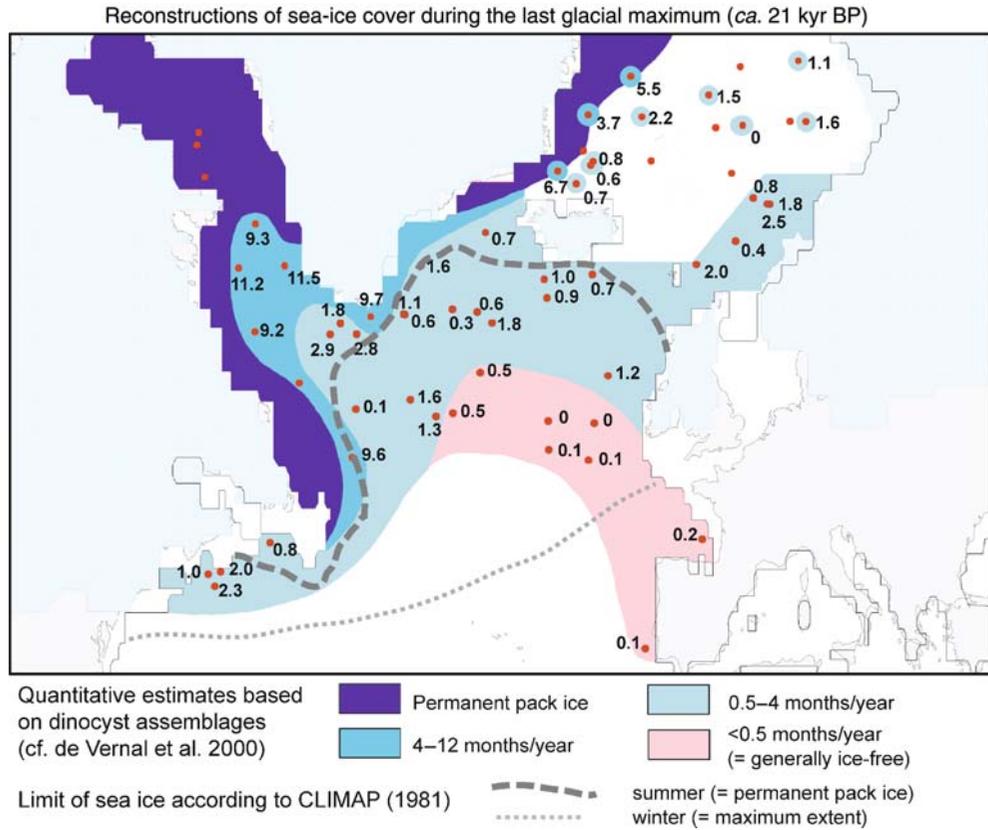

Figure A30 Map showing the reconstructed extent of sea ice cover in the northern North Atlantic during the Last Glacial Maximum. The CLIMAP estimates for the limits of sea ice are qualitatively based on indirect evidence, notably the occurrence of coccoliths and foraminifers. The quantitative estimates of sea ice occurrence in number of months per year by de Vernal et al. (2000) rely on the best analogue transfer function technique applied to dinoflagellate cyst assemblages.

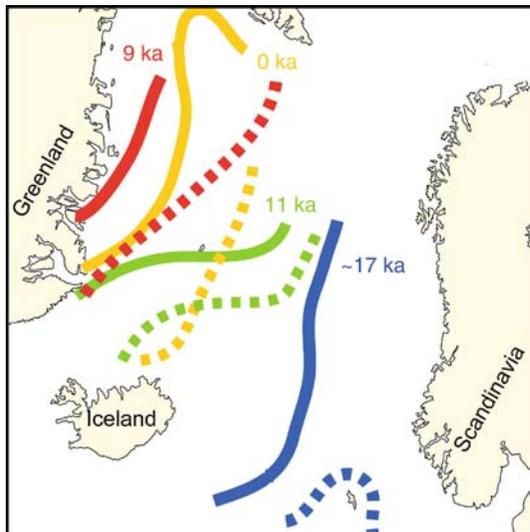

Figure A31 Map showing the variations of the sea ice limits in the Nordic seas since the Last Glacial Maximum based on diatom assemblages (Koç et al. 1993). The *full lines* represent the limit of the pack ice, whereas the *dashed lines* represent the position of the Arctic Front, which corresponds to extreme limit of the annual sea ice. The time intervals are expressed in thousand of calendar years (ka) before present.

of the Arctic Ocean during the early or mid-Pleistocene, as indicated by submarine imagery of the bottom topography showing iceberg scouring (Polyak et al., 2001).

ARID CLIMATES AND INDICATORS

The nature of aridity

Arid lands cover about a third of the Earth's land surface and occur in every continent including Antarctica (Goudie, 2002). They are areas where there is a severe shortage of moisture, predominantly because precipitation levels are low. In some years they may even receive no rain at all. In some deserts, aridity is in part also the result of high temperatures, which means that evaporation rates are great (Manguet, 1999).

Definitions of aridity relate to the water balance concept. This is a relationship that exists between the input of water in precipitation (P), the losses arising from evaporation and transpiration (evapotranspiration) (E), and any changes that may occur in storage (soil moisture, groundwater, etc.). In arid regions there is an overall deficit in water balance over a year, and the size of that deficit determines the degree of aridity. The actual amount of evapotranspiration (AE) that occurs varies according to whether there is available water to evaporate;

climatologists have therefore devised the concept of potential evapotranspiration (PE_i). This is a measure of the evapotranspiration that would take place from a standardized surface never short of water. The volume of PE_i will vary according to four climatic factors: radiation, humidity, temperature, and wind. Thornthwaite (1948) developed a general aridity index based on PE_i :

When $P = PE_i$ throughout the year, the index is 0.

When $P = 0$ throughout the year, the index is -100 .

When P greatly exceeds PE_i throughout the year, the index is $+100$.

Areas with values below -40 are regarded as arid, those with values between -20 and -40 as semi-arid, and those with values between 0 and -20 as sub-humid (Meigs, 1953). The arid category can be further subdivided into arid and extreme arid, with extreme aridity being defined as the condition in any locality where at least 12 consecutive months without any rainfall have been recorded, and in which there is not a regular seasonal rhythm of rainfall.

Extremely arid areas, such as occur in the Atacama, Namib, and the central and eastern Sahara, cover about 4% of the Earth's surface, arid about 15%, and semi-arid about 14.6%. In addition, deserts can be classified on the basis of their proximity to the oceans. Coastal deserts, such as the Namib or the Atacama have very different temperatures and humidity characteristics from the deserts of continental interiors. They have relatively modest diurnal and seasonal temperature ranges and are subject to frequent fogs. They are also very dry. In addition to the coastal and inland deserts of middle and low latitudes, there are also the cold polar deserts. Precipitation in the Arctic regions can be as low as 100 mm per annum and at Vostok in Antarctica can be less than 50 mm.

The causes of aridity

Most of the world's deserts derive their character from the fact that they receive little rainfall. This is because they tend to occur in zones where there is subsiding air, relative atmospheric stability and divergent air flows at low altitudes, associated with the presence of great high-pressure cells around latitude 30° . Such areas are seldom subjected to precipitation-bearing disturbances and depressions either from the Intertropical Convergence Zone (ITCZ) of the tropics or from the belt of mid-latitude depressions associated with the circumpolar westerlies. The trade winds that blow across these zones are evaporating winds, and, because of the trade-wind inversion, they tend to be areas of subsidence and stability.

The subtropical highs are the major cause of aridity, though deserts are not always continuous around the earth at 30° N. For instance, the Asian monsoon gives large quantities of rain over northern India, and elsewhere the high-pressure cells are disrupted into a series of local cells, notably over the oceans, where air moving clockwise around the equatorial side of the cell brings moisture-laden air to the eastern margins of the continents.

The global tendencies produced by the subtropical highs are often reinforced by local factors. Of these, *continentality* is a dominant one and plays a part in the location and characteristics of the deserts in areas like central Asia. The *rain-shadow* produced by great mountain ranges can create arid areas in their lee, as in Patagonia, where the Andes play this role. Other deserts are associated with the presence of cold currents offshore. In the case of the Namib and the Atacama, for example, any winds that do blow onshore tend to do so across cold

currents produced by the movement of water from high latitudes to low and are associated with zones of upwelling of cold waters from the depths of the oceans. Such winds are stable because they are cooled from beneath and have a relatively small moisture-bearing capacity. They reinforce the stability produced by the dominance of subsiding air in desert areas.

Indicators of aridity

Indicators of aridity can be grouped into three main categories: geomorphological, sedimentological and biological (Table A2). These indicators have demonstrated that arid conditions have been both greater and less than today and have shown frequent and substantial changes through time.

In present desert environments, indicators of higher levels of precipitation (pluvials) in the past include: high lake levels marked by ancient shorelines that are now dry, salty, closed basins; expanses of fossil soils of humid type, including laterites and other types indicative of very marked chemical changes under conditions of humidity; great spreads of spring-deposited *tufa*; river systems that are currently inactive and blocked by dune fields; and animal and plant remains, together with evidence of former human habitation, in areas now too dry for people to survive.

The evidence for formerly drier conditions includes the presence of degraded, stable sand dunes in areas that are now too wet for sand movement to occur.

Some of the more important indicators will now be considered in more detail (summarized in Table A2).

Table A2 Evidence for paleoenvironmental reconstruction in drylands

Evidence	Inference
<i>Geomorphological</i>	
Fossil dune systems	Past aridity
Breaching of dunes by rivers	Increased humidity
Discordant dune trends	Changed wind direction
Lake shorelines	Balance of hydrological inputs and outputs
Old drainage lines	Integrated hydrological network
Fluvial aggradation and siltation	Desiccation
Colluvial deposition	Reduced vegetation cover and stream flushing
Karstic (e.g., cave) phenomena	Increased hydrological activity
Frost screes	Paleotemperature
<i>Sedimentological</i>	
Lake floor sediments	Degree of salinity, etc.
Lee dune (lunette) stratigraphy	Hydrological status of lake basin
Spring deposits and tufas	Groundwater activity
Duricrusts and paleosols	Chemical weathering under humid conditions
Dust and river sediments in ocean cores	Amount of eolian and fluvial transport
Loess profiles and paleosols	Aridity and stability
<i>Biological and miscellaneous</i>	
Macro-plant remains, including charcoal (e.g., in pack-rat middens)	Vegetation cover
Pollen analysis of sediments	Vegetation cover
Faunal remains	Biome
Disjunct faunas	Biomes
Isotopic composition of groundwater and speleothems	Paleotemperature and recharge rates
Distribution of archeological sites	Availability of water
Drought and famine record	Aridity

Eolian sediments and landforms

The existence of large tracts of dunes provides unequivocal evidence of aridity, so that the existence of heavily vegetated, deeply weathered, gullied and degraded dunes indicates that there has been a shift towards more humid conditions (Tchakerian, 1999). There is some dispute about the precise precipitation thresholds that control major dune development. Undoubtedly wind strength and the nature of the vegetation cover have to be considered, but systems of palpably inactive dunes are today widespread in areas of relatively high precipitation. Dunes may also provide evidence for multiple periods of sand movement because of the presence of paleosols in them. Furthermore, comparison of modern winds and potential sandflows with those indicated by fixed dunes may suggest that there have been changes in wind regimes and atmospheric circulation.

Dunes developed from lake basins by deposition of material deflated from their beds on lee sides (lunettes) may indicate the nature of changing hydrological conditions. Dunes composed of clay pellets tend to form from desiccated saline surfaces, and those with a predominance of quartzose and sand-size material tend to form from lake beaches developed at times of higher lake levels (Bowler, 1973).

The interrelationships of dunes and rivers may indicate the alternating significance of eolian (dry) and fluvial (wet) conditions, as is made evident by consideration of the courses of some tropical rivers, which have in their histories been ponded up or blocked by dunes.

Other eolian features that have paleoclimatic significance are loess sheets. These are the product of deflation from relatively unvegetated surfaces. Within loess profiles there may be multiple paleosols that resulted from stabilization of land surfaces. A detailed treatment of the significance of such fine-grained eolian materials is provided by Pye and Sherwin (1999). In recent years, luminescence techniques have greatly facilitated the dating of aeolian sediments.

Paleolakes

The identification of high shorelines around closed lake basins and the study of deposits from cores put down through lake floors provide evidence for hydrological changes. These may be related to estimates of former higher precipitation and/or evaporation. There are problems in assessing the relative importance of temperature and precipitation in determining the water balance of a lake and some changes result from non-climatic factors (e.g., anthropogenic activity, tectonic disturbance, etc.). Nonetheless, correlations of dated shorelines and deposits have done much to improve knowledge of the extent and duration of humid phases in the Quaternary (Street and Grove, 1979).

Changes in effective precipitation may be reflected in the frequency and range of floods in desert rivers and in their load: discharge ratios. In particular, in sensitive piedmont zones, marked alternations may occur between planation and incision.

Although phases of fan aggradation and entrenchment may be a response to changes in precipitation, they can also result from tectonic changes, from changes in sediment supply resulting from changes in the operation of such temperature-controlled processes as frost-shattering, or from the inherent instability of fan surfaces.

Less contentious are the remains of fluvial systems in areas where flow is either very localized or non-existent under present conditions. For example, large wadi systems, traced by

the presence of both paleochannels and associated coarse gravel deposits, occur in hyper-arid areas such as the southeastern Sahara (Pachur and Kröpelin, 1987; Brookes, 2001).

Caves, karst, tufas and groundwaters

Solutional attack on limestones to produce karstic phenomena (e.g., major cave systems) requires water, therefore such phenomena may give some indication of past humidity. However, of more significance is that caves are major sites for deposition. Their speleothems often provide a record of environmental change that can be studied by sedimentological and isotopic means. Other sediments that may be preserved in cave systems are roof spall deposits produced by particular weathering processes.

Also of significance for environmental reconstruction are limestone precipitates that occur on the margins of limestone areas in the form of tufas (travertines). These may contain plant and animal remains, paleosols, etc., which may yield environmental information. The tufas themselves may be indicative of formerly more active groundwater and fluvial systems (Nicoll et al., 2001).

The isotopic dating of groundwater reserves has provided information on when groundwater was being recharged and when it was not. For example, Sonntag and collaborators (1980) have indicated that limited groundwater recharge in the Sahara occurred during the last glacial maximum (20,000–14,000 BP), confirming that this was a period of relative aridity.

Miscellaneous geomorphological indicators

Geomorphological indicators are often suggestive of significant change in environmental conditions, but it is often difficult to be precise about the degree of change involved, and to separate the role of climate from other influences.

In some arid areas there are weathering crusts and paleosols that exist outside what are thought to be their normal formative climatic ranges, and their current state of breakdown may indicate that they are out of equilibrium with the present climate. Examples of this are the iron-rich or silica-rich duricrusts of the southern margins of the Sahara and arid Central Australia.

Elsewhere, slope deposits provide evidence of changes in precipitation. For example, slumping along the escarpment of the plateaus of Colorado has been attributed to cooler and wetter conditions, which caused shales to become saturated and unstable. Ancient landslides are also widespread in the central Sahara (Busche, 1998). Likewise, in southern and central Africa, there are sheets of colluvium, which have infilled old drainage lines, and which may have formed when steep slopes behind the pediments on which the colluvium was deposited were destabilized by vegetation sparsity under arid conditions, providing more sediment supply than could be removed by pediment and through flowing stream systems (Price-Williams et al., 1982). The presence of extensive relict frost scree has also been seen as having climatic significance, having been produced under colder, but probably moist, conditions.

Faunal and floral remains

Pollen analysis provides evidence of past vegetation conditions, from which past climatic circumstances may, with care, be unraveled. Particular care has to be taken in assessing the significance of any pollen type that is known to be produced in large quantities and that can be preferentially transported and deposited over large distances by wind or other mechanisms.

Other evidence of past vegetation conditions is provided by charcoal, which, with the help of scanning electron microscopy, can enable the identification of woody plants, sometimes to the species level.

Inferences of paleoclimate may also be drawn from faunal remains and knowledge about their modern habitat preferences. For example, the relative proportions of grazers and browsers may indicate the importance of grassland or predominantly bushy vegetation respectively (Klein, 1980). Caves may preserve the remains of small rodents and insectivores, many of which are the result of deposition of regurgitated pellet material by birds such as owls. These can indicate environment both through their species composition and through the size of bones, which may be related to paleotemperature (Avery, 1982). In the southwestern USA there are some remarkable deposits that were accumulated by pack rats – a rodent of the genus *Neotoma*. Their middens contain extensive plant debris, and those sheltered in caves or overhangs may remain intact for tens of thousands of years (Wells, 1976).

Historical and archaeological evidence

The changing distributions and fortunes of human groups have been used to infer changes in the suitability of deserts for human habitation. The absence of human habitation has been used to infer increased aridity, while their existence in hyper-arid areas has been used to infer the existence of more humid conditions. Considerable care needs to be exercised in attributing the rise and fall of particular cultures to climatic stimuli of this type, given the range of other factors that could be important, but there are some instances where the evidence is relatively unambiguous. For example, in the hyper-arid Libyan Desert of Egypt, artefactual materials occur in areas that are far too dry for human habitation today (Wendorf et al., 1976). In historical times, attempts have been made to reconstruct African climates on the basis of famine and drought chronologies, and geographical and climatic descriptions in travelers' reports and diaries (Nicholson, 1996).

The evidence from the oceans

One of the most important developments in environmental reconstruction over the past four decades has been the use of deep-sea cores. Information derived from deep-sea cores covers long time spans. Such information is also less fragmented by past erosion and diagenesis than most terrestrial evidence.

Ocean floors off the world's major deserts have been depositories for sediments derived by aeolian and fluvial inputs from neighboring landmasses (Sirocko and Lange, 1991). These sediments contain a range of information for environmental reconstruction, and have the advantage that they may be susceptible to relatively accurate dating. They record the relative importance of fluvial and aeolian inputs, the degree of weathering of river-borne feldspars, the pollen and phytolith rain, the salinity of the ocean or sea, the intensity of monsoonal winds and of upwelling activity (Prell et al., 1980), and the temperature of offshore waters recorded by oxygen isotope ratios in foraminiferal tests.

The age of deserts

Although in the late nineteenth century and the first half of the twentieth century many deserts were regarded to be a result of post-glacial progressive desiccation, it is now clear that many

of our present desert areas are of considerable antiquity. This applies particularly in the case of the Namib and the Atacama coastal deserts. The development of their climate was closely related to plate tectonics and sea-floor spreading in that the degree of aridity must have been controlled to a considerable extent by the opening up of the seaways of the Southern Ocean, the location of Antarctica with respect to the South Pole, and the development of the cold offshore Benguela and Peruvian Currents. Arid conditions appear to have existed in the Namib for some tens of millions of years, as is made evident by such remarkable phenomena as the Tertiary Tsonab Sandstone – a lithified erg (Ward, 1988). Likewise, the Atacama appears to have been predominantly arid since at least the late Eocene, with hyper-aridity since the middle to late Miocene. The uplift of the Andes during the Oligocene and early Miocene produced a rain-shadow effect while the development of cold Antarctic bottom waters 15–13 million years ago created another crucial ingredient for aridity.

In India and Australia, the latitudinal shifts associated with sea-floor spreading caused moist conditions during much of the Tertiary, but they entered latitudes where conditions were more conducive to aridity in late Tertiary times. Isotopic studies in the Siwalik Foothills of Pakistan illustrate increasing aridity in the late Miocene. In China, Miocene uplift and a transformation of the monsoonal circulation caused the development of aridity. The eolian deposits (red clays and loess) of China may have started to form around 7.2–8.5 million years ago (Qiang et al., 2001). Indeed, it is possible that the uplift of mountains and plateaus in Tibet and North America caused a more general change in precipitation in the Late Miocene, as is made evident by the great expansion of C4 grasses in many parts of the world (Pagani et al., 1999).

With regard to the Sahara, sediment cores from the Atlantic contain eolian material that indicates that a well-developed arid area existed in North Africa in the early Miocene, around 20 million years ago (Diester-Haass and Schrader, 1979). It is possible that uplift of the Tibetan Plateau played a role, by creating a strong counter-clockwise spiral of winds that drove hot, dry air out of the interior of Asia and across Arabia and northern African (Ruddiman, 2001).

Pleistocene accentuation of aridity

Although deserts may have existed before the Pleistocene, there is evidence that aridity was intensified in many regions in the late Pliocene and Pleistocene. It appears to have become a prominent feature of the Sahara in the late Cenozoic, partly because of the cooling of the oceans and partly because the buildup of ice caps created a steeper temperature gradient between the Equator and the Poles. This in turn led to an increase in trade-wind velocities and in their ability to mobilize dust and sand. DeMenocal (1995) recognized a great acceleration in dust loadings in ocean cores off the Sahara and Arabia after 2.8 Ma, and attributed these to a decrease in sea surface temperatures associated with the initiation of extensive Northern Hemisphere glaciation. Likewise, loess deposition became more intense in China after around 2.5 Ma ago and eolian activity in the American High Plains dates back beyond 1.4 million ybp. The study of sediments from the central parts of the North Pacific suggest that eolian processes (dust deposition) became more important in the late Tertiary, accelerating greatly between 7 and 3 Ma (Leinen and Heath, 1981). It was around 2.5 Ma ago that the most dramatic increase in eolian sedimentation occurred – an increase that accompanied the onset of Northern Hemisphere glaciation. In Arabia, humid

conditions in the late Tertiary caused deep weathering and fluvial incision of lava flows dated to 3.5 Ma. Such signs are absent in early Pleistocene flows (Hötzl et al., 1978).

Environmental fluctuations within the Pleistocene

All deserts show the impact of Pleistocene climatic changes; no deserts were immune. On the one hand, the deserts expanded from time to time, covering areas that are now wooded and forested. As a consequence, stabilized sand seas occur in areas where rainfall levels are currently in excess of 800 mm. A large tract of dead ergs occurs on the south side of the Sahara from Senegal in the west to Sudan in the east, while in southern Africa the Mega-Kalahari extended into Angola, Zambia, Zimbabwe and the Congo Basin. Relict dunes are also present in various parts of South America, including the Llanos in the north and the Pampas in the south. The High Plains of America also have extensive areas of stabilized dunes. In North West India, the dunes of the Mega-Thar can be traced southwards into Gujarat and eastwards towards Delhi, while in Australia large linear dunes can be traced in the tropical north. Changes in the extent of sand seas (e.g., Sarnthein, 1978) may partly be the result of changes in precipitation, but it is also possible that high glacial trade wind velocities played a role (Ruddiman, 1997). These may also have had a marked influence on deflation and dust storm activity. There is clear evidence for increased dust inputs into the oceans at the time of the Last Glacial Maximum. Dust fluxes appear to have been 2–4 times higher than at present (Grousset et al., 1998). Studies of wind-transported materials (including diatoms deflated from desiccated lakes) have been made to plot wind strength changes over extended periods (e.g., Shi et al., 2001).

Conversely, at other times, large freshwater lakes occupied the Altiplano basins of South America, the many depressions of the Basin and Range Province in the USA (notably Lahontan and Bonneville), the Aral-Caspian of Central Asia, the Chad-Bodélé Depression in the Sahara, the Dead Sea in the Middle East and the Lake Eyre basin in Australia. Even in the hyper-arid heart of the Sahara and the Libyan Deserts, there are lake deposits, tufas, old drainage lines and other evidence of enhanced hydrological activity (Rognon, 1963).

Although some of the evidence for pluvial conditions can be explained by reduced rates of moisture loss under cooler conditions, this is by no means an adequate or universal explanation, not least for the many areas that were moist during interglacial times. It appears that inputs of precipitation were substantially increased. For example, studies of the Altiplano lakes in South America suggest that rainfall may have been 400–600 mm in areas that today receive just 200 mm (Clayton and Clapperton, 1997). Likewise, it has been estimated that, in the early Holocene, parts of the Nubian Desert, which now effectively are completely arid, received as much as 700 mm of rainfall (Hoelzmann et al., 2001).

The frequency of climatic change

In addition to being severe, climatic changes in deserts were frequent in the Quaternary. This is indicated by high-resolution studies of ocean and lake cores and because of the increasing availability of high-resolution luminescence dates for aeolian sediments. The multiple glaciations and deglaciations of high latitudes and the multiple climatic flickers within glacial and interglacials all indicate the instability of Quaternary climates. They were all associated with major changes in the oceans,

pressure systems and wind belts, which in turn impacted on deserts. Lake level fluctuations in arid basins may indicate short-lived fluctuations that correlate with Heinrich events (Benson et al., 1998) and Dansgaard-Oeschger cycles (Lin et al., 1998), while the Younger Dryas also seems to have its counterparts in arid regions (e.g., Zhou et al., 2001). Dunes were repeatedly reactivated and stabilized, both in the Pleistocene and the Holocene, lakes rose and fell over short spans of time, and pulses of dust were deposited in the world's oceans. The timing and correlation of these events is controversial, and there are reasons why climatic tendencies would have differed between temperate and tropical deserts and between northern and southern hemispheres, but a coherent pattern is starting to emerge. Dry conditions during and just after the Late Glacial Maximum and humid conditions during part of the early to mid-Holocene appear to have been characteristic of tropical deserts, though not of the southwest USA (Street and Grove, 1979).

The climatic context of change

Pluvials were not in phase in all areas and in both hemispheres (Spaulding, 1991). In a mid-latitude situation like the southwestern United States, there was greatly increased effective moisture at the time of the Last Glacial Maximum, as recognized by Smith and Street-Perrott (1983). This was partly caused by decreased rates of evaporation, but also by intensified zonal circulation and equatorward displacement of mid-latitude westerlies and associated rain-bearing depressions, particularly in winter.

Lower latitudes were much less influenced by the displaced westerlies during the full glacial, and they experienced relatively dry conditions at that time. They experienced major pluvials in early to mid-Holocene times (Grove and Goudie, 1971). Under warmer conditions monsoonal circulation was intensified, and in the Northern Hemisphere the ITCZ would have shifted northwards, bringing rainfall into areas like West Africa, Ethiopia, Arabia and Northwest India. The basis for this change may have been increased summer insolation associated with the 23,000 year rhythm of orbital precession, for at around 9,000 YBP, Milankovitch-forcing led to Northern Hemisphere summers with almost 8% more insolation than today (Kutzbach and Street-Perrott, 1985). Higher insolation caused greater heating of the land, stronger rising motion, more inflow of moist air and more summer monsoonal rainfall. In contrast, weaker insolation maxima around 35,000 and 60,000 years ago would have created weaker monsoons (Ruddiman, 2001).

Changes in insolation receipts at 9,000 BP can help to explain the Northern Hemisphere low latitude pluvial, but they have less direct relevance to the Southern Hemisphere (Tyson and Preston-Whyte, 2000). Also important in determining the spatial and temporal patterning of precipitation change are sea surface temperature conditions associated with the build-up and disintegration of the great ice-sheets (Shi et al., 2000). For example, the presence of a vigorous cold current off the Canary Islands and Northwest Africa, related to glacial meltwater and iceberg discharge into the North Atlantic, might account for arid conditions in the Late Glacial Maximum at a time when the presence of westerly winds might have been expected to produce moister conditions (Rognon and Coudé-Gaussen, 1996). Also important may have been the effects that changes in snow and ice cover over Asia, including Tibet and the Himalayas, could have had on the monsoon circulation (Zonneveld et al., 1997).

The Holocene may have experienced a series of abrupt and relatively brief climatic episodes, which have caused, for example, dune mobilization in the American High Plains (Arbogast,

1996) and alternations of pluvials and intense arid phases in tropical Africa. The Holocene in low latitudes was far from stable and benign, and it is possible that a climatic deterioration around 4,000 years ago could be involved in the mysterious collapse or eclipse of advanced civilization in Egypt, Mesopotamia, and Northwest India (Dalfes et al., 1997). These events cannot be readily accounted for by solar radiation changes, so other mechanisms need to be considered, including changes in the thermohaline circulation in the oceans, or in land surface conditions (Gasse and van Campo, 1994).

What is apparent is that the mechanisms causing changes in atmospheric circulation have been both numerous and complex, and that there will have been lagged responses to change (e.g., slow decay of ice-masses, etc.), it is also apparent that there will have been differing hemispheric and regional responses to change (deMenocal and Rind, 1993). For example, Arabia and Northeast Africa may have been especially sensitive to changes in North Atlantic sea surface temperatures, while monsoonal Asia may have been especially affected by snow and ice conditions in its high mountains and plateaux.

ASTRONOMICAL THEORY OF CLIMATE CHANGE

Abstract

The astronomical theory of paleoclimates aims to explain the climatic variations occurring with quasi-periodicities lying between tens and hundreds of thousands of years. Such variations are recorded in deep-sea sediments, in ice sheets, and in continental archives. The origin of these quasi-cycles lies in the astronomically driven changes in the latitudinal and seasonal distributions of energy that the Earth receives from the Sun. These changes are then amplified by feedback mechanisms which characterize the natural behavior of the climate system like those involving the albedo-, the water vapor-, and the vegetation-temperature relationships. Climate models of different complexities are used to explain the chain of processes which finally link the long-term variations of three

astronomical parameters to the long-term climatic variations at time scale of tens to hundreds of thousands of years.

Past climates at astronomical time scales

Our Ice Age, which the Earth entered 2–3 Ma ago is called the Quaternary Ice Age and is composed of the Pleistocene and the Holocene. Its last 1 Ma is characterized by multiple switches of the global climate between glacial (with extensive ice sheets) and interglacials (with a climate similar to or warmer than today). These past climates are reconstructed from analysis of proxy data taken from deep-sea cores, ice cores, and land records (e.g., Alverson et al., 2003). Throughout this last 1 million years, the glacial-interglacial cycles have occurred with a dominant quasi-periodicity of 100 ka. The astronomical theory of paleoclimates aims to explain the recurrence of these cycles. The last one goes from the Eemian interglacial, centered roughly 125 ka BP, to the current Holocene interglacial which peaked 6 ka BP, and also includes the Last Glacial Maximum (LGM) which occurred 21 ka BP.

The LGM was documented in great detail by the Climate Long-Range Investigation Mapping and Prediction group (CLIMAP, 1976; Schneider et al., 2000). In the Northern Hemisphere, the LGM world differed strikingly from the present in the huge land-based ice sheets, which reached approximately 2–3 km in thickness. Sea level was lower by at least 115 m which represents roughly $50 \times 10^6 \text{ km}^3$ more ice than now. Aerosol loading was higher than present and CO_2 levels were about 200 ppmv (much less than the 280 ppmv of the Pre-Industrial Revolution and than the 370 ppmv of AD 2000) but the global average surface air temperature was only 5°C below present (Petit et al., 1999).

In the glacial world, climate shifts occurred also over periods as short as a few decades to millennia (e.g., Heinrich, Dansgaard-Oeschger-Bond events; Bard, 2002). During the deglaciation, between the LGM and the onset of the Holocene, at about 10 ka BP, climate underwent another series of abrupt events with global impacts (e.g., the Bølling-Allerød-Dryas oscillation). This kind of millennium-scale climatic variability probably does not occur in direct response to the insolation forcing.

The astronomical theory of paleoclimates, an historical point of view

Over the last 1 million years the waxing and waning of ice sheets occurred in a more or less regular way. In Figure A32, one can recognize a saw tooth shape with a 100-ka quasi-cycle which is far from being constant and over which shorter quasi-cycles of roughly 41 and 21 ka are superimposed. These kinds of broad climatic features can be explained by the astronomical theory of paleoclimates (Berger, 1978). This astronomical theory is the oldest explanation of the existence of glacial periods found in the geological record of the Quaternary Ice Age. Through the Milankovitch approach, it is currently the most popular. In broad terms, proponents of this theory claim that the changes in three Earth's orbital and rotational parameters have been sufficiently large as to induce significant changes in the seasonal and latitudinal distributions of irradiation received from the Sun and so, to force glacial and interglacials to recur as seen in geological records.

Climatic variations at similar time scales also occurred during non-Ice Age periods and can also be explained by the astronomical theory (Shackleton et al., 1999).

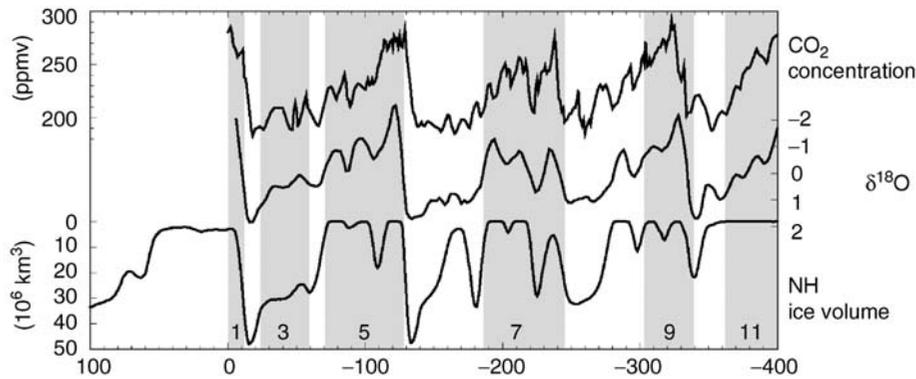

Figure A32 Long-term variations over the last 400 ka of the atmospheric CO_2 from Vostok (Petit et al., 1999), of the $\delta^{18}\text{O}$ recorded from the oceanic core MD900963 (Bassinot et al., 1994), and of the Northern Hemisphere continental ice volume simulated by the LLN 2-D NH model (Loutre, 2003).

Pioneers of the astronomical theory

Only a few years after the address delivered by L. Agassiz in 1837 (Agassiz, 1838) at the opening of the Helvetic Natural History Society at Neuchatel, "Upon Glaciers, Moraines and Erratic Blocks," Adh mar (1842) published his book explaining Agassiz's hypothesis on the existence of ice ages on the basis of the known precession of the equinoxes. An astronomer in Paris, Urbain Le Verrier (1855), famed for discovering the orbital anomalies of Uranus which led to the discovery of Neptune, immediately calculated the planetary orbital changes of the Earth over the last 10^5 years.

Within the next few decades, largely because of the discovery of the repetitive aspect of global glaciation, for example in the Vosges, in Wales, and in the American records of the Illinoian deposits, glacial geology became strongly tied to astronomy. In the mid nineteenth century, James Croll initiated a series of important works that would continue to bear much fruit into modern times. Three major astronomical factors were recognized in his model: axial tilt, orbital eccentricity and precession (Croll, 1875). A specific characteristic of his model essentially lies in his hypothesis that the critical season for the initiation of a glacial is Northern Hemisphere winter. He argued that a decrease in the amount of sunlight received during the winter favors the accumulation of snow and that any small initial increase in the size of the area covered by snow would be amplified by the snowfields themselves (positive feedback). After having determined which astronomical factors control the amount of sunlight received during the winter, he concluded that the precession of the equinoxes must play a decisive role. He also showed that changes in the shape of the orbit determine how effective the precessional wobble is in changing the intensity of the seasons. Croll's first theory predicts that one hemisphere or the other will experience an ice age whenever two conditions occur simultaneously: a markedly elongate orbit and a winter solstice that occurs far from the Sun. Later, Croll hypothesized that an ice age would be more likely to occur during periods when the axis is closer to vertical, for then the polar regions receive a smaller amount of heat.

As time went on, many geologists in Europe and America became more and more dissatisfied with Croll's theory, finding it at variance with new evidence about the last ice age.

Milankovitch era

It is only during the first decades of the twentieth century that Spitaler (1921) rejected Croll's theory. He adopted the opposite view, first put forward by Murphy (1876), that a long, cool summer and a short, mild winter are the most favorable. This diminution of heat during the summer half year was later recognized by Br ckner, K ppen, and Wegener (Br ckner et al., 1925) as the decisive factor in glaciation. However, it is Milankovitch who was the first to complete a full astronomical theory of Pleistocene ice ages, computing the orbital elements and the subsequent changes in the insolation and climate.

Milutin Milankovitch was a Yugoslavian engineer – geophysist – astronomer who was born in Dalj in 1879 and died in Beograd in 1958 (Milankovitch, 1995). He was a contemporary of Alfred Wegener (1880–1930), with whom he became acquainted through Vladimir K ppen (1846–1940), Wegener's father-in-law (Schwarzbach, 1985).

Milankovitch's first book (written in French) dates from 1920, but his massive Special Publication of the Royal Serbian Academy of Science was published in German in 1941. It was translated into English in 1969, which edition was re-edited in 1998. His theory actually requires that the summer in northern high latitudes must be cold enough to prevent the winter snow from melting. This allows a positive value in the annual budget of snow and ice, which initiates a positive feedback cooling of the Earth through a further extension of the snow cover and a subsequent increase of the surface albedo. On the assumption of a perfectly transparent atmosphere and of the northern high latitudes being the most sensitive to insolation changes, that hypothesis requires a minimum in the Northern Hemisphere summer insolation at high latitudes. This is why the essential product of the Milankovitch theory is his curve showing how the intensity of summer irradiation varied over the past 600,000 years at 65°N . It is on this curve that he identified the four European ice ages reconstructed 15 years earlier by Albrecht Penck and Eduard Br ckner (Penck and Br ckner, 1909).

Milankovitch debate

Until roughly 1970 the Milankovitch theory was largely disputed because the discussions were based on fragmentary geological sedimentary records and on inaccurate time scales

and because the climate was considered too resilient to react to “such small changes” in the Milankovitch summer half-year caloric insolation. Moreover, the accuracy of the astronomical solution for the Earth’s orbit and rotation and of the related insolation (namely in polar latitudes) had also to be verified.

The first criteria to test the astronomical theory used a visual or statistical relationship between minima and maxima of geological and insolation curves (e.g., Brouwer, 1950). The Milankovitch summer radiation curve for 65° N was used more frequently because of the more extensive nature of Pleistocene glaciation in the Northern Hemisphere. These qualitative coincidences will, however, remain somewhat illusory until the ambiguities stemming from a priori assumptions about sensitive latitudes and response mechanisms are resolved. As an attempt to solve this problem, many insolation values for different seasons and latitudes were used up to the late 1970s (e.g., Broecker, 1966; Kukla, 1972).

In the meantime, climatologists (Budyko, 1969; Sellers, 1970; Saltzman and Vernekar, 1971) started to analyze the problem theoretically, but they found that the climatic response to orbital change was too small to account for the succession of Pleistocene ice ages. However, these early numerical experiments were also open to question because the models used much too simple parameterizations of important physical processes.

Milankovitch renaissance

In the late 1960s, judicious use of radioactive dating and other techniques gradually clarified the details of the time scale and better instrumental methods came on the scene for reconstructing past climatic variations (Shackleton and Opdyke, 1973). At the same time, atmospheric general circulation models and more realistic climate models became available (Alyea, 1972).

Owing to these improvements, Hays et al. (1976) showed for the first time that quasi-periods of 100, 41, 23 and 19 ka are significantly present in proxy records of the past climate. Independently, these periods were being found in the long term variations of the eccentricity, obliquity and climatic precession using a new more accurate solution of the planetary system (Berger, 1978). These results were definitely at the origin of a revival of the astronomical theory of paleoclimates. New results were going being initiated in all four main steps of any astronomical theory, namely, (a) the computation of the astronomical elements, (b) the computation of the appropriate insolation parameters, (c) the development of suitable climate models, and (d) the analysis of geological data in the time and frequency domains (Imbrie et al., 1984) in order to investigate the physical mechanisms which are responsible for the long-term climatic variations and to calibrate and validate the climate models.

Long-term variations of the astronomical parameters

As here we are primarily interested by the glacial-interglacial cycles, we will focus only on the long-term variations of the energy received by the Earth from the Sun (here called the insolation) at time scales of tens to hundreds of thousands of years.

The incoming solar radiation changes from day to day due to the annual revolution of the Earth around the Sun. But there are other changes of interest related to the planetary system and the Sun’s interior. In particular, the solar output (the so-called solar constant) and the opacity of the interplanetary medium

are changing, but their effects remain difficult to prove at our time scales. More directly related to our problem, the seasonal and latitudinal distributions of insolation have long-term variations which are related to the orbit of the Earth around the Sun and to the inclination of its axis of rotation. These involved three well-defined astronomical parameters: the eccentricity, e (a measure of the shape of the Earth’s orbit around the Sun), the obliquity, ε (the tilt of the equator with respect to the plane of the Earth’s orbit), and the climatic precession, $e \sin \tilde{\omega}$, a measure of the Earth-Sun distance at the summer solstice ($\tilde{\omega}$, the longitude of the perihelion, being a measure of the angular distance between the perihelion and the vernal equinox that are both in motion). The present-day value of e is 0.016. As a consequence, although the Earth’s orbit is very close to a circle, the Earth-Sun distance, and consequently the insolation, varies by as much as 3.2 and 6.4% respectively over the course of 1 year. The obliquity, which defines our tropical latitudes and polar circles, is presently 23°27′. The longitude of the perihelion is 102°, which means that the Northern Hemisphere winter occurs when the Earth is almost closest to the Sun.

Celestial mechanics allows precession, obliquity and eccentricity to be expressed in trigonometrical form as quasi-periodic functions of time:

$$e \sin \tilde{\omega} = \Sigma P_i \sin(\alpha_i t + \eta_i) \quad (1)$$

$$\varepsilon = \varepsilon^* + \Sigma A_i \cos(\gamma_i t + \zeta_i) \quad (2)$$

$$e = e^* + \Sigma E_i \cos(\lambda_i t + \phi_i) \quad (3)$$

where the amplitudes P_i , A_i , E_i , the frequencies α_i , γ_i , λ_i and phases η_i , ζ_i , ϕ_i have been recomputed by Berger in 1978. They can be used over a few millions of years (Berger and Loutre, 1992) but for more remote times numerical solutions are necessary (Laskar, 1999).

These formulae show that ε and e vary quasi-periodically only around the constant values ε^* (23.32°) and e^* (0.0287). This implies that, in the estimation of the order of magnitude of the terms in insolation formulae where ε and e occur, they must be considered as a constant in a first approximation. Moreover, the amplitude of $\sin \tilde{\omega}$ is modulated by eccentricity in the term $e \sin \tilde{\omega}$. The envelope of $e \sin \tilde{\omega}$ is therefore given exactly by e , the frequencies of e originating strictly from combinations of the frequencies of $\tilde{\omega}$; for example: $\lambda_1 = \alpha_2 - \alpha_1$, $\lambda_2 = \alpha_3 - \alpha_1$, $\lambda_3 = \alpha_3 - \alpha_2$, $\lambda_4 = \alpha_4 - \alpha_1$, $\lambda_5 = \alpha_4 - \alpha_2$, and $\lambda_6 = \alpha_3 - \alpha_4$ (Berger and Loutre, 1990). This leads to conclude that the periods characterizing the expansion of e are non-linear combinations of the precessional periods and, in particular, that the eccentricity periods close to 100,000 years originate from the precession periods close to 23,000 and 19,000 years.

Over the past 3 million years, the orbit varied between near circularity ($e = 0$) and slight ellipticity ($e = 0.07$) with a quasi-period of about 400 ka over which a period of about 100 ka is superimposed. The tilt of the Earth’s axis varied between about 22° and 25° at a period of nearly 41 ka. As far as precession is concerned, two phenomena must be considered. The first is the axial precession. The second is related to the counterclockwise absolute motion of the perihelion whose period, measured relative to the fixed stars, is about 100 ka (the same as for the eccentricity). The two effects together result in what is known as the climatic precession of the equinoxes. This motion is mathematically described by $\tilde{\omega}$, the equinoxes and solstices shifting slowly around the Earth’s orbit, relative to the

perihelion, with a mean period of 21 ka. This period results actually from the existence in equation (1) of four periods which are close to 23 and 19 ka.

Figure A33 gives the long-term variations of these three astronomical parameters over the past 200,000 years and into the future for the next 100,000 years. It shows in particular that the 100-ka period is not stable in time (Berger et al., 1998) being remarkably shorter over the present time. It can also be shown that the most important theoretical period of eccentricity, 400 ka, is weak before 1 Ma BP, but becomes particularly strong over the next 400 ka, with the strength of the components in the 100-ka band varying in opposite ways. It is worth pointing out that this weakening of the 100-ka period started about 900 ka ago when this period began to be very strong in paleoclimate records. This implies that the 100 ka period found in paleoclimatic records can not, by any means, be considered to be linearly related to the eccentricity.

While today the Northern Hemisphere winter solstice occurs near perihelion, at the end of the deglaciation, roughly 10 ka BP, it occurred near aphelion. Moreover, because the length of the seasons varies in time according to Kepler's second law, the solstices and equinoxes occur at different calendar dates during the geological past and in the future. Presently in the Northern Hemisphere, the longest seasons are spring (92.8 days) and summer (93.6 days), while autumn (89.8 days) and winter (89 days) are notably shorter. In AD 1250, spring and summer had the same length (as did autumn and winter) because the winter solstice was occurring at perihelion. About 4,500 years into the future,

the northern hemisphere spring and winter will have the same short length and consequently summer and fall will be equally long. But we are now approaching a minimum of e at the 400-ka time scale and 27 ka from today, the Earth's orbit will be circular.

Daily irradiation

Let us call daily insolation, \bar{W} (in W m^{-2}), the energy received at the Earth's surface over a unit area divided by 24 hours without caring about the atmosphere. This value usually referred to as "at the top of the atmosphere" can be calculated exactly. It depends upon the solar constant, the distance from the Earth to the Sun, r , and the length of the day, L . For a given ecliptical longitude – it means for more or less a given day – the long term variations of r are a function of precession only and those of L are a function of ε only. The mathematical expression of \bar{W} show clearly (Berger et al., 1993) that (a) it is principally affected by variations in precession, although the obliquity plays an important role at high latitudes, mainly in the winter hemisphere; (b) at the equinoxes, insolation for each latitude is only a function of precession; (c) at the solstices, both precession and obliquity influence insolation, although precession is dominant at most latitudes. However, the total energy received during one particular season at a given latitude is only a function of ε as a consequence of Kepler's second law.

These behaviors differ from those of the caloric insulations introduced by Milankovitch. Indeed, he defined the caloric seasons as being exactly half a year long to avoid the variations

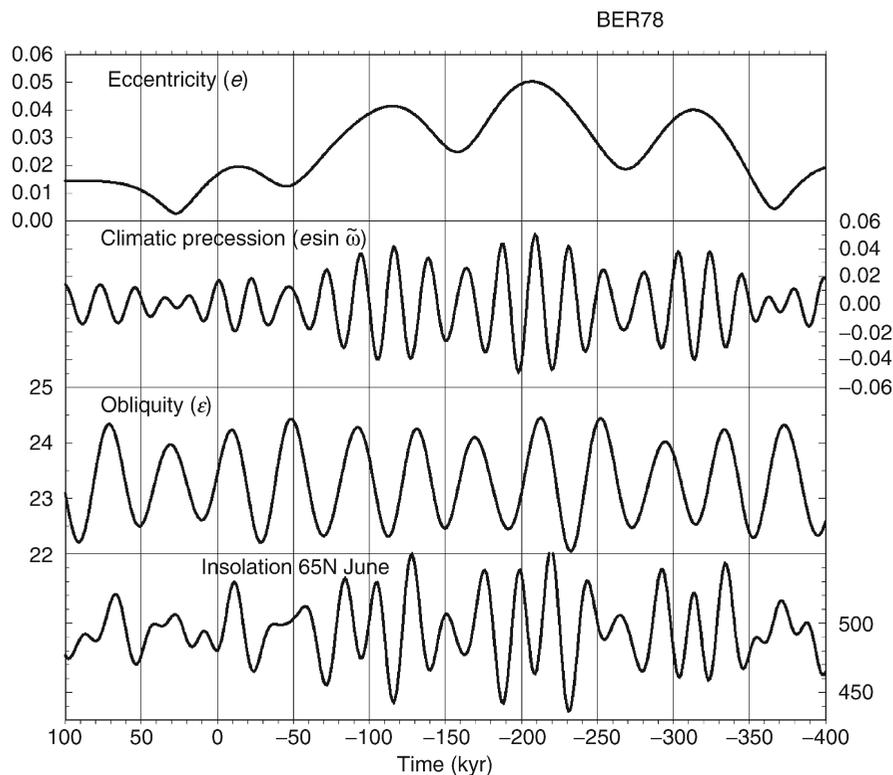

Figure A33 Long-term variations over the last 400 ka and the next 100 ka of eccentricity, climatic precession, obliquity and 65° N insolation at the summer solstice in W m^{-2} (Berger, 1978).

in length of the astronomical ones. The summer half-year comprises actually all the days receiving, each, more irradiation than any of the winter half-year. The resulting caloric insolutions (i.e., the total irradiation received during a half-year caloric season) are mainly a function of precession in low latitudes and of obliquity at high latitudes. We must stress that this is far from solving the difficulty of having to deal both with the total energy received during one season and with its length. The caloric seasons as defined by Milankovitch indeed raise two problems: first, their beginnings change with time; second, it is difficult to define them in the equatorial regions where the seasonal march of insolation has two maxima and two minima. Nevertheless the daily irradiation and the caloric insolutions are different approaches to the problem and they may be considered as complementary.

The geometry of the insolation problem allows one to calculate the insolation changes due to changes in obliquity and precession. Changes in incoming solar radiation due to changes in tilt are the same in both hemispheres during the same local season: an increase of ϵ leads to an increase of insolation in the summer hemisphere and a decrease in the winter hemisphere (Figure A34). As the strength of the effect is small in the tropics and maximum at the poles, an obliquity increase amplifies the seasonal cycle in the high latitudes of both hemispheres simultaneously. The precession effect can cause warm winters and cool summers in one hemisphere while causing the opposite effect in the other hemisphere. As shown

in Figure A34, going from a summer solstice occurring at aphelion to occurring at perihelion increases the energy received on Earth from the spring equinox to the fall equinox.

It must be stressed finally that the pattern of solar irradiation at the top of the atmosphere differs significantly from the pattern of radiation absorbed by the Earth's surface, particularly in high latitudes where the surface albedo is large (Tricot and Berger, 1988). This remark must be kept in mind when using directly the astronomical insolation for trying to explain the climatic variations reconstructed from proxy data.

Astronomical impact on climate

In order to test the possible climatic influence of the long-term variations of insolation, a climate model of intermediate complexity has been built (Gallée et al., 1991). It has been used for many different climatic situations covering the last 3 Ma. In particular, an atmospheric CO₂ concentration decreasing linearly from 320 ppmv at 3 Ma BP (Late Pliocene) to 200 ppmv at the Last Glacial Maximum was used to force this model in addition to the insolation. Under such conditions, the model simulates the entrance into our Ice Age, 2.75 Ma ago, the Late Pliocene – Early Pleistocene 41-ka cycle, the emergence of the 100-ka cycle around 850 ka BP and glacial-interglacial cycles over the last 600 ka (Berger et al., 1998). Sensitivity tests have also shown the importance of all the feedbacks related to the planetary albedo, water vapor, height and continentality of the inlandsis and the isostatic response of the lithosphere. They also confirmed that,

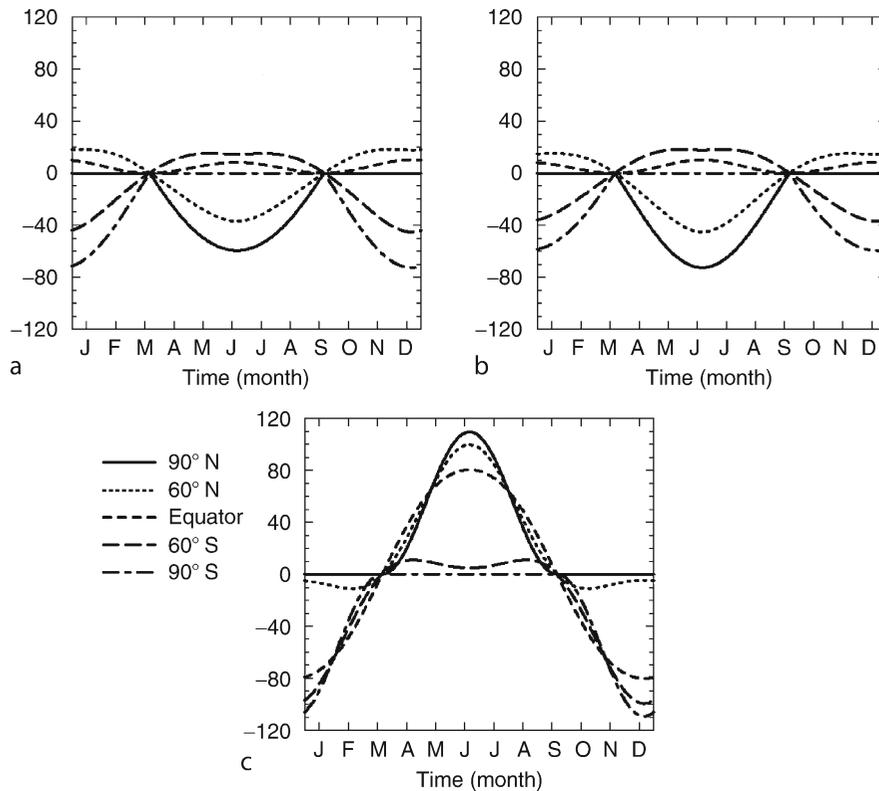

Figure A34 Changes in $W m^{-2}$ along the year of the daily insolation at 90° N, 60° N, the equator, 60° S and 90° S (1) for obliquity changing from 25° to 22°: (a) summer solstice at aphelion; (b) summer solstice at perihelion and (2) for summer solstice changing from aphelion to perihelion, with obliquity being kept at 23.445°. (c). In all figures, $e = 0.05$.

in our model, the astronomical forcing alone can generate glacial-interglacial cycles, but only if the atmospheric CO₂-concentration is lower than 230 ppmv. On the contrary, if the astronomical forcing is kept constant, the CO₂ variations cannot reproduce the ice volume variations characteristic of the glacial-interglacial cycles. Using both the long term variations of insolation and of CO₂ deduced from the Vostok ice cores (Petit et al., 1999) allows one finally to reproduce the glacial-interglacial cycles of the last 400 ka, in broad agreement with the reconstructions of the ice volume from proxy records. These simulations have also shown that the Marine Isotopic Stage 11–400 ka ago – is a much better analog of our Holocene than the Eemian, at least from the astronomical point of view. This result has led to a tentative projection of the future climate over the next tens of thousands of years. Under natural conditions, our interglacial would last exceptionally long (up to 50 ka AP) and man's activities might create a super-interglacial over the next millennia with a complete melting of the Greenland ice sheet from 10 to 20 thousands years into the future (Berger and Loutre, 2002).

Conclusions

It is now more and more accepted that the astronomically induced insolation variations are the pace-maker of the climatic variations over the Quaternary at time scale going from tens to hundreds of thousands of years. The feedback mechanisms related to the planetary albedo, greenhouse gases and ice sheets, are all necessary for amplifying the astronomical signal and to simulate glacial-interglacial cycles in agreement with reconstructions obtained from proxy records. Modeling past climatic variations, through the astronomical theory in particular, allows not only to better understand how the climate system works, but also to attempt modeling our future climate. This is why, in addition to acquiring proxy records for past climate reconstructions, models of diverse complexities must be constructed to test the reliability of the results described in this paper.

ATMOSPHERIC CIRCULATION DURING THE LAST GLACIAL MAXIMUM

Introduction

The Last Glacial Maximum (LGM) offers us an opportunity to assess how the atmospheric circulation changes when in a different climate regime, one characterized by much colder temperatures ($\sim 5^\circ\text{C}$, globally), and different effective topography (i.e., the presence of large ice sheets on land at upper mid-latitudes). Yet, there are many aspects of the circulation that are known imperfectly. The evidence, to the extent that it exists, is generally indirect, especially for wind changes. Moisture and temperature changes are generally better known, and from these we have an indication of how the circulation may have been altered. Even with these parameters, however, there are major uncertainties, in particular associated with temperature changes in the tropics and subtropics.

An alternate line of evidence comes from General Circulation Model (GCM) studies of this time period. Here too, however, there is uncertainty, associated both with the LGM boundary conditions (e.g., sea surface temperatures [SSTs], and ice sheet topography) and with the models themselves. While model studies often give similar temperature change results (when forced with the same boundary conditions), circulation changes can differ, especially on the regional scale.

A third line of evidence comes from theoretical considerations. Basic quasi-geostrophic theory as applied in the extratropics suggests how the atmospheric circulation should respond in a climate change situation, associated, for example, with changes in the latitudinal temperature gradient. Of course, once again, our understanding of the latitudinal temperature gradient for the LGM is only as good as the paleoclimate evidence.

Given this state of affairs, a likely indication of some aspects of the circulation of the LGM can be offered. As more data is obtained, and model and theory improved, the assessment should become more refined.

The following will discuss circulation with respect to its latitudinal and altitude distribution in the extratropics and tropics.

The analysis will be reviewed with respect to the three tools noted above: GCMs (which allow the most direct assessments of circulation changes), observations, and theoretical considerations.

GCM analysis of circulation changes

Various general circulation models have been run with specified or calculated LGM boundary conditions, such as SSTs (a partial list includes the simulations of Gates, 1976; Hansen et al., 1984; Manabe and Broccoli, 1985; Rind and Peteet, 1985; Kutzbach and Guetter, 1986; Rind, 1987; COHMAP, 1988; Hall et al., 1996; Bonfils et al., 1998; Kageyama et al., 1999; Pinot et al., 1999a; and Hewitt et al., 2003). The specified SSTs were generally derived by the CLIMAP (Climate Long-Range Investigation Mapping and Prediction, 1981) reconstruction, although a few of the earlier analyses used colder tropical SSTs than CLIMAP generated, and a few later simulations have added arbitrary cooling to the CLIMAP tropical values (e.g., Toracinta et al., 2004). The calculated SSTs in models have been derived either from analyses using a mixed layer or slab ocean with specified ocean heat transports (e.g., Webb et al., 1997), or with truly coupled dynamical atmosphere-ocean models (e.g., Shin et al., 2003). The calculated SSTs have been almost uniformly colder than the CLIMAP reconstructions in the tropics. Controversy still exists over the proper tropical SST values. The degree of tropical temperature change strongly affects our understanding of LGM dynamics because of its influence on latitudinal temperature gradients and low latitude circulation.

Models have also used several different land ice sheet topographies, chiefly the Denton and Hughes (1981) reconstruction that was part of the CLIMAP LGM reconstruction, but more recently the topography set generated by Peltier (1994). The latter estimate, produced by a model of glacial isostatic adjustment, gives considerably lower (of order 1 km) ice sheet topography estimates, and is not consistent with the dynamics of ice sheet models (Clark et al., 2001). An alternative is to derive the topography from an ice sheet model (e.g., Fastook and Prentice (1994)), which restores the higher altitude (Toracinta et al., 2004). This too makes a difference in LGM dynamics, in particular by altering the magnitude by which the big ice sheets over North America influence the flow field and atmospheric waves.

Unfortunately, the uncertainties in important boundary conditions that influence the depiction of the general circulation in GCMs and atmospheric dynamics of the LGM can seriously impact our understanding. This must be borne in mind in the subsequent discussion. In particular, with calculated SSTs, and greater tropical cooling, the shifts in storm generation in the extratropics are more muted, and the Northern Hemisphere Hadley Cell change is larger. With reduced height of the ice sheets, the associated anticyclone is weaker (Ramstein and Joussaume, 1999; Bromwich et al., 2004).

Extratropics

With the previous caveats in mind, we can now describe the circulation in the LGM extratropics as depicted by GCMs. The sea level pressure field featured big high-pressure sheets over the Laurentide Ice Sheet region (primarily in winter) and the Scandinavian Ice Sheet (primarily in summer); in some models, storms were directed over the Laurentide Ice Sheet in summer, providing precipitation for snow cover. The high

pressure was generated by cooling over the ice sheet – a function of its height, in that with greater altitude of the land surface there is less atmosphere above and hence less greenhouse gas concentration (primarily water vapor) to reduce outward radiative fluxes. The albedo of these ice sheets, a very uncertain parameter, played a role in keeping the region cooler in summer, along with the difficulty of raising the surface air temperature above freezing, given the mass of snow and ice to melt. Winds around these features provided a greater west wind flow at the surface over the Arctic than currently exists, with weaker westerly winds to the south, helping the eastern and central United States to have a “more continental” climate (e.g., Kutzbach and Guetter, 1986). In a higher resolution model, strong katabatic winds came off the Laurentide Ice Sheet. There was a tendency towards some degree of warming south of the ice sheets, due to subsidence or altered advection (Rind 1987; Feltzer et al., 1996).

Storm systems and baroclinicity also underwent strong shifts in locations. Currently baroclinicity is highest over eastern Asia and North America. The presence of the cold Laurentide Ice Sheet produced a strong temperature gradient over North America that led to increased storm generation over land. At the same time, the strong gradient between warm air to the south, over the North Atlantic, and cold air in the vicinity of the southward-displaced sea ice edge led to increased baroclinic generation extending to the eastern North Atlantic. Hence, storms and storm tracks occurred across eastern North America all the way to western Europe (Hall et al., 1996; Kageyama et al., 1999; Bromwich et al., 2004). The stronger latitudinal temperature gradient also intensified the jet stream in its subtropical position, both coming across the Pacific and extending from the eastern Atlantic across southern Europe; hence, storms followed these altered paths. The main ocean low-pressure systems were thus displaced southward from their current locations. With a split flow in the jet stream (see below), storms also increased to the north of the ice sheets, along coastal Alaska and into the Arctic (Bromwich et al., 2004).

As to the intensity of the storms, there is little consistent indication of strengthening, despite the increased baroclinicity. Nor is there any agreement on the nature of the change between standing and transient wave energy. While the added topography would suggest greater stationary wave energy, the increased latitudinal temperature gradient aided transient energy generation. As these processes can work against one another, via poleward transport of heat, different models favor one over the other (e.g., in the study of Rind et al., 2001, standing wave energy actually decreased despite the big ice sheets). Surface winds also did not increase greatly in intensity – on the order of 10% in some models (Crowley, 1988).

At higher levels, the position of the standing wave troughs, which are currently over eastern North America, eastern Asia and eastern Europe in winter, appeared to undergo no major change, although there was amplification in some models (e.g., Felzer et al., 1996). In addition to the southward shift of the jet stream, some models produce a “split-jet” around the Laurentide Ice Sheet, bringing Pacific air over the Arctic, and intensifying flow south of the ice. There is no agreement on this feature, however, which varies in intensity from model to model and it is completely missing in some. Bromwich et al. (2004) show that it can be affected by the model resolution, as well as the presumed height of the ice sheet topography.

While most model simulations did not specifically address the vertical profiles of climate change, cooling undoubtedly occurred throughout the troposphere, associated with colder surface conditions, reduced atmospheric carbon dioxide, and reduced water vapor (from reduced evaporation) (Hansen et al., 1984; Rind et al., 2001). There was also a likely reduction in high-level cloudiness, associated with decreased convection. The most likely response of tropical and subtropical cooling is that the temperature was reduced in the tropical upper troposphere even more than at the surface. In the extratropics, maximum cooling would have been at heights just above the ice sheets. The resulting increased temperature gradient at low altitudes, and decreased temperature gradient at high altitudes, would likely have led to increasing west winds in the low-to-middle troposphere at mid-latitudes, with decreased west winds at higher levels. In the Northern Hemisphere polar regions, the latitudinal temperature gradient was actually reversed – colder conditions now occurred south of the Arctic Circle, so stronger east winds were likely at the highest latitudes. In the North Atlantic, the southward shift of the storm track in most models resulted in a more negative North Atlantic Oscillation phase, although in the study of Bromwich et al. (2004), the northern branch of the split jet stream maintained a vigorous westerly circulation (positive NAO phase). Considering all longitudes, a more negative Arctic Oscillation (AO) phase would have maximized at the surface, and diminished with altitude within the troposphere.

The tropopause was likely at a lower altitude in the colder climate, although its temperature change is uncertain. In at least one study (Rind et al., 2001) its temperature was unchanged. While the troposphere was cooling, the stratosphere was warming (due to reduced CO₂). Total stratospheric ozone would have increased due to the expanded stratosphere. HO_x and NO_x would have decreased because of lower concentrations of methane, tropospheric water vapor and N₂O, further increasing ozone. However, the warmer stratosphere would have favored less ozone photochemically, although this effect was unlikely to have offset the other gains. The stratospheric polar vortex was likely weaker in the stratosphere (again the negative AO phase) (Rind et al., 2001), due in part to increased planetary wave activity propagating up from the troposphere. Hence the stratospheric winds during winter were likely weaker. Gravity wave drag, which acts to decelerate the stratospheric winds, could also have been greater if the ice sheets had a sufficiently corrugated topography to generate them.

The summer time circulation had many current winter-like features, although weaker in intensity, due to the presence of the cold air masses produced by the ice sheets. In addition to the higher pressure over eastern Canada and western Europe in some models, the North American and North Atlantic troughs were amplified (Broccoli and Manabe, 1987; Felzer et al., 1996), with more storms over the North Atlantic, as the land/ocean temperature contrast was altered with respect to current conditions. As noted previously, a subset of models produced storm tracks up onto the Laurentide Ice Sheet during this season.

In the Southern Hemisphere, the consensus is that storms shifted poleward due to greater temperature gradients at higher latitudes, with a more equatorward extension of the sea ice field; major increases occurred in particular in the Indian Ocean sector. The “split-jet” seen in the Pacific therefore weakened or disappeared altogether (Hall et al., 1996).

Tropics/Subtropics

The major question concerning the LGM circulation in the tropics is the extent to which the Hadley Cell changed, both in terms of its magnitude and in terms of its latitudinal extent. Models, usually using CLIMAP SSTs, generally indicate that the July Hadley circulation, with rising air in the northern subtropics and descending air in the Southern Hemisphere, decreased in intensity. This was associated with cooler conditions over land, particularly over Asia. The most obvious expression was a weakened Indian monsoon, although a weaker monsoon in North America has also been noted (Hall et al., 1996).

The features of the Hadley Cell change are affected by the SST field used for the tropics and subtropics. Hall et al. (1996) found that the Hadley Cell moved north of the equator and strengthened in December to February, associated with the warm subtropical Pacific SSTs in the CLIMAP reconstruction. Felzer et al. (1996) found that the Northern Hemisphere portion of the Hadley Cell intensified in both seasons, with the major decrease during June to August occurring in the Southern Hemisphere component. Rind and Perlwitz (2004) found that, when using the CLIMAP SSTs, the December-February Hadley Cell intensified by some 10%, while the June-August intensity was some 20% lower; when using calculated (and colder) SSTs, the December-February change was similar, but June-August intensified by close to 70%. This latter result was due to a $\sim 70\%$ increase in the SST gradient between 27° N and 27° S, and emphasizes how closely related the Hadley Cell strength is to the SST gradient (also noted by Toracinta et al., 2004, especially for the Indian monsoon region). In these analyses, the poleward extent during December-February increased by some 5° of latitude, associated with dynamical processes involving the ice sheets; Ramstein et al. (1998) obtained a similar result.

Models have not yet been used to assess significant changes in El Niño-Southern Oscillation (ENSO) events during the LGM. The specified SST reconstructions of CLIMAP led to increased precipitation in the eastern tropical Pacific relative to the west (Joussame, 1999), implying a weakening of the Walker circulation. With calculated SSTs there was little systematic change.

An additional factor concerns the possible occurrence of hurricanes during the LGM. Hobgood and Cerveny (1988) used output from a GCM that used the CLIMAP SSTs and found that weak hurricanes were still possible, factoring in possible reductions in outgoing thermal radiation associated with the colder climate. Full-fledged hurricanes would presumably be less likely if colder SST values were to be employed.

Observational analysis of circulation changes

Given the uncertainties in the modeling results based on uncertainties in the boundary conditions used to force the models, can we use observations to imply what dynamical changes occurred? While most observational parameters are directly related to the paleodata (temperature, precipitation), we can potentially infer circulation responses by observing the pattern of these changes.

Extratropics

In the extratropics, wetter conditions in the southwestern U.S. and drier conditions in the northwestern U.S. are consistent with a southward shift of the jet stream and storm tracks. The model responses tend to be much smaller than observations imply

(Bromwich et al., 2004), for reasons that are not apparent. In addition, comparison of model and observed conditions for the LGM in southern Europe indicate that the models produced temperatures that were too high there, undoubtedly influenced by the CLIMAP SSTs but also with computed SSTs (Pinot et al., 1999b). This may imply circulation features that are not properly simulated in models, in particular cold air advection from regions further north; this suggests in turn a more active polar front jet stream relative to the subtropical jet (and hence cooler tropical temperatures, which would weaken the subtropical jet). Additional feedbacks, such as those associated with vegetation feedback, may also contribute (e.g., Levis et al., 1999).

Another intriguing feature was the CLIMAP reconstruction showing little additional ice growth in Alaska, which would be consistent with more southerly flow into the region, associated with a southeastward displacement of the Aleutian Low that has been seen in some models and the split-jet stream influence on storm tracks (Bromwich et al., 2004). However, Hall et al. (1996) found that drainage off the ice sheets actually kept Alaska cold in their model simulation.

Observations imply stronger surface winds, on the order of 20–40% (Crowley, 1988). This contrasts with a much smaller increase in model-generated surface winds (and storm intensities).

Tropics/Subtropics

At low latitudes, the Hadley Cell response is indicated by changes in soil moisture in the tropics and subtropics. High lake levels in northwestern Sahara, the Mediterranean region and sites in the Middle East (Farrera et al., 1999) may imply an increase in precipitation minus evaporation for this region of the subtropics. Markgraf (1989) and Colinvaux (1991) find similar subtropical moistening in southern and northern subtropical regions of the Americas (see also Street-Perrott et al., 1989), but changes of this nature are not uniformly recorded throughout the subtropics. In the tropics themselves, from Central America to western Africa, drier conditions prevailed, with only eastern Africa becoming wetter. There is thus some indication that the Hadley Cell weakened, with less subsidence in the subtropics and less rising air in the tropics, but the data is not definitive. Models often reproduce the nature of the change but not the magnitude, underestimating the extent of drying with and without CLIMAP-specified SSTs (although colder tropical/subtropical SSTs can lead to better qualitative agreement (Toracinta et al., 2004)). No moisture records are available from the Indian subcontinent to ascertain the extent to which reduced monsoons really occurred in this region (Farrera et al., 1999). Chylek et al. (2001) suggested that enhancement of dust source areas during past glacial periods implied a contraction of the Hadley Cell of some 3° of latitude.

Some reconstructed SSTs in the tropical Pacific suggest a relaxation of tropical temperature gradients, weakened Hadley and Walker circulation, southward shift of the Intertropical Convergence Zone, and a persistent El Niño-like pattern in the tropical Pacific (Koutavas et al., 2002). In contrast, Trend-Staid and Prell (2002) concluded that SSTs in the western tropical Pacific were relatively unaffected, while the eastern tropical Atlantic cooled substantially. Hence, it is not possible to determine what the circulation was like in this region; model simulations that use a particular SST depiction will produce a Walker circulation consistent with them (Joussame, 1999).

Theoretical considerations of circulation changes

Extratropics

The increased latitudinal temperature gradient driven by the existence of cold ice sheets at upper mid-latitudes likely increased the baroclinic generation of storms. Over the ice sheets themselves, and in the downstream areas to the east, large high-pressure systems, generated by radiative cooling from the high-altitude ice surface, would have dominated the circulation, with storms moving less poleward and more eastward at mid-latitudes. This would correspond, in effect, to the negative phase of the Arctic Oscillation and the North Atlantic Oscillation, although if the downstream trough in the North Atlantic were to be sufficiently amplified, a more positive phase would be possible (Bromwich et al., 2004). While the existence of the added topography features associated with the ice sheets would have seemed likely to generate greater standing wave energy, in some studies this failed to materialize as the increase in latitudinal temperature gradient resulted in a large increase in transient wave energy, which dominated the energy cycle change. This distinction would help determine whether the paleorecord would feature a more longitudinally uniform response of precipitation changes, or not.

The polar front jet stream was clearly further south, associated with the ice sheets, and this jet may have split to the north and south of the ice sheets, although different GCMs produce somewhat different results (which in turn would affect the air arriving at the Greenland Ice Sheet, and consequently the interpretation of isotope changes within the ice cores). The change in the subtropical jet is likewise somewhat uncertain. With relatively warm subtropics, it may have increased in intensity, while with the more likely cooler tropics and subtropics it may well have diminished in general. The change in frequency of El Niños would also affect this result, at least periodically.

Given the greater baroclinicity, stronger storms would have been expected, with substantial increases in surface winds at mid-latitudes, especially at locations featuring the contrast between the cold high-pressure cells off the ice sheets and storms propagating across North America. The model results indicating no marked strengthening of either storms or surface winds are surprising; presumably other limiting factors come into play (including perhaps the model resolution). In the vicinity of the big high pressure cells themselves, covering upper mid-latitudes, surface winds would have been weaker.

Tropics/Subtropics

The Hadley Cell during December-February is quite sensitive to the latitudinal gradient in SSTs. With the CLIMAP reconstruction, there is a tendency for increased circulation north of the equator and decreases to the south due to the warm subtropical SSTs. On the other hand, that distribution is not particularly conducive to drying out the tropics, for the warm subtropics provides plenty of moisture for tropical condensation, despite any reduced upwelling associated with the Hadley Cell decrease. Colder conditions in both the tropics and subtropics (but more so in the tropics) favor equatorial drying, although the impact on the Hadley Cell would be less and wetter conditions in the subtropics more problematical. None of the models produced these effects even when calculating their own SSTs. Hence, the extent to which the Hadley Cell was actually reduced during the LGM is not well known, although a reduction, associated with a decrease in the global hydrologic cycle, is probable.

Concerning the change in the poleward extent of the Hadley Cell, all else being equal, an increase in the equator to pole temperature gradient would have led to an expansion of the latitudinal extent (Held and Hou, 1980). However, a reduced tropopause height and increase baroclinicity in the extratropics would have affected the result.

Had the Hadley Cell intensity been reduced, the trade winds would have been weaker, probably resulting in weaker El Niño/La Niña oscillations (although perhaps locking into a more permanent El Niño state). What actually happened to the ENSO oscillation would have depended upon the temperature of the upwelling water as well, in response to ocean circulation changes (e.g., North Atlantic Deep Water and Intermediate Water changes).

Other aspects of the tropical circulation also depend on the actual SSTs. The occurrence of easterly waves is presumably associated with active convection. If the tropical SSTs were actually considerably colder, convection also would likely have been reduced. The tropical low-level jet, which may promote wave formation via barotropic instability, depends on the temperature gradient between the deep tropics and the warmer subtropics. If the Hadley Cell weakened, and this gradient reduced, the amplitude of the easterly jet would have been reduced as well.

Finally, the existence of hurricanes depends on the SSTs. Hurricanes derive their energy primarily from the latent heat release associated with moisture supplied by evaporation, largely in the subtropics. With substantial cooling in the subtropics, this source would have been less available, and without abundant convection the easterly waves that convert to hurricane vortices would have been less prevalent. Hurricanes, therefore, would likely have decreased.

Summary

Utilizing these three different approaches, can we reach any consensus on how the circulation of the LGM compared to that of the present day climate? The following is a summary of the main points.

- Cold high pressure systems built over the ice sheets, especially over North America during winter.
- Increased baroclinicity generated storms over a broader longitudinal area than currently.
- The jet stream probably shifted southward over North America and the North Atlantic, perhaps elsewhere during winter.
- Reduced Hadley Cell upwelling was likely over Asia in July.
- Hurricanes were likely weaker or non-existent.

More definitive results await a better understanding of LGM tropical SSTs, ice sheet topography, and perhaps increased model resolution.

ATMOSPHERIC EVOLUTION, EARTH

Today's atmosphere plays a critical role in making Earth a habitable planet. It warms the surface with a greenhouse effect, and it blocks ultraviolet radiation that is harmful to life. The properties depend strongly on the concentrations of gases and aerosols in Earth's atmosphere that are in turn determined by a steady state balance between the amounts of gases, solids, and liquids that are added to, removed from, and interconverted by unidirectional chemical reactions. Terrestrial life has, in turn, had an impact on the composition of today's atmosphere. Dry air includes approximately 78% molecular nitrogen and 21% molecular oxygen that largely reflect the role of biological nitrogen fixation and oxygenic photosynthesis.

Many of the parameters that controlled atmospheric composition in the geologic past are the same as those that determine it today. Solar radiation drives atmospheric chemical reactions and sets the boundary conditions for Earth's greenhouse.

Biological activity and geological processes are responsible for significant addition and removal of gases such as oxygen, nitrogen, and carbon dioxide from the atmosphere. In addition to changes in the addition and removal of gases from the atmosphere (sources and sinks), interactions between gases and other elements of the Earth system (feedbacks) also impact atmospheric composition. A distinction is often made between short and long term controls on atmospheric composition. Short term variations of atmospheric composition are attributed to factors such as biological productivity and anthropogenic emissions. Longer term changes in atmospheric composition have been attributed to geological factors that change weathering sinks and volcanic sources, evolutionary events such as the evolution of oxygenic photosynthesis and the colonization of land by plants, in addition to changes in solar radiation through time.

The question of the origin of Earth's atmosphere is at its heart a complex one. Earth's primordial atmosphere is thought to have been lost as a result of atmospheric escape processes (Pepin, 1991), with this early atmosphere replaced by a secondary atmosphere whose origin was attributed initially to degassing of Earth's interior, but more recent thinking attributes much of this secondary atmosphere to extraterrestrial sources (Kasting and Catling, 2003). In the following discussion we will trace the evolution of greenhouse gases and the evolution of oxygen in this secondary atmosphere as well as one of the fundamental feedbacks that has controlled atmospheric composition and the surface temperature conditions of the Earth through time, known as the CO₂-weathering feedback loop (Walker et al., 1981).

Greenhouse gases in the precambrian atmosphere (4400–543 million years ago)

Evidence for liquid water at the surface of the Earth is present in the geologic record beginning 4.4 billion years ago (Mojzsis et al., 2001; Wilde et al., 2001). These observations have been interpreted to indicate that the concentrations of greenhouse gases in Earth's early atmosphere and throughout geologic history have been sufficient to maintain surface temperatures near those dictated by the stability field of liquid water (0–100 °C).

The factors that determine Earth's surface temperature include incoming and outgoing radiation, planetary albedo, and the greenhouse effect. The blackbody temperature for Earth is presently 255 K and matches the balance of incoming radiation from the Sun. The average surface temperature is considerably higher (289 K), however, because infrared active (greenhouse) gases in Earth's atmosphere trap outgoing radiation in the lower atmosphere. A large part of the greenhouse effect in today's atmosphere can be attributed to the role of water and carbon dioxide. In many cases, greenhouse gases occur only in trace concentrations (<1%) in today's atmosphere, but their strong absorption of infrared radiation makes their impact on Earth's surface temperature significant. In the Earth's early atmosphere, these gases also would have played a role in the greenhouse effect.

Standard models for solar evolution (Gilliland, 1989) indicate that the amount of radiation from the solar disk (solar luminosity) changes over time. At the time that Earth formed, 4.6 billion years ago, the amount of solar radiation is thought to have been as much as 25% lower than present-day values. A number of modeling studies indicate that Earth's climate would not have supported the presence of liquid water without higher concentrations of greenhouse gases in the early

atmosphere to compensate for reduced solar luminosity (Sagan and Mullen, 1972).

Studies of the 2.7 billion year old Mount Roe paleosol have used the presence of siderite (an iron carbonate mineral) and greenalite (an iron-bearing phyllosilicate mineral) to place upper limits on the concentration of CO₂ (100 times present atmospheric levels, PAL) in the atmosphere at this time (Rye et al., 1995). Energy balance models using these limits, and constraints imposed by reduced solar luminosity at 2.7 billion years ago, have been used to place limits on the amounts of a second major greenhouse gas (in addition to carbon dioxide) that would have been required to prevent global glaciations. Methane is presently the best candidate for this second greenhouse gas because it is not destroyed by the deep ultraviolet radiation that is thought to have penetrated Earth's early atmosphere.

A recent study presents an alternative solution that does not require enhanced greenhouse gas concentrations, but instead relies on significant changes in Earth's obliquity (tilt of the rotational axis) to inhibit icehouse conditions (Jenkins, 2000). According to this hypothesis, liquid water could have persisted on Earth if obliquity remained high throughout much of Earth's history, and low latitude glaciations would be possible when landmasses occupied equatorial positions. Evidence in the geologic record of Paleoproterozoic rocks of 2.4–2.2 billion years ago and Neoproterozoic rocks from between 750 and 500 million years ago shows a series of widespread, low-latitude glaciations (Hoffman et al., 1998; Bekker et al., 2001) and has been interpreted to reflect collapse of Earth's early greenhouse states, assuming an Earth with low obliquity. The first series of these events, termed "snowball Earth" events, consisted of at least three glacial cycles and is thought to represent the collapse of the Earth's early carbon dioxide plus methane greenhouse as a result of changes in the oxygen content of the Earth's atmosphere. The second series of events has been attributed to several causes including a similar reduction in atmospheric methane concentrations (Pavlov et al., 2003) or a runaway carbon dioxide sink that was associated with silicate mineral weathering reactions that occurred because all continental landmasses were situated at the equator.

In contrast to the inferred collapse of Earth's greenhouse that accompanies snowball Earth events, there have been periods when enhanced greenhouse states have been proposed. These include warm periods 500–400 and 150–55 million years ago and extreme greenhouse events (hothouse events) that have been suggested to have immediately followed Neoproterozoic snowball Earth events. Carbon dioxide levels suggested for these hothouse events are up to 350 times the present atmospheric level and are thought to have built up as a result of limited carbon dioxide sinks due to weathering during the immediately preceding snowball Earth episodes. These levels are, however, strongly dependent on the model simulations of conditions that would be required to overcome snowball-Earth conditions (Hoffman et al., 1998).

Greenhouse gases in the phanerozoic atmosphere (543 million years ago – present)

Estimates of atmospheric carbon dioxide in the past 543 million years have been made using a variety of techniques (Royer et al., 2001). Measurements of the carbon isotopic composition of soil carbonates (pedogenic carbonates) and carbonate associated with the iron oxy-hydroxide mineral goethite have been

combined with physical models of soil-atmosphere carbon dioxide exchange to constrain atmospheric carbon dioxide concentrations at the time of soil carbonate formation (Cerling, 1991; Yapp and Poths, 1992). A second technique uses measurements of carbon isotope ratios in marine organic matter and marine carbonate. These measurements are evaluated in the context of biosynthetic isotope fractionations that depend on the partial pressure of carbon dioxide in ocean water. Atmospheric carbon dioxide is then determined from estimates of oceanic carbon dioxide content. Recently, measurements of the density of stomatal openings observed in fossil leaves have been used to constrain paleo-carbon dioxide levels. An empirical relationship between stomatal density and atmospheric carbon dioxide concentrations was calibrated using modern plants and formed the basis for these methods. A fourth method relies on the boron isotope ratio of biogenic carbonate to determine the pH and $p\text{CO}_2$ of paleo-seawater. Reconstructions of atmospheric carbon dioxide made on the basis of these methods indicate that high levels of carbon dioxide (>20 times PAL) occurred 500 million years ago and decreased to near present-day values by about 300 million years ago. Carbon dioxide levels rose again by about 200 million years ago to a peak at eight times PAL at 150 Ma. Since 150 Ma, atmospheric CO_2 concentrations have decreased to values near present-day values. Smaller magnitude oscillations in atmospheric carbon dioxide concentrations (from levels near 180 to 240 ppm) have been documented for glacial and interglacial cycles over the last 430,000 years (Petit et al., 1999). Recent changes in greenhouse gas concentrations as a result of human activity have been documented and include introduction of greenhouse gases for which there are few or no natural sources (e.g., halocarbons) as well as significant increases in other greenhouse gases (e.g., CO_2 , CH_4 , N_2O , O_3) (Houghton et al., 2001).

Oxygen in the precambrian atmosphere (4400–543 million years ago)

The abundance of molecular nitrogen and molecular oxygen in Earth's atmosphere is much higher than in the atmospheres of Venus and Mars, our two nearest neighbors, and reflects the significant influence of biology on their sources and sinks (photosynthesis, respiration, and nitrogen fixation). Nitrogen in Earth's early atmosphere is thought to have existed predominantly as molecular N_2 because of its stability compared with more reduced and oxidized atmospheric nitrogen compounds such as NH_3 and NO (Kasting and Catling, 2003). Photochemistry involving oxygen produces atomic oxygen that reacts to form oxidized species like ozone (O_3), hydrogen peroxide (H_2O_2), and the hydroxyl radical (OH^*). In the present atmosphere, these species are abundant enough to determine the atmospheric lifetimes of reduced atmospheric species such as methane and carbon monoxide. In Earth's early atmosphere, the concentrations of these oxidized species may not have been high enough to determine the lifetimes of reduced atmospheric species.

Early in Earth's history, the abundance of oxygen is thought to have been considerably lower than it is today, and at some point in Earth's history the atmosphere is thought to have been reduced. The reduced state of the early atmosphere has been inferred because the materials that accreted to form Earth contained abundant hydrogen. Preston Cloud (1972) and Heinrich D. Holland (1984) argued on the basis of evidence from paleosols, iron formations, and the presence of detrital uraninite (UO_2) and pyrite (FeS_2), that the oxidation of Earth's atmosphere occurred just after the Archean-Proterozoic boundary

between 2.5 and 2.2 billion years ago. Under low oxygen conditions iron is leached from soils as Fe^{2+} , in aqueous phase; however, in oxygen-rich conditions Fe^{3+} remains in the soil as hematite Fe_2O_3 . Rye and Holland (1998) argue that Fe depletions in soil profiles developed before 2.2 billion years ago indicate reduced environments and are consistent with a low oxygen atmosphere. Banded iron formations peak in frequency about 2.5 billion years ago and, except for a few occurrences, are largely absent from the geologic record since 1.8 billion years ago. The presence of these sedimentary rocks is thought to reflect a change in ocean chemistry and oxidation state, namely the oxidation of oceanic Fe^{2+} (Canfield, 1998), and also to reflect a change in atmospheric oxidation state. The observation of uraninite and pyrite of detrital origin in Archean sediments (older than 2.5 billion years) has been interpreted as an indication that oxidative weathering was suppressed. In oxidized environments, uraninite (UO_2) oxidizes to UO_2^{2+} which is soluble in water, and pyrite (FeS_2) oxidizes to Fe_2O_3 and SO_4^{2-} . The arguments of Cloud and Holland have not been uncontested, and alternate interpretations that do not hinge on changes in atmospheric oxidation state have been suggested (Ohmoto et al., 1993). However, the arguments that call for a change in atmospheric oxygen content between 2.0 and 2.5 billion years ago have been largely accepted by the geological community.

Recent sulfur isotope measurements of sediments and metamorphosed sedimentary rocks have provided a new way to evaluate the abundance of oxygen in Earth's early atmosphere and the timing of atmospheric oxidation. A large anomalous sulfur isotope signature is present in samples of sediments and metamorphosed sedimentary rocks that are older than 2.45 billion years old, but not in younger rocks (Figure A35). This signature can be represented by the quantity $\Delta^{33}\text{S}$, which is the parts per thousand enrichment of the $^{33}\text{S}/^{32}\text{S}$ of a sample relative to that of a reference that follows the terrestrial mass fractionation array. The terrestrial mass fractionation array is a grand average of the variations of $^{33}\text{S}/^{32}\text{S}$, $^{34}\text{S}/^{32}\text{S}$, and $^{36}\text{S}/^{32}\text{S}$ that are produced by biological and geological chemical and physical processes. The widespread and global nature of this signature in Archean rocks has been interpreted to indicate that oxidative and reductive cycling of sulfur similar to that operating today was suppressed. Sulfur isotope signatures of this type are thought to be exclusively of atmospheric origin. Pavlov and Kasting used a one-dimensional model of atmospheric chemistry to determine that the presence of this signature in the rock record also requires efficient transfer of atmospheric sulfur and sulfate to Earth's surface. A second exit channel opens so that $\text{S} \rightarrow \text{S}_2 \rightarrow \text{S}_4 \rightarrow \text{S}_8$ chemistry can occur when oxygen levels drop below 10^{-5} of present atmospheric oxygen levels (PAL), making the sulfur isotope evidence the strongest argument in favor of a reduced Archean atmosphere (Pavlov and Kasting, 2002). The timing of the transition near 2.45 billion years ago has been interpreted to reflect the time when oxygen levels in the atmosphere first rose.

The rise in atmospheric oxygen that occurred ~ 2.45 billion years ago is thought to have been a step function, or a series of step functions, rather than a gradual rise in atmospheric oxygen (Walker et al., 1983). Archean oxygen levels were thought to have been maintained at levels $<10^{-12}$ PAL because oxygen sink reactions associated with volcanic outgassing out-competed source reactions. Once sources exceeded these sinks, oxygen levels rose until the point at which the next sink reaction would balance the sources. In the present atmosphere, these sink reactions are related to the oxidative weathering of Fe-bearing minerals on the continents. Intermediate oxygen sinks

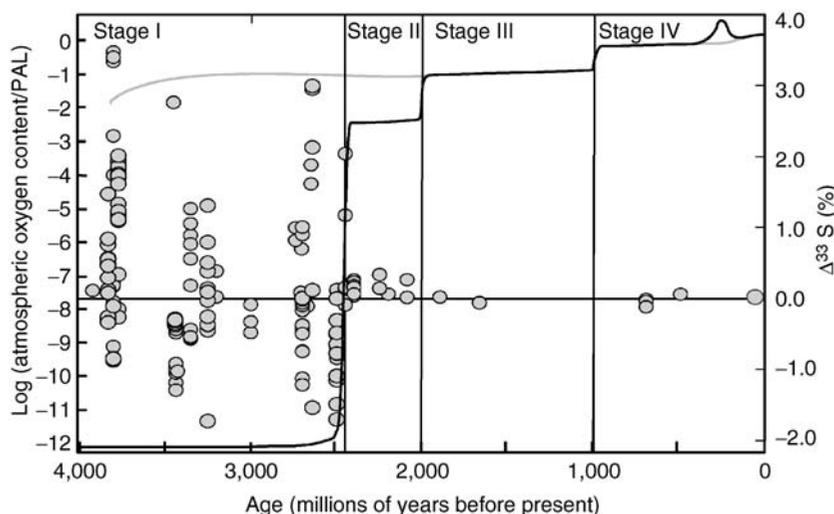

Figure A35 Schematic illustration of the evolution of atmospheric oxygen (*dark line*) with bounds provided by alternate interpretations (*gray line*) (e.g., Ohmoto, 1993). Data points are sulfur isotope data, plotted as $\Delta^{33}\text{S}$, that are used to infer the early evolution of oxygen and to divide the history into stages I (large positive and negative $\Delta^{33}\text{S}$), II (small positive $\Delta^{33}\text{S}$), III (near zero $\Delta^{33}\text{S}$, and $<40\%$ range for $\delta^{34}\text{S}$), and IV (near zero $\Delta^{33}\text{S}$, and $>40\%$ range for $\delta^{34}\text{S}$). The transition between stage I to stage II is marked by the disappearance of large positive and negative $\Delta^{33}\text{S}$ and the transition between stage II and stage III is marked by the disappearance of small $\Delta^{33}\text{S}$ that have been attributed to mass-independent chemistry (Farquhar et al., 2000). The transition between stages III and IV is marked by a change in the range of $^{34}\text{S}/^{32}\text{S}$ fractionations, described by Canfield and Teske (1996).

associated with ocean chemistry involving dissolved species such as Fe^{2+} and sulfide can also act as sinks and stabilize oxygen at intermediate levels (Walker et al., 1983). Arguments about the timing of changes in ocean chemistry associated with sulfide chemistry that are made on the basis of the magnitude of sulfur isotope variations for $^{34}\text{S}/^{32}\text{S}$ have been used to argue that oxygen levels in the atmosphere rose to near present levels sometime between 1 billion and 800 million years ago (Canfield and Teske, 1996).

An unresolved question in studies of atmospheric evolution is why the evidence for oxygenic photosynthesis predates geochemical evidence for an oxidized atmosphere by more than 200 million years. It has been recognized that photosynthesis produces both oxygen and reduced organic matter, and unless the reduced material is removed, no net long-term oxidation of the atmosphere or crust will occur. A number of hypotheses have been presented to account for the removal of reduced material from the atmosphere-crust-ocean system. These include burial of reduced organic matter in sediments, cycling of reduced material to the mantle, and loss of hydrogen to space. Catling et al. (2001) have recently argued that photodissociation of CH_4 in the upper atmosphere, followed by hydrogen escape, was the main loss process for reduced material from the atmosphere, and the reason that the atmosphere-ocean-crust system became oxidized ~ 2.45 billion years ago. Others have argued for changes in mantle redox state, changes in volcanic gases, or that the lag represents the time that it took for photosynthetic bacteria to flourish (Kasting and Siefert, 2002).

Oxygen in the phanerozoic atmosphere (543 million years ago – present)

Berner (2001) and others have investigated the geological evolution of oxygen over the past 543 million years using a variety

of techniques that include building a model that is based on carbon isotope and sulfur isotope variations in the geological record. They reconstruct the mass balance of the amounts of reduced and oxidized carbon and sulfur from their respective isotopic records. This can be done because the most significant carbon and sulfur isotope fractionations are introduced by oxidation/reduction reactions – photosynthesis in the case of carbon isotopes and bacterial sulfate reduction in the case of sulfur isotopes. From this information they have been able to quantify two of the largest source and sink terms for atmospheric oxygen, and in turn, to reconstruct the history of atmospheric oxygen over the past 543 million years. The most recent reconstructions of paleoatmospheric oxygen levels by Berner and colleagues indicate that oxygen levels may have been 25–50% PAL between 543 and 400 million years ago, but rose to 175% PAL by about 300 million years ago during the Permo-Carboniferous, a time when abundant organic rich carbon (coal was buried), vertebrates invaded land, and giant insects (dragonflies) lived. The high oxygen levels of the Permo-Carboniferous reconstructions have not been universally accepted (Lenton, 2001) because it is thought by some detractors that runaway fires would have obliterated forests, yet evidence for trees and vegetation exists.

On shorter timescales, variations in oxygen levels are thought to be strongly dependent on changes in bioproductivity. Variations in the isotopic composition of oxygen gas trapped in ice cores have been used to reconstruct variability of oxygen on orbital timescales associated with the $\sim 20,000$ year precession (wobble) of Earth's orbit (Petit et al., 1999). These variations are thought to reflect changes in biomass and carbon burial that were caused by orbitally-induced changes in solar insolation. Variations in the abundance and isotopic composition of molecular oxygen have also been found to vary on daily to yearly timescales as a result of

variations in biological activity (Bender et al., 1998). These variations point to the strong control of atmospheric oxygen content by bioproductivity in the short term.

In spite of their critical role in determining the lifetime of many trace atmospheric species, the abundances of species such as ozone, hydrogen peroxide, and the hydroxyl radical are much more difficult to constrain from the geological record. The abundance of these gases is linked to oxygen content in the atmosphere, but is also dependent on other factors. We have discussed sulfur isotope evidence (mass-independent fractionations, see above) that can be used to place upper limits on the concentrations of ozone during the first 2 billion years of Earth's history (Farquhar et al., 2001). More recent studies of the oxygen isotopic composition of sulfate in the ice core record using similar isotopic techniques (measurement of ^{16}O , ^{17}O , and ^{18}O) suggest that changes in oxidation pathways for sulfate over Antarctica have occurred over the course of the last glacial cycle (Alexander et al., 2002). Measurements of ozone concentrations made over the last 50 years have documented a decrease in stratospheric ozone that is attributed to chemistry involving chlorine and an increase in tropospheric ozone that is attributed to chemistry involving hydrocarbons (Houghton et al., 2001).

Our understanding of the evolution of Earth's atmosphere is only as good as the physical and chemical modeling studies and interpretations of geological and geochemical evidence upon which it has been constructed. Some of the tools used to study atmospheric evolution have only recently been developed. Future studies that provide new data and test underlying assumptions will undoubtedly refine and possibly provide unanticipated changes in our understanding of atmospheric evolution.

ATMOSPHERIC EVOLUTION, MARS

Introduction

Today, Mars is a cold, dry global desert. However, there is considerable evidence that Mars' climate and its inventory of volatiles (substances that tend to form gases or vapor) have changed greatly during the planet's history. The evidence comes from a variety of sources, including the geomorphology and mineralogy of the surface, the atmospheric composition, and the nature of subsurface materials inferred from the analysis of Martian meteorites reviewed by Kieffer et al. (1992) and Carr (2006). In general, geochemical observations suggest that a once much greater volatile inventory was mostly lost very early in Martian history. We discuss below how isotopic data, in particular, suggests that as much as 99% of the original nitrogen and carbon atmospheric inventory of Mars was lost before about 3.8 Ga, $\sim 0.9\%$ has been lost since, and perhaps only $\sim 0.1\%$ remains. The geomorphology suggests a period of early Martian history when liquid water was present on the surface, although perhaps only sporadically. This period is largely coincident with the time before ~ 3.8 Ga when Mars was undergoing heavy bombardment from asteroid and comet impacts. Taken as a whole, the evidence suggests that Mars has likely been cold and dry for much of the last 4 Gyr. During this time, the surface of Mars has been altered by the effect of atmospheric sedimentation of dust and ice, and wind erosion. The climatic effects of quasi-periodic "ice ages" driven by changes in orbital parameters have probably been an important influence. During such times, polar ice, including both carbon dioxide and water ice, has extended down to much lower latitudes than today.

In discussing how the atmosphere has evolved, we use the geologic timescale for Mars. This timescale is divided up into three periods of increasing age: the Amazonian, the Hesperian, and the Noachian. Surfaces on Mars are categorized into these periods according to the density of superimposed impact craters. Older surfaces are those that have accumulated more impact craters. A Noachian surface is defined as one where an area of 10^6 km² has accumulated at least 200 impact craters with diameters larger than 5 km and 25 craters larger than 16 km. Over the same area, a Hesperian surface will have accumulated at least 67 larger impact craters larger than 5 km and 400 craters larger than 2 km, but not enough craters to be classified as Noachian. Amazonian surfaces have insufficient craters to be Hesperian. The absolute ages corresponding to these cratering intensities are poorly constrained. However, the impact cratering record of the Moon has been radiometrically dated using samples returned by the Apollo missions, and lunar cratering rates have been extrapolated to Mars via models to estimate absolute ages of cratered Martian surfaces. In this way, the Noachian is determined to end around 3.7 Ga, while the Hesperian-Amazonian boundary is estimated to be around 2.9–3.3 Ga (Hartmann and Neukum, 2001).

The present-day atmosphere and surface environment

The thin, present-day atmosphere of Mars exerts a spatial and annual average surface pressure of only ~ 600 Pa compared to Earth's sea-level pressure of 10^5 Pa. According to mass spectrometry measurements made by the Viking probes in the 1970s, the atmosphere is well mixed up to 120 km altitude

and is principally composed of carbon dioxide (95.3% by volume), with minor components of nitrogen (2.7%), argon (1.6%) and trace gases (Table A3). Mars is about 50% farther from the Sun than Earth, so on average the solar flux is 43% less. Were the atmosphere to be absent, the mean global temperature on Mars would be 210 K. However, the thin, dry Martian atmosphere provides a modest greenhouse warming of ~ 5 –8 K, which raises the mean global temperature to around 215–218 K. Temperatures and pressures are too low for liquid water to be in equilibrium with the atmosphere, and water persists at the surface only as vapor or ice. Water vapor is seasonally and geographically variable but typically exerts a partial pressure of only ~ 0.1 Pa. Consequently, the absolute abundance of water vapor is $\sim 10^3$ – 10^4 times less than in the Earth's atmosphere. Mars is also cold enough that the main constituent of the atmosphere condenses at the poles each winter, forming 1–2 m thick CO₂ ice deposits. During northern summer, CO₂ ice entirely sublimates away from the north polar cap to reveal underlying water ice. The southern cap is partially covered year round with CO₂ ice, although water ice is known to lie beneath. Measurements of the energy spectrum of neutrons emanating from Mars into space suggest that water ice also exists in the shallow subsurface in certain areas. Cosmic rays enter the subsurface and cause neutrons to be ejected with a variety of energies that can be related to the distribution of elements in the subsurface to a depth of ~ 1 meter. Hydrogen serves as a proxy for water and hydrated minerals. At latitudes greater than about 55° in each hemisphere, water ice is inferred to exist within 1 m of the surface at an average mass abundance of 50%. Hydrogen is also found to be relatively abundant (2–10% by mass) in certain low-latitude locations, such as Valles Marineris and Arabia Terra (Feldman et al., 2004). This may indicate either buried relic ice from ancient climate regimes or, more probably, hydrated minerals.

There is much interest in the possibility of life on Mars but the contemporary surface environment that we just described is hostile to life for several reasons. First, there is a lack of liquid water, which is thermodynamically unstable. Second, Mars has no ozone layer. Thus, ultraviolet (UV) light with wavelengths down to about 200 nm (below which CO₂ absorbs) reaches

Table A3 Basic planetary parameters for Mars and current atmospheric composition

Parameter	Value on Mars
Mean surface pressure (bar)	0.006
Mean global surface temperature (K)	215–218
Mass relative to Earth's mass of 5.97×10^{24} kg	$0.107 \approx 1/9$
Mean radius relative to Earth's mean radius of 6371 km.	$0.532 \approx 1/2$
Composition of the atmosphere (by volume) below 120 km	CO ₂ 95.32% N ₂ 2.7% Ar 1.6% O ₂ 0.13% CO 0.08% H ₂ O 0.03% (varies) NO ~ 100 ppm Ne 2.5 ppm Kr 0.3 ppm Xe 0.08 ppm O ₃ 0.04–0.2 ppm (varies)
Column dust content of the atmosphere	0.3–5 visible optical depth

the surface and sterilizes the soil. Third, photochemistry in the lower atmosphere produces peroxides, such as hydrogen peroxide (H_2O_2), that oxidize and destroy organic material in the soil. As a result, most hopes for extant life on Mars reside in the possibility that a primitive biota exists in the deep subsurface where geothermal heat might support aquifers. There is also much speculation about past life on early Mars when the ancient surface environment may have been less hostile.

Recently, methane (CH_4) has been spectroscopically detected in the Martian atmosphere at an average abundance of ~ 10 ppb (Formisano et al., 2004). Currently, a range of methane values have been reported and differences have yet to be reconciled. Methane only has a lifetime in the atmosphere of a few hundred years because photochemistry converts it to carbon dioxide and water. To maintain 10 ppb requires significant sources to replenish it, which at present are a matter of speculation. On Earth, methane production is dominated by biology. Biogenic methane production from subsurface life cannot be ruled out for Mars, but abiotic production from geothermal activity and photochemical reactions must be considered more probable at present if the methane detection is real.

Geological and geochemical inferences of past climates

Evidence for past liquid water from geomorphology

The present Martian climate contrasts sharply with a warmer, wetter ancient climate that has been commonly inferred from several types of eroded geological features seen on the Martian surface (Carr, 1996).

Dendritic valley networks are observed in the Noachian highlands (Figure A36). Valleys are typically a few kilometers wide, 100–200 m deep, with flat floors and steep walls. They often have some tributaries but generally with a much lower areal density than terrestrial river valleys. How the valleys were formed is debatable, but majority opinion holds that the process was gradual and required liquid water to flow at or near the surface. Various erosive valley formation mechanisms have been suggested, including runoff from rainfall, groundwater sapping (i.e., subsurface flow of water accompanied by collapse of overlying ground), and discharge from hot springs. Low drainage densities, rounded alcove-like termini, and relatively rectangular U-shaped cross-sections (unlike V-shaped valleys commonly seen on Earth) generally favor a sapping origin. However, valley networks are not uniform. Some valley morphologies are more consistent with formation from surface runoff and some valleys that originate at crater rim crests are incompatible with formation from sapping. Certain valleys also are associated with distributary fans. Figure A37 shows such a fan-like feature where the general pattern of the channels and low topographic slopes provide strong circumstantial evidence for a delta, i.e., a deposit made when a river or stream enters a body of water.

Noachian craters often have degraded rims and infilling, which suggests a more erosive Noachian climate. Rates of Noachian erosion, however, are still only comparable to those in drier regions on Earth. On post-Noachian surfaces, estimated erosion rates drop by a factor of about 10^3 . This strongly suggests a causal link between the heavy bombardment and the relatively higher ancient erosion rates. Some crater degradation models suggest that the erosion was in part caused by fluvial activity. However, the image data suggests that craters were also degraded or obscured by impacts, eolian transport, and mass wasting.

Figure A36 Nanedi Vallis (5.5° N, 48.4° W) imaged by the Mars Orbiter Camera (MOC) on NASA's Mars Global Surveyor (MGS) spacecraft. At the top of the image, the sinuous path of this valley is suggestive of river meanders. In the upper third of the image, a central channel is observed and large benches also indicate earlier river terraces. These features suggest that this valley was formed by sustained fluid flow (the inset in the figure shows a lower-resolution Viking Orbiter image for regional context; portion of image MOC-8704, NASA/Malin Space Science Systems).

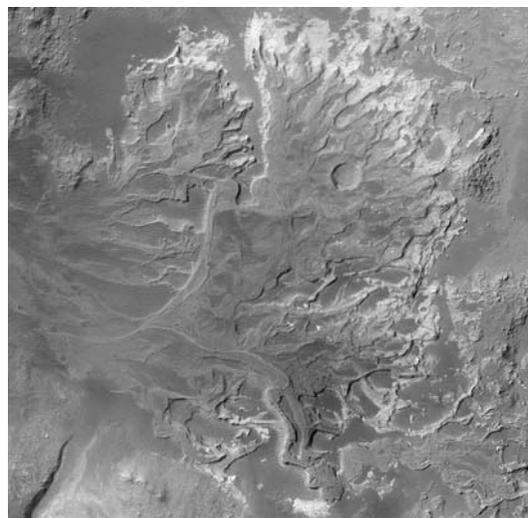

Figure A37 A 14 km by 13.3 km mosaic of high-resolution images taken by the camera on NASA's MGS spacecraft. North is up and the scene is illuminated by sunlight from the left. The picture shows a remnant distributary fan in a 64 km diameter crater northeast of Holden Crater. The floors of channels in the fan stand out in relief because of differential erosion. Presumably the material deposited in valley floors was more resistant to erosion than surrounding material (image MOC2-543a, NASA/Malin Space Science Systems).

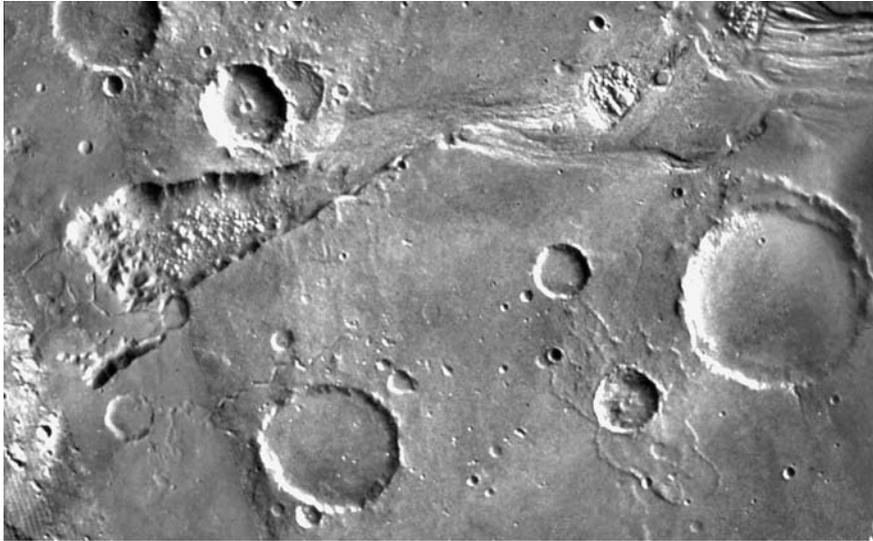

Figure A38 A mosaic of Viking Orbiter images showing the 300 km long head of the channel Ravi Vallis. The source region for the channel on the left is in an area of chaotic terrain. Ravi Vallis feeds into a system of channels that flow northward into Chryse Basin in the northern lowlands of Mars (NASA/Lunar and Planetary Institute).

Outflow channels are a further type of feature generally thought to have a fluvial origin (Baker, 2001). Such channels are 20–100 km wide and can extend for thousands of kilometers (Figure A38). The outflow channel interiors are generally not heavily cratered, and so the channels are inferred to be less ancient than the valley networks. Because the source of outflow channels often originates in chaotic terrain (areas where the ground is collapsed and broken), the expulsion of groundwater in floods is widely held to have been responsible for channel genesis. Such floods could conceivably have occurred in a cold environment similar to that of today, initiated by geothermal heating of subsurface ice or hydrated salts (Montgomery and Gillespie, 2005). Other workers have emphasized that wind and ice may have widened outflow channels over geologic time (Cutts and Blasius, 1981). Liquid CO₂ has also been suggested as a possible agent of erosion. However, CO₂ is unable to discharge as a liquid under present Martian conditions (it would turn into vapor under any plausible conditions) and also there is no well-defined mechanism for recharging CO₂ “aquifers.” Outflow channels drain into the northern lowlands on Mars, where possible shoreline features have been identified, which some interpret as the boundaries of a past ocean (Carr and Head, 2003). The shoreline features remain controversial because high-resolution images do not reveal distinctive geomorphology (Malin and Edgett, 1999) and “shorelines” have also been interpreted as tectonically-derived wrinkle ridges (Withers and Neumann, 2001).

Other intriguing geological features on Mars include gullies on the sidewalls of impact craters and valleys (Figure A39). These features are geologically recent because they lack superimposed small craters and sometimes have debris that overlies sand dunes. Such gullies are found preferentially on poleward-facing slopes at latitudes higher than 30° in both hemispheres. Longevity of ice is favored on such poleward-facing slopes. Consequently, it is possible that snowpack or ice formed in past

Figure A39 Gully-like features on the sidewall of a crater near 33.3° S, 267.1° W. The arrow indicates a light-toned material, probably rich in ice. This layer appears to be genetically associated with the gullies, given that the tops of the gullies originate from the same level as the top of the light-toned layer. The picture is about 2.8 km by 5.8 km, a portion of MOC image M09–02875 (NASA/JPL/Malin Space Science Systems).

orbital-driven climate regimes melted at its base, causing the formation of the gullies (Figure A39) (Christensen, 2003). However, the exact formation mechanism for gullies is currently uncertain.

Evidence for past liquid water from surface geochemistry and sedimentology

Although the surface of Mars is dominated by igneous rock (Christensen et al., 2001), infrared spectroscopy from NASA's Mars Global Surveyor orbiter indicates spectral absorption features consistent with the presence of coarse-grained crystalline hematite (Fe_2O_3) in a few unique locations on Mars where it outcrops from exhumed layered terrain. In 2004, NASA's Mars Exploration Rover B, or "Opportunity" rover, landed in Meridiani Planum to examine the hematite there (Squyres et al., 2006). The hematite is found in small spheres (with $>50\%$ Fe_2O_3 as hematite) uniformly distributed in laminated sulfate-rich sandstones. The sandstone is crumbling away due to wind erosion, and the hematite spherules, which are more resistant to erosion, are falling out. Hematite spherules or their broken fragments litter the plains of Meridiani and represent leftovers of several hundred thousand square kilometers of erosion. The spherules are concretions that form when water carries dissolved minerals through soft sediments or porous rock and minerals precipitate radially or concentrically, incorporating or replacing surrounding sediment. Although the Meridiani rocks are mostly wind-deposited sandstones, some upper sandstone beds show sinuous-crested ripples of a few centimeters height characteristic of sand that was subject to flow in shallow water. Overall, the geologic history in Meridiani Planum is inferred to have gone through three stages: (a) Basalt was altered by acid sulfate to produce sand grains consisting of sulfates and a residue of aluminum-rich amorphous silica. (b) Grains were eroded and re-deposited as sandstone by the wind. (c) Subsequently, groundwater penetrated the sandstone and even pooled at the surface in some areas. The groundwater produced hematite concretions and dissolved some soluble components in the rock. Because only wind has subsequently modified the sandstone, water has likely been scarce at Meridiani for the past several billion years.

Sulfates are an important component of the Martian surface according to many spacecraft observations. A companion rover to Opportunity, named Spirit, found sulfate-rich rocks in the Columbia Hills region, near Gusev Crater, while measurements by NASA's Mars Pathfinder and Viking landers showed that sulfur is a substantial component of soil ($\sim 7\text{--}8\%$ by mass) and surface rocks. Hydrated sulfate deposits have also been identified in numerous deposits, some the size of mountains, in the Martian tropics from near-infrared spectra obtained by the European Space Agency's Mars Express spacecraft. Observed sulfate minerals include gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$), while jarosite has been found by Opportunity (jarosite is $\text{XFe}_3(\text{SO}_4)_2(\text{OH})_6$, where "X" is a singly charged species such as Na^+ , K^+ , or hydronium (H_3O^+)). Anhydrous sulfates, such as anhydrite (CaSO_4), may also be present but would give no signature in the spectral region studied by Mars Express. In general, the sulfates are thought to have formed from alteration of basaltic rocks by sulfuric acid.

Mars Express has also discovered clays in a few locations in the oldest exhumed Noachian terrain (Poulet et al., 2005). These clays incorporate Fe^{3+} and Fe^{2+} . Such clays generally form when basaltic rocks are altered by water. Given that clays often deposit in alkaline or near-neutral conditions, it has been proposed that they formed in a different environment from the acid sulfates found elsewhere. In addition, surface and orbital measurements have found silica (SiO_2) deposits, which is expected from the aqueous alteration of basaltic minerals.

Climate implications

Because liquid water is widely thought to have been the erosive agent that sculpted the ancient valley networks and produced the various hydrated minerals described above, it is often assumed that Mars must have had a persistently warmer and wetter climate in the Noachian than it does today. However, there are several problems with this hypothesis. First, the solar luminosity was about 30% lower 4 Gyr ago compared to today, which requires a very thick CO_2 atmosphere (up to ~ 5 bar surface pressure) to generate enough greenhouse warming to maintain a warm, wet climate at that time (Pollack et al., 1987). Such thick atmospheres on Mars are not physically plausible because at ~ 1 bar, CO_2 condenses into clouds and the CO_2 ice particles rain out (Kasting, 1991). Although there has been speculation that CO_2 ice clouds themselves could act as a greenhouse blanket, recent models suggest that they could not warm the surface above freezing because such warming is self-limiting: by heating the air, the clouds cause themselves to dissipate (Colaprete and Toon, 2003). Other significant greenhouse gases such as CH_4 and SO_2 are problematic. Enough CH_4 could only be sustained if there were a global microbial biosphere comparable to Earth's. Volcanic SO_2 would quickly dissolve and rain out if Mars had been warm enough for a hydrological cycle. Moreover, the net effect of sulfur dioxide on Earth and Venus is cooling through sulfate aerosols that reflect sunlight. There is no geochemical evidence that a thicker CO_2 atmosphere persisted long because under warm, wet conditions atmospheric CO_2 would weather rocks and make abundant carbonate sediments. No carbonate outcrops have been observed spectroscopically at the 100 m scale, despite a global search from spacecraft. Atmospheric dust particles contain a few percent carbonate but carbonate weathering of dust may have occurred in the prevailing cold dry climate and the total amount of carbonate may be small, depending on the global average depth of dust. Upon reflection, it is not surprising that carbonate outcrops are absent whereas sulfate deposits are relatively widespread. In the presence of abundant sulfuric acid, carbonate would be converted to sulfate with release of CO_2 to the atmosphere where CO_2 would be subject to various loss processes discussed below.

Atmospheric origin

Volatiles important to the origin of Mars' atmosphere include water, carbon and nitrogen. The depletion of noble gases on Mars relative to solar abundance indicate that when Mars formed it did not accrete gases directly from the solar nebula. Instead, volatiles must have been acquired as solids. For example, water would have been acquired as water ice or the water of hydration bound in silicate minerals, and carbon would have been acquired as solid hydrocarbons or perhaps carbonates. Mars acquired volatiles either during planetary accretion or during subsequent bombardment by impacting asteroids or comets. Computer simulations of the formation of planets suggest that Earth acquired much of its crustal and surface water from large "planetary embryos" that grew in the asteroid belt between the orbits of Mars and Jupiter before they were ejected by the gravitational influence of Jupiter towards Earth or outward from the Sun. Comets are ruled out as the source of Earth's oceans on isotopic and dynamical grounds (Zahnle, 1998). In contrast, to explain the smallness of Mars requires that it suffered essentially no giant collisions from planetary

embryos and that it grew through smaller asteroidal bodies that accreted later. This means that Mars could have started out with a much smaller fraction of the volatiles than the Earth (Lunine et al., 2003). However, an alternative school of thought argues that Mars and Earth acquired volatiles from local planetesimals in a cold nebula, which would argue for a similar volatile fraction on Earth and Mars (Drake and Righter, 2002).

Atmospheric loss: impact erosion, hydrodynamic escape, sputtering, and surface sinks

Today, the Martian atmosphere has little carbon and nitrogen, which suggests considerable atmospheric loss. The Earth is estimated to have the equivalent of 60–90 bar of CO₂ locked up in carbonate rocks, such that if it were all released, Earth's atmosphere would be similar to that of Venus. Mars, scaling by its relative mass, presumably had an original inventory of no more than 10 bar of CO₂, if we conservatively assume that Mars' volatile fraction had been similar to Earth's. However, there is no evidence for a large CO₂ inventory today. With an area of 88 km² and a thickness between 1 and 100 m, the residual southern cap contains no more than 0.6–60% as much CO₂ as the atmosphere. The regolith on Mars contains an unknown amount of adsorbed CO₂, but probably <0.04 bar (Kieffer and Zent, 1992). Martian meteorites contain <0.5% carbonate salts by volume, which scaled to the crust provide <0.25 bar CO₂ equivalent per kilometer depth. Thus, the current CO₂ inventory of Mars is perhaps a few times 0.1 bar, which, to the nearest order of magnitude, is ~0.1% of the original estimated inventory. This depletion is consistent with isotopic constraints discussed below. Similarly, the current atmospheric N₂ inventory is merely 1.6×10^{-4} bar, compared to 0.78 bar and 3.3 bar N₂ in the atmospheres of Earth and Venus, respectively. Nitrogen could perhaps exist on Mars as nitrate minerals, but the lack of nitrates in Martian meteorites and the absence of spectral evidence for nitrates on the surface do not support such speculation.

Impact erosion

One efficient mechanism for atmospheric loss is impact erosion. Impact erosion occurs when the hot vapor plume from a large asteroid or comet impact imparts sufficient kinetic energy as heat for atmospheric molecules to escape en masse. The impact velocity must be large enough to create a plume that expands faster than the planet's escape velocity. Consequently, Mars, with its small escape velocity, is much more prone to atmospheric impact erosion than Earth or Venus. Modeling based on the estimated cratering rate on early Mars suggests that the early atmosphere was reduced in mass by a factor of ~100 (Figure A40) (Melosh and Vickery, 1989). Thus, if Mars started with a 5 bar atmosphere after accretion, it would have had a 0.05 bar atmosphere by ~3.8–3.5 Ga, when bombardment had subsided, assuming that the CO₂ was in the atmosphere and subject to escape rather than locked up as carbonates in the surface.

Hydrodynamic escape

Another atmospheric loss process that is thought to have operated very early in Martian history is hydrodynamic escape. This escape mechanism applies to a hydrogen-rich primitive atmosphere, which may have existed from 4.5 Ga to roughly about 4.2 Ga. The source of hydrogen would have been volcanism generated by a much more radioactive mantle than today.

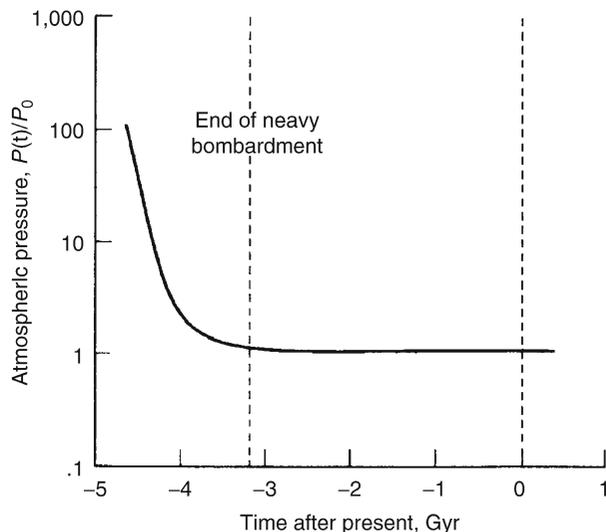

Figure A40 The effect of impact erosion on the surface atmospheric pressure $P(t)$ as a function of time, normalized to present surface pressure, P_0 (from Melosh and Vickery, 1989).

During this early time, the upper atmosphere was heated by high fluxes of extreme ultraviolet radiation (EUV) from the young sun. (Although the young sun was fainter than today overall, astronomical observations and theory show that young stars have much greater output of EUV). Hydrodynamic escape occurs when the typical thermal energy of hydrogen in the upper atmosphere becomes comparable to the gravitational binding energy. As a result, the atmosphere expands into the surrounding vacuum of space. The same process currently happens to the solar atmosphere and results in the solar wind. By analogy, hydrodynamic escape of a planetary atmosphere is termed a *planetary wind*. The escape rate is so rapid that the outward speed of the atmosphere at high altitudes reaches and then exceeds the speed of sound. Heavy atoms get dragged along when collisions with hydrogen push the heavy atoms upward faster than gravity can pull them back. This leads to loss of heavy gases and mass fractionation between different isotopes of the same element. The noble gases on Mars display isotopic patterns consistent with fractionation by early hydrodynamic hydrogen escape (see below). Consequently, bulk gases, such as CO₂ and N₂, should have also been lost through hydrodynamic escape.

Sputtering and nonthermal escape

A further atmospheric loss mechanism is sputtering, also known as solar wind stripping of the atmosphere. Ions in the upper atmosphere are “picked up” by magnetic fields generated by the flow of the solar wind around the planet. The ions undergo charge exchange, which is the process where a fast ion passes its charge to a neutral atom through collision and becomes a fast neutral atom. The large energy is then imparted to surrounding particles through further collisions. Fast, upward-directed particles generated in this process can escape. Today Mars has no global dipole field, but solar wind stripping would have been prevented by the presence of a substantial global magnetic field on early Mars, which would have forced the solar wind to flow around the planet at a greater distance, without significant atmospheric interaction. Mars is known to

have once had a global field because the planet has regions of large remnant magnetization, where new volcanic rocks crystallized in the presence of a magnetic field. Thus, sputtering would have only been important after Mars lost its magnetic field. The timing of the shut-off of the global magnetic field is uncertain. However, there are clues. Unlike much of the other ancient terrain, the Hellas impact basin and surrounding areas lack any magnetic signature. This is most easily explained if the Hellas impact, which is at least 4 Gyr old (based on its size), occurred when Mars no longer possessed a global magnetic field. Thus stripping of the atmosphere by the solar wind would have occurred since about ~ 4 Ga, but not before. Models suggest that solar wind stripping may have removed up to 90% of the post-4 Ga atmosphere. Such atmospheric losses are cumulative. For example, if impacts and hydrodynamic escape removed 99% of the earliest atmosphere and sputtering removed a further 90% of the remainder, the total loss would be 99.9%.

Atmospheric escape is happening today by sputtering and other means. Escape occurs from the base of the Martian exosphere, which is at about 230 km altitude. In the exosphere, the probability of collisions is so small that particles with sufficient upward velocities escape from the planet. The most important species that escape today are hydrogen, oxygen, nitrogen, and carbon. Hydrogen and oxygen loss are coupled. Water vapor photolysis in the lower atmosphere produces H_2 . Above ~ 120 km altitude, hydrogen diffuses upwards and gets converted to atomic hydrogen by photochemical reactions. Atomic hydrogen possesses enough thermal energy to escape to space, so the rate of escape is limited by slow diffusion through the upper atmosphere, and, in turn, by supply of hydrogen-bearing species from the lower atmosphere. Although oxygen produced from water vapor photolysis is too heavy to escape to space through its thermal motion alone, another mechanism exists for oxygen loss. Ionized oxygen molecules (O_2^+) in the ionosphere combine with electrons in “dissociative recombination.” Recombination dissociates the molecules into O atoms with enough kinetic energy to escape ($O_2^+ + e^- \rightarrow O + O$). On Mars, it has been hypothesized that the oxygen escape flux adjusts itself so that it balances the hydrogen escape flux in a 2:1 ratio, i.e., effectively, water escapes (McElroy and Donahue, 1972). However, recent estimates of O escape suggest that the H:O escape ratio is $\sim 20:1$, implying a surface sink for oxygen (Lammer et al., 2003).

Isotopic ratios of D/H and $^{18}O/^{16}O$ in the atmosphere and in Martian meteorites provide weak constraints on the amount of water that has escaped over Martian history. Upper bounds on the estimates of water loss range up to 30–50 m of equivalent global ocean (Krasnopolsky, 2002). These amounts are roughly

comparable to estimates of the inventory in the current polar caps and regolith. Nitrogen and carbon are also able to escape via dissociative recombination. Such loss mechanisms have probably been important for the last 4 Gyr of Martian history and can account for observed C and N isotopic ratios on Mars (see below).

Surface sinks

A final possible atmospheric loss mechanism is to the surface. In the presence of liquid water, CO_2 will dissolve to form carbonic acid and react with the surface through chemical weathering. Carbonic acid reacts with silicate minerals in igneous rocks to release cations (such as Mg^{2+} , Ca^{2+} , Fe^{2+} , K^+ , and Na^+), bicarbonate (HCO_3^-) and other anions, and silica. The ions so released would be expected to precipitate in sediments producing abundant carbonates such as siderite ($FeCO_3$), calcite ($CaCO_3$) and magnesite ($MgCO_3$). Weathering and deposition thus produce overall reaction of the type $CO_2 + CaSiO_3 = CaCO_3 + SiO_2$. The weathering lifetime of a massive CO_2 atmosphere is geologically so short ($\sim 1.5 \times 10^7$ years) that a recycling mechanism such as thermal decomposition by volcanism must be hypothesized to maintain the CO_2 (Pollack et al., 1987). A 1 bar CO_2 atmosphere, if it were all eventually converted to calcite, would generate a global layer of calcite about 200 m thick. But there is no evidence from remote spectroscopy for even a single carbonate outcrop. If Mars started out with abundant CO_2 , the most likely loss appears to have been to space and not to the surface. Noble gas constraints strongly support this idea.

Inferences from noble gases and the isotopic composition of the atmosphere

The isotopic composition of the atmosphere of Mars was measured directly on the surface of Mars by mass spectrometers on two Viking lander spacecraft in the 1970s. For noble gases, more precise measurements have become available from gases trapped within Martian meteorites (Table A4). Atmospheric gases were incorporated into these meteorites when they were melted under the shock of impact that ejected them from Mars. The compositional and isotopic similarity of such meteorite gases to the Viking measurements is convincing evidence that such meteorites come from Mars. Isotopic measurements of gases in the shergottite meteorite sub-class of Martian meteorites have proved particularly valuable because the shergottites originated from shallow depths on Mars so that they are not generally contaminated with gases that have emanated from the Martian interior.

The isotopic composition of volatiles on Mars points to loss of the early atmosphere. Both $^{40}Ar/^{36}Ar$ and $^{129}Xe/^{132}Xe$ noble

Table A4 The isotopic composition of the atmosphere of Mars as measured by the Viking lander spacecraft and in trapped gas bubbles in Martian shergottite meteorites (Owen, 1992; Bogard et al., 2001)

Isotopic ratio	Martian atmosphere (Viking)	Martian atmosphere (Shergottites)	Earth's atmosphere	Martian isotope ratio relative to terrestrial
D/H	$(9 \pm 4) \times 10^{-4}$	6.9×10^{-4}	1.56×10^{-4}	$\sim 4.4\text{--}5$
$^{12}C/^{13}C$	90 ± 5	not reported	89	~ 1
$^{14}N/^{15}N$	170 ± 15	>181	272	>0.6
$^{20}Ne/^{22}Ne$	not measured	~ 10	9.8	~ 1
$^{16}O/^{18}O$	490 ± 25	~ 490	489	~ 1
$^{40}Ar/^{36}Ar$	3000 ± 500	1800 ± 100	296	~ 6
$^{36}Ar/^{38}Ar$	5.5 ± 1.5	≤ 3.9	5.3	<0.7
$^{129}Xe/^{132}Xe$	2.5^{+2}_{-1}	2.4–2.6	0.97	~ 2.5

gas ratios are considerably larger than terrestrial values (Table A4). The “radiogenic isotopes,” ^{40}Ar and ^{129}Xe , result from the decay of radioactive ^{40}K and ^{129}I , respectively. In contrast, the “primordial isotopes,” ^{36}Ar and ^{132}Xe , are not radioactive decay products and were assimilated when Mars formed. The relative enrichment of the radiogenic isotopes suggests that the primordial isotopes were lost. ^{40}K has a ~ 1.28 Gyr half-life, while ^{129}I has a half-life of only ~ 16 Myr, which suggests that most of the ^{132}Xe was lost from Mars very early. A plausible loss mechanism for the primordial isotopes is intense impact erosion in the early Noachian.

Isotopic measurements also indicate that hydrogen, argon, carbon, nitrogen and oxygen have escaped from Mars by gradual processes that continue to operate today. As a result, the light isotopes are depleted relative to the heavy ones; for example, ^{14}N relative to ^{15}N (Table A4). This isotopic fractionation arises because above 120 km altitude, gases separate diffusively according to mass and the heavier isotopes decrease in abundance more rapidly than light isotopes. Consequently, more light isotopes are available for removal at the base of the exosphere. Thus, the atmosphere below becomes enriched in heavy isotopes. This enrichment indicates a loss of 50–90% of the atmospheric species to space (Jakosky and Jones, 1997; Jakosky and Phillips, 2001).

Hydrodynamic escape can reasonably account for the isotopic fractionation of some of the noble gases found in the Martian atmosphere: argon, neon and xenon. Hydrodynamic escape has been invoked to explain the Martian $^{36}\text{Ar}/^{38}\text{Ar}$ ratio of < 3.9 , which is isotopically heavy compared with a terrestrial ratio of 5.32 and the average carbonaceous chondrite value of ~ 5.3 (thought to be representative of the material from which Mars formed). However, if argon escapes and fractionates, neon must also fractionate because it is lighter. Martian atmospheric $^{20}\text{Ne}/^{22}\text{Ne}$ appears to be ~ 10 , similar to the terrestrial atmospheric ratio but smaller than a chondritic value, ~ 13.7 . If the original Martian ratios of $^{36}\text{Ar}/^{38}\text{Ar}$ and $^{20}\text{Ne}/^{22}\text{Ne}$ were 5.35 and 13.7, respectively, hydrodynamic escape models produce a $^{20}\text{Ne}/^{22}\text{Ne}$ ratio no greater than 9.5 ± 1.3 , similar to observation. Interpretation of xenon isotopes is complicated by virtue of its nine stable isotopes, several of which have been affected by the decay of extinct radionuclides. However, fractionation of non-radiogenic xenon isotopes can plausibly be explained by mass fractionation during hydrodynamic escape of hydrogen (Pepin, 1991). Xenon, in particular, is too heavy to escape by means such as sputtering or thermal escape, so early hydrodynamic escape would seem to be required.

Atmospheric loss has also left an imprint on the overall abundance of volatiles. The stable and most abundant isotope

of krypton, ^{84}Kr , is probably the best volatile tracer of atmospheric loss because it should not be subject to fractionation by gradual atmospheric escape of the kind that occurs today for hydrogen, nitrogen, carbon and oxygen. Thus, krypton has probably been retained ever since the end of heavy bombardment around 3.8 Ga. The ratio $\text{C}/^{84}\text{Kr}$ is $\approx 4 \times 10^7$ for Earth and Venus but $\approx (4.4\text{--}6) \times 10^6$ on Mars. This suggests that the amount of CO_2 that Mars had when heavy bombardment and impact erosion ended was 10 times greater (i.e., a 90% loss, consistent with isotopic fractionation of nitrogen). Given that Mars has ~ 6 mbar CO_2 now, the atmosphere may have had ~ 60 mbar CO_2 at around 3.8 Ga. In addition, ^{84}Kr per kg on Mars is only about 1% of that on Earth. This implies a factor of ~ 100 depletion (of both krypton and carbon) due to early impact erosion before 3.8 Ga, which is consistent with the predictions of impact erosion models. A primordial inventory of ≥ 6 bar CO_2 would be inferred, consistent with inferences about Mars’ original endowment of volatiles.

Taken together, we see that the isotopic and abundance evidence suggests that Mars may have lost $\sim 99\%$ of its atmospheric volatiles by the end of heavy bombardment and has perhaps since lost a further $\sim 90\%$ of what remained at that time. This conclusion is tempered by the knowledge that some volatiles, like water, readily form solids in the subsurface, which affords protection against loss to space.

Martian Milankovitch cycles, chaotic obliquity fluctuations, and quasi-periodic climate change.

Mars has very large variations in its orbital elements compared to the Earth (Table A5; Figure A41). Today, the eccentricity of the Martian orbit is 0.093, about 5 times greater than for the Earth, which means that Mars receives about 40% more insolation at perihelion than aphelion. Mars’ rotation rate and obliquity (the angle between its spin axis and the normal to the orbital plane) are similar to Earth’s. Consequently, daily and seasonal changes are analogous. Today, the obliquity of Mars, 25.2° , is close to its mean value over the last 10 Myr but obliquity has varied considerably during that time. Moreover, the spin dynamics are chaotic, with an exponential divergence timescale of 3–4 million years, so that for timescales longer than 10^7 years, the obliquity could have varied between 0° and 60° . The average obliquity for Mars over geologic time was $< 40^\circ$, and sometimes the obliquity may have reached as high as 80° (Laskar et al., 2004). In recent history, eccentricity and obliquity have oscillated with a primary period of $\sim 10^5$ years, modulated on timescales of 2.4 and 1.2 Myr, respectively (Figure A41). In addition, the spin axis orientation (which determines the season of perihelion) has precessed with a 51,000-year period.

Table A5 The orbital elements of Mars and the Earth and their variability

Parameter	Present mars	Martian variability		Present Earth	Terrestrial variability	
		Range	Cycle (years)		Range	Cycle (years)
Obliquity ($^\circ$)	25.19	$\sim 12\text{--}47^{\text{a}}$	120,000 ^b	23.45	22–24	41,000
Eccentricity ^c	0.093	0–0.12	120,000 ^d	0.017	0.01–0.04	100,000
Longitude of perihelion ($^\circ$)	250	0–360	51,000	285	0–360	21,000

^aFor times older than about 10 Ma, obliquity variations are chaotic and would have varied between 0 and 60° (Touma and Wisdom, 1993).

^bThe amplitude of obliquity oscillation is modulated with a ~ 1.2 Myr period envelope.

^cEccentricity, e , is defined by $e = (1 - (b/a)^2)^{0.5}$ where a is the semi-major axis and b is the semi-minor axis of the ellipse traced by the planet’s orbit around the Sun.

^dThe amplitude of eccentricity oscillation is modulated with a ~ 2.4 Myr period envelope.

Of the three parameters (season of perihelion, eccentricity and obliquity), obliquity exerts the largest influence on the climate because changes in obliquity alter the latitudinal distribution of sunlight. Indeed, above 54° obliquity, the poles receive more annual average insolation than the equator. However, the global annual mean surface temperature is calculated to drop at high obliquity because of the increased extent of the bright seasonal CO_2 ice caps. The larger caps would also cause the mean annual surface pressure to be somewhat lower at high obliquity, assuming that the amount of exchangeable CO_2 desorbed from polar regolith is small. If the obliquity were 45° (with other orbital parameters the same as today's), the southern winter cap would reach the equator of Mars during southern winter (Haberle et al., 2003). Consequently, polar ice may have reached the equator even in the last 10 Myr.

Probable evidence for orbital-driven climate change can be found in geologic features on Mars. Both polar regions have extensive layered terrain, which is ~ 10 Myr old based on the

lack of craters. The polar layered terrain consists of multiple layers, each meters to tens of meters thick, with variable brightness. One possible explanation for the origin of layered terrains is that quasi-periodic oscillations in Mars' orbital parameters cause the climate to oscillate. In particular, the shuffling of the climate regimes causes cyclic changes in ice and dust deposition over time. For example, higher (or lower) eccentricity will mean more (or less) dust transport, modulated with $\sim 10^6$ year cyclicity. The short period obliquity and precession cycles will also modulate deposition and erosion over 10^5 years. The two spatial frequencies observed in the polar-layered terrain may be related to these two temporal frequencies (Figure A42).

A thin, patchy mantle of material, apparently consisting of cemented dust, has also been observed within a $30\text{--}60^\circ$ latitude band in each hemisphere (Figure A43). The material is interpreted to be an atmospherically deposited ice-dust mixture

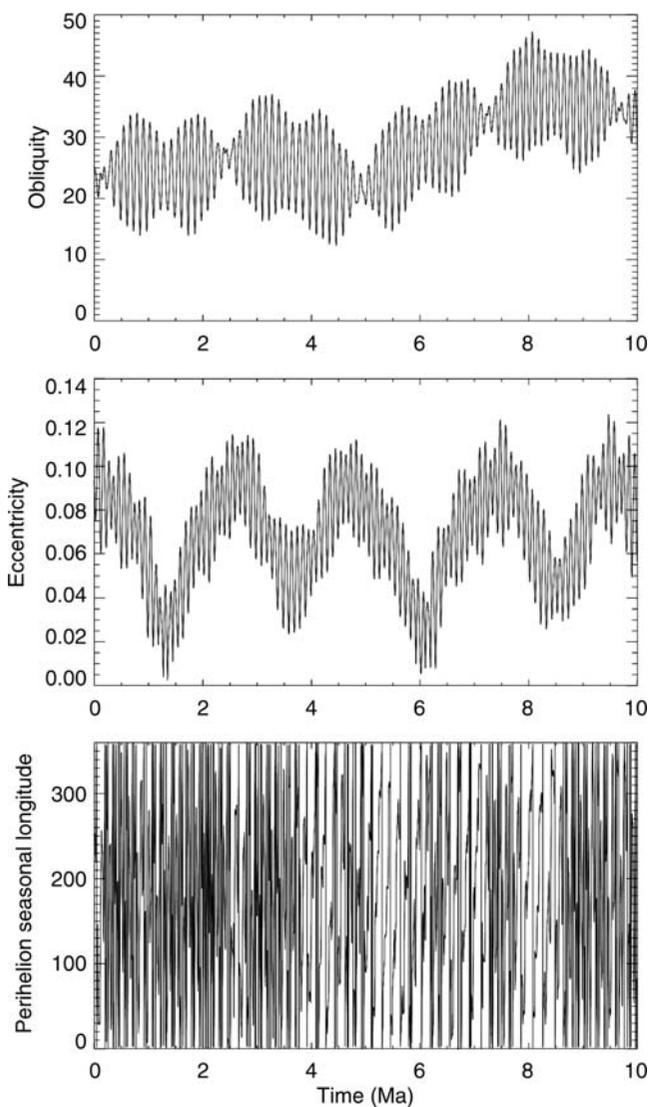

Figure A41 Simulated variations of Martian orbital elements over the last 10 Myr (data courtesy of J. Armstrong).

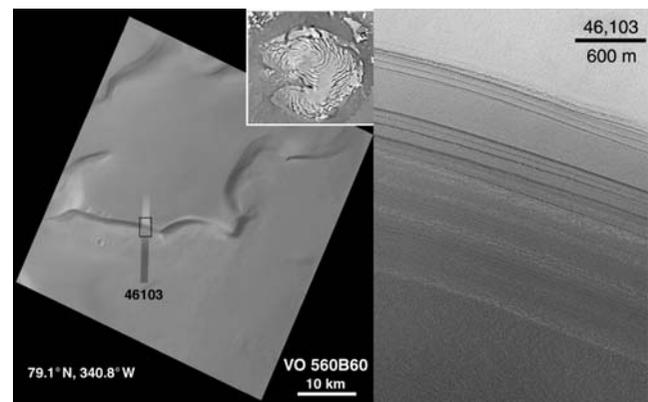

Figure A42 Polar layered deposits. Top inset shows a picture of the north polar cap. Left is a blow-up of the edge of the permanent north polar cap in a Viking Orbiter image (VO 560B60). This image shows a box, which is magnified further in the right-hand MOC image from the MGS spacecraft (portion of image number SP2-46103 near 79.1° N, 340° W). The high-resolution image shows that the polar cap is made up of many layers with thicknesses tens of meters in scale or less. Layers that are ~ 100 m thick have many discrete layers within them (images MOC2-70A-70B, NASA/JPL/Malin Space Science Systems).

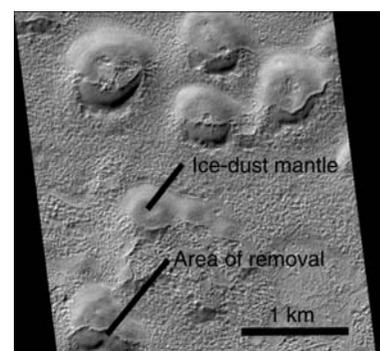

Figure A43 Ice-dust mantling material located at 43.7° S, 239.6° W. The material is being removed, typically on equator-facing slopes. In areas where the material is completely removed, the surface is rough and dissected at this scale (portion of MOC image FHA01450 NASA/JPL/Malin Space Science Systems).

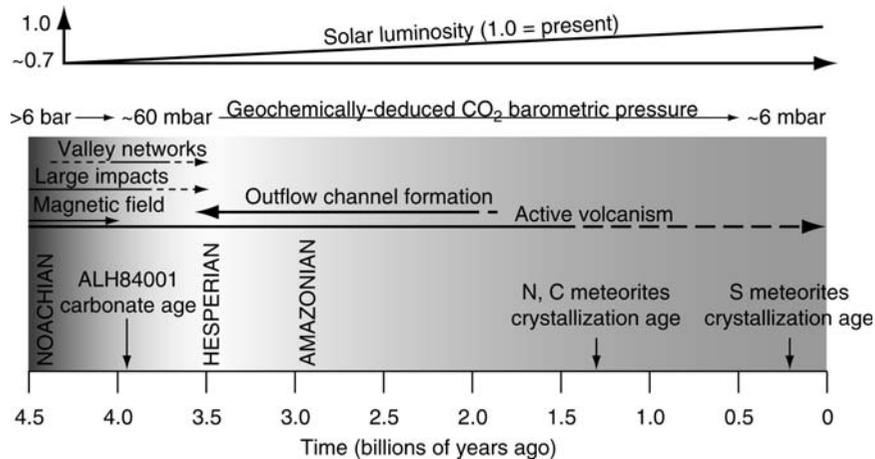

Figure A44 A schematic overview of the history of Mars, showing three periods: the Noachian, Hesperian and Amazonian. The igneous crystallization ages of Martian meteorites are shown, which indicate that Mars has been volcanically active throughout its history (N: nahklites; C: Chassigny; S: shergottites). The oldest meteorite, ALH84001, has a crystallization age of about 4.5 Ga, but contains carbonate salts of 3.9 Ga age. In the Noachian, the planet had a magnetic field and suffered heavy impact bombardment. Valley networks formed mainly in the Noachian. Later, the large outflow channels formed. As Mars aged, the Sun's brightness increased. Also the Martian atmosphere grew thinner, mostly in the Noachian.

from which the ice has sublimated, leaving behind a loosely cemented material. Such residue would be susceptible to wind erosion, which would account for its patchy nature. Today, near-surface ground ice is stable poleward of $\pm 60^\circ$ latitude (Feldman et al., 2004), whereas the two latitude bands where the mantling material is observed correspond to places where the stability of near-surface ice has occurred over the last few million years due to orbital changes. Viscous flow features and gullies, which are probably associated with ice from past climate regimes, are also found within these same latitude bands (Milliken et al., 2003). In addition, some geologic features at low latitudes resemble dust-covered glaciers or rock glaciers (Head et al., 2005).

Long-term atmospheric evolution: a synthesis of evidence and theory

The history of the Martian atmosphere is clearly subject to different interpretations because of uncertainty about the climate conditions under which various geological features were formed. However, certain geochemical indicators, such as inferences from the isotopic composition of the atmosphere, are less ambiguous.

Taken together, geochemical data and models support the view that most of the original CO_2 and nitrogen volatile inventory was lost very early by impact erosion and hydrodynamic escape. Models of impact erosion and the absolute abundance of volatiles like nitrogen and krypton suggest that as much as 99% of the original inventory may have been lost by 3.8 Ga. Before this time, however, large impacts would have provided sufficient heat to decompose carbonates and vaporize subsurface volatiles, such as water and CO_2 ice. Consequently, impacts could have generated temporary ($\sim 10^2$ – 10^3 years) warm, wet climates (Segura et al., 2002). During such episodes, rainwater would erode valley networks or recharge aquifers, producing conditions that allowed groundwater flow and sapping. During such warm episodes, SO_2 would be washed from the atmosphere and react with the surface to make sulfates. Such a scenario

would explain the apparent coincidence between the end of heavy bombardment and the large drop in erosion rates. It would also explain why valley networks are largely confined to heavily cratered Noachian terrains. During quiescent periods, and after heavy bombardment, water and carbon dioxide would be lost from the atmosphere to polar caps, to the subsurface, and to space. The disappearance of the global dipole field some time before 4.0 Ga allowed the solar wind to strip the upper atmosphere of Mars. As a result of solar wind stripping, as well as thermal and other nonthermal escape processes, another 50–90% of the Mars' volatile inventory of carbon and nitrogen was probably lost after 3.8 Ga. This is most clearly reflected today in the ratios of the stable isotopes of nitrogen and argon. In addition, the ratio of $\text{C}/^{84}\text{Kr}$, when compared to Earth and Venus, indicates loss of carbon that is consistent with calculations of escape to space. Outflow channels presumably formed as a result of geothermal activity that melted ground ice (perhaps accumulated near the equator during high obliquity or an ancient time when the pole was at a different location (Schultz, 1985)). Alternatively, hydrous salts were dehydrated. However, the huge size of outflow channels remains enigmatic. In recent epochs, the variation of the orbital elements of Mars in Milankovitch-type cycles has almost certainly caused ice to be stable at lower latitudes than today. As the ice has retreated, it has left behind a variety of telltale features including remnant loess from desiccated dust-ice mixtures, gullies, and perhaps remnant polar terrain at low latitudes. However, none of these features require an atmosphere that is substantially different from that of today (Figure A44).

ATMOSPHERIC EVOLUTION, VENUS

Overview

Venus and Earth are generally regarded as sister planets because Venus is the planet with mass, size, and mean density closest to that of the Earth (see [Table A6](#)). Cosmochemical and geochemical models also suggest that Venus' bulk composition is similar to that of the Earth (Lodders and Fegley, 1998; Tables 5.8 and 5.9). Despite these broad similarities, Venus' atmosphere is dramatically different from that of the Earth. These differences are primarily due to Venus' depletion in water relative to the Earth. As discussed below, Venus may either have formed “dry,” or may have formed “wet” and subsequently lost most of its water. A choice between these two alternatives is impossible at present and there are arguments for and against both models (Lewis and Prinn, 1984; Yung and DeMore, 1999).

Atmospheric evolution on Venus has probably been different than the evolution of the terrestrial atmosphere. However, before discussing this somewhat speculative topic it makes sense to review basic properties of Venus' atmosphere, and to compare its atmosphere to that of the Earth. This article is based on Fegley (2004), Prinn and Fegley (1987), and Warneck (1988). Readers seeking more information about Venus should consult the following sources. *The Encyclopedia of Planetary Sciences* (Shirley and Fairbridge, 1997) has several articles about Venus' atmosphere, geology, and geophysics. Brief reviews are given by Fegley (2004) and Lodders and Fegley (1998). Book-length treatments of results from Soviet missions are given by Barsukov et al. (1992), of *Pioneer Venus* results by Hunten et al. (1983), of *Magellan* results by Bougher et al. (1997), and atmospheric chemistry on Venus and Mars by Krasnopolsky (1986). Three recommended monographs about different aspects of the chemistry and physics of planetary atmospheres are Chamberlain and Hunten (1987), Lewis and Prinn (1984), and Yung and DeMore (1999).

Venus' present day atmosphere

Venus' atmosphere is mainly CO₂ (96.5% by volume) and N₂ (3.5%), with smaller amounts of noble gases (He, Ne, Ar, Kr, Xe), and chemically reactive trace gases (SO₂, H₂O, CO, OCS, H₂S, HCl, SO, HF, and elemental sulfur vapor). The average temperature and pressure at Venus' surface are 740 K

Table A6 Some properties of Venus and Earth (after Lodders and Fegley, 1998)

Property	Venus	Earth
Semi-major axis (10^6 km)	108.21	149.60
(A.U.)	0.7233	1.00
Average radius (km)	6051.4	6371.0
Mass (10^{24} kg)	4.8685	5.9736
Density (kg m^{-3})	5,243	5,515
Volume (10^{10} km ³)	92.84	108.3
Lithospheric mass (10^{24} kg)	3.14 (64.5%)	4.03 (67.5%)
Core mass (10^{24} kg)	1.73 (35.5%)	1.94 (32.5%)
Lithospheric volume (10^{10} km ³)	78.2 (84.2%)	90.6 (83.7%)
Core volume (10^{10} km ³)	14.6 (15.8%)	17.7 (16.3%)
Escape velocity (km s^{-1})	10.361	11.186
Sidereal orbital period (days)	224.70	365.26
Average length of day	116.75	1.0
Mean gravitational acceleration (m s^{-2})	8.870	9.820
Solar constant (W m^{-2})	2613.9	1367.6
Geometric albedo	0.76	0.30
Absorbed solar energy (W m^{-2})	166	243
Mean surface temperature (K)	740	288
Black body temperature (K)	240	250
Mean surface pressure (bar)	95.6	1.0
Scale height at surface (km)	15.90	8.42
Atmospheric lapse rate at surface (K km^{-1})	8.0	6.5
Dry adiabatic lapse rate at surface (K km^{-1})	7.8	9.8
Atmospheric composition of dry gas	CO ₂ (96.5%), N ₂ (3.5%), SO ₂ (0.015%)	N ₂ (78.1%), O ₂ (20.9%), Ar (0.93%), CO ₂ (0.036%)
Atmospheric mean formula weight (g mol^{-1})	43.45	28.97
Atmospheric mass (10^{18} kg)	495	5.28
Atmospheric water vapor ^a	0.003%	1–4%
Cloud composition and coverage (%)	H ₂ SO ₄ (100%)	H ₂ O (50%)
Important greenhouse gases	CO ₂ , SO ₂ , H ₂ O	CO ₂ , H ₂ O, CH ₄ , N ₂ O, CFCs ^b

^aTropospheric values. Water vapor is only a few ppmv in Earth's stratosphere and above Venus' clouds.

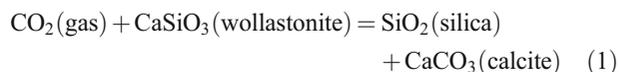

^bCFC gases are chlorofluorocarbon gases such as CF₂Cl₂, CFCl₃, and CF₄.

and 95.6 bar, respectively, at the modal radius (6051.4 km). The temperature gradient throughout Venus' troposphere (0–60 km altitude) is very close to the dry adiabatic gradient for a mixture of CO₂ (96.5%) and N₂ (3.5%). A global cloud layer composed of aqueous sulfuric acid droplets (H₂SO₄·2 H₂O) at ~45 to ~70 km altitude continuously shrouds Venus' surface from our view. The clouds also play a key role in Venus' current climate. They reflect about 75% of incident solar radiation back to space. Thus Venus absorbs only ~66% as much solar energy (160 W m^{-2}) as Earth (243 W m^{-2}) even though the incident solar radiation is ~1.9 times larger than at Earth. In addition, ~70% of the sunlight absorbed by Venus is deposited in the upper atmosphere and clouds, in sharp contrast with Earth, where ~66% of solar energy is absorbed at the surface. A cloud-free Venus would have a much different climate than Venus does today.

The abundances of CO₂, N₂ and the noble gases are apparently constant throughout much of Venus' atmosphere (0–100 km). However, many trace gas abundances vary with altitude, time, and location. These variations are due to photochemical reactions (including photochemical oxidation of SO₂ to aqueous sulfuric acid cloud droplets) that primarily occur in the upper atmosphere and clouds, and to thermochemical reactions that primarily occur in the hot, dense atmosphere below the clouds. Surprisingly, the *Pioneer Venus* gas chromatograph reported an altitude-dependent N₂ abundance below the clouds in the 22–52 km region (see below). Microwave spectroscopy from Earth, the *Pioneer Venus*, and *Magellan* spacecraft indicates that H₂SO₄ vapor is present below the

clouds with an abundance of about 12 parts per million by volume (ppmv). Sulfur trioxide vapor, which has not yet been observed, is expected to be present below the cloud layer in equilibrium with H₂SO₄ gas and water vapor. Both H₂SO₄ and SO₃ have several infrared (IR) absorption bands in the 2–20 μm region and are potentially important greenhouse gases, although at larger concentrations than probably exist in Venus' atmosphere today. Photochemical models predict potentially observable amounts of Cl, Cl₂, ClO, and O₂ in Venus' upper atmosphere (Yung and DeMore, 1999). Tables A6 and A7 summarize chemical and physical data about Venus' atmosphere.

The large abundance of CO₂ in Venus' atmosphere is equivalent to a global layer of calcium carbonate (CaCO₃) 0.88 km thick. This is about twice Earth's crustal carbon inventory, which corresponds to a global CaCO₃ layer 0.44 km thick. Volcanic outgassing is probably the major CO₂ source on Venus. The two major CO₂ sinks are solar UV photolysis to CO and O₂ in the upper atmosphere and carbonate formation on Venus' surface. The latter sink is exemplified by the Urey reaction

but other carbonates and carbonate-bearing minerals such as scapolite may also be involved. (Scapolite is a solid solution between marialite Na₄[Al₃Si₉O₂₄]Cl and meionite Ca₄[Al₆Si₆O₂₄]CO₃. Sulfate and OH anions may also substitute for the chloride and carbonate anions.)

Several arguments suggest that Venus' surface and interior contain carbonates. Degassing of ^{40}Ar on Venus is incomplete and the atmosphere contains only $24 \pm 10\%$ of the ^{40}Ar from radioactive decay (Kaula, 1999). The argon data imply that degassing of CO_2 is also incomplete because argon is degassed more easily than CO_2 (Ar is less soluble in silicate melts than is CO_2). Mass deficits in elemental analyses made by X-ray fluorescence (XRF) spectroscopy at the *Venera 13*, *14*, and *Vega 2* landing sites can be attributed to carbonates, as with the *Viking* XRF data for Mars. Calculated carbonate abundances are about

4–10% CaCO_3 (Kargel et al., 1994). Geochemical interpretations of the elemental analyses suggest that Venus' mantle contains more CO_2 than the terrestrial mantle (Kargel et al., 1993). Finally, some flow features in *Magellan* radar images may result from carbonatite magmas that have water-like rheologies.

The N_2 abundance in Venus' atmosphere is $3.5 \pm 0.8\%$ (see Table A7). Consequently the CO_2 abundance is also uncertain by $\pm 0.8\%$. The uncertainty reflects disagreements between N_2 abundances measured by mass spectrometers on *Pioneer Venus* and *Venera 11–12* and gas chromatographs on the same

Table A7 Chemical composition of Venus' atmosphere^a

Gas	Abundance	Source(s)	Sink(s)	Comments
CO_2	$96.5 \pm 0.8\%$	Outgassing	Solar UV photolysis, carbonate formation	Major greenhouse gas 2.7, 4.3, 15 μm bands
N_2	$3.5 \pm 0.8\%$	Outgassing	NO_x formation by lightning	Altitude-dependent mixing ratio needs confirmation
SO_2^b	0.01–1 ppmv (cloud top)	Outgassing, and oxidation of OCS and H_2S	Photochemical oxidation to H_2SO_4 cloud droplets, reaction with Ca-bearing minerals on Venus' surface to form anhydrite (CaSO_4), reduction to OCS and H_2S	Most abundant sulfur gas, important greenhouse gas 7.3, 8.7, 19.3 μm bands
	150 ± 30 ppmv (22–42 km)			
	25–150 ppmv (12–22 km)			
H_2O^b	30 ± 15 ppmv (0–45 km)	Outgassing, and cometary impacts	Hydrogen escape to space, and oxidation of ferrous iron minerals	Most abundant hydrogen gas, important greenhouse gas 0.9, 2.7, 6.3 μm bands
^{40}Ar	31^{+20}_{-10} ppmv	Outgassing (^{40}K decay)		About 3–4 times less ^{40}Ar than on Earth (g/g basis)
^{36}Ar	30^{+20}_{-10} ppmv	Outgassing (primordial)		About 70 times more ^{36}Ar than on Earth (g/g basis)
CO^b	45 ± 10 ppmv (cloud top)	CO_2 photolysis, and outgassing	Photochemical oxidation to CO_2 via catalytic cycles. Also consumed by thermochemical reactions with sulfur gases and ferric iron minerals	4.66 μm fundamental, potentially important greenhouse gas, involved in Venus atmospheric sulfur cycle
	30 ± 18 ppmv (42 km)			
	28 ± 7 ppmv (36–42 km)			
	20 ± 3 ppmv (22 km)			
	17 ± 1 ppmv (12 km)			
$^4\text{He}^c$	0.6–12 ppmv	Outgassing (U, Th decay)	Escape to space	
Ne	7 ± 3 ppmv	Outgassing (primordial)		About 20 times more Ne than on Earth (g/g basis)
^{38}Ar	5.5 ppmv	Outgassing (primordial)		
OCS ^b	4.4 ± 1 ppmv (33 km)	Outgassing, sulfide weathering	Conversion to SO_2	4.8, 11.6, 19.1 μm bands
H_2S^b	3 ± 2 ppmv (<20 km)	Outgassing, sulfide weathering	Conversion to SO_2	3.8, 4.2, 8.5 μm bands
HDO ^b	1.3 ± 0.2 ppmv (sub-cloud)	Outgassing	Hydrogen escape to space	
HCl	0.6 ± 0.12 ppmv (cloud top)	Outgassing	Formation of Cl-bearing minerals	3.46 μm fundamental
	0.5 ppmv (35–45 km)			
^{84}Kr	25^{+13}_{-18} ppbv	Outgassing (primordial)		
SO^b	20 ± 10 ppbv (cloud top)	Photochemistry	Photochemistry	
S^b_{1-8}	20 ppbv (<50 km)	Sulfide weathering, outgassing	Conversion to SO_2	
HF	$5^{+5}_{-2.5}$ ppbv (cloud top)	Outgassing	Formation of F-bearing minerals	2.52 μm fundamental
	4.5 ppbv (35–45 km)			
^{132}Xe	<10 ppbv	Outgassing (primordial)		
^{129}Xe	<9.5 ppbv	Outgassing (^{129}I decay)		

Modified from Fegley (2004).

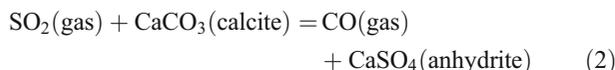

^aAbundance by volume, ppm = parts per million by volume, ppb = parts per billion by volume.

^bThe abundances of these gases are altitude-dependent.

^cThe He abundance has only been measured above the homopause where diffusive separation occurs. This value is 12^{+24}_{-6} ppm by volume (von Zahn et al., 1983). The value listed above is a model-dependent extrapolation below the homopause.

spacecraft. Volcanic outgassing is probably the major N_2 source on Venus and the formation of nitrogen oxides (NO_x) by lightning may be a N_2 sink. The chemical lifetime of N_2 in Venus' atmosphere is possibly very long ($\sim 10^9$ years). In any case, the apparent dependence of the N_2 abundance on altitude is hard to understand and new measurements are required to resolve this issue.

Sulfur dioxide is the major sulfur gas in Venus' atmosphere, the third most abundant gas overall, and one of the three most important greenhouse gases. It is intimately involved in the formation of the global sulfuric acid clouds, the energy budget and greenhouse effect in Venus' lower atmosphere, and atmosphere-lithosphere interactions such as volcanism and chemical weathering. *In situ* and Earth-based measurements of the SO_2 abundance in Venus' lower atmosphere give an average abundance of about 150 ppmv (22–42 km), which decreases at higher and lower altitudes (Krasnopolsky, 1986; Bézard et al., 1993). At higher altitudes photochemical oxidation converts SO_2 into aqueous sulfuric acid cloud droplets and efficiently removes it from Venus' upper atmosphere, which contains about 15,000 times less SO_2 (10 ppbv above the clouds vs. 150 ppmv below them). At lower altitudes gas phase thermochemistry reduces SO_2 to OCS. On a longer time-scale of ~ 1.9 million years, thermochemical reactions with CaO-bearing minerals on Venus' surface convert SO_2 into anhydrite ($CaSO_4$)

irreversibly removing SO_2 and the sulfuric acid clouds formed from it. The SO_2 lost from the atmosphere must be replenished by volcanism to maintain the global cloud cover. We return to this topic when we discuss volcanic outgassing and climate change.

Water vapor has an average abundance of about 30 ppmv below Venus' clouds. It is even less abundant above the clouds where only a few parts per million of water vapor are observed. Water reacts with H_2SO_4 to form hydronium (H_3O^+) and bisulfate (HSO_4^-) ions. Thus the concentration of "free" H_2O in concentrated sulfuric acid is very small. As a result, the H_2O partial pressure over the cloud droplets is less than that over water ice at the same temperature. The atmospheric H_2O abundance varies spatially and temporally (above and below the clouds). Although a trace gas, H_2O is the major hydrogen reservoir in Venus' atmosphere and is one of the three most important greenhouse gases. It is also involved in gas-solid reactions that regulate, or buffer, atmospheric HCl and HF. These reactions apparently equilibrate rapidly because HCl and HF concentrations above the clouds are the same, within error, as those below the clouds measured about 20 years later. Over a much longer time scale (10^8 – 10^9 years), water loss via H escape to space and oxidation of ferrous iron minerals in Venus' lithosphere regulate the oxidation state of Venus' atmosphere and surface. Volcanism and possibly cometary impacts replenish atmospheric water vapor. The H_2O abundance in Venus' atmosphere is equivalent to a global layer of water one cm thick. However, liquid water is unstable on Venus' hot surface. We consider the isotopic composition of Venusian water when we discuss atmospheric evolution.

The strong infrared nightglow of O_2 at 1.27 μm and the Herzberg II nightglow at 400–800 nm show that molecular oxygen is a trace species in the 100–130 km region of Venus'

upper atmosphere (Krasnopolsky, 1986). The spectroscopic upper limit for O_2 in Venus' lower atmosphere below ~ 100 km is less than 0.3 ppmv. For comparison, the Martian atmosphere contains 1300 ppmv O_2 , which is also produced by solar UV photolysis of CO_2 . The extremely small O_2 abundance on Venus shows that the catalytic recombination of $O + CO$ produced by solar UV photolysis of CO_2 is very efficient because the O_2 abundance is at least 4,300 times smaller than on Mars although the solar flux is about four times larger than on Mars. Yung and DeMore (1999) describe the CO_2 photochemical cycles on Mars and Venus.

Comparisons to Earth's atmosphere

Earth is an interesting and informative contrast to Venus. Oxygen makes up about 21% of dry air in Earth's atmosphere, with the balance being mainly N_2 (78%), Ar (9340 ppmv), and CO_2 (387 ppmv). The average surface temperature and pressure at sea level are 288 K and one atmosphere. The temperature gradient in the terrestrial troposphere (0–12 km) is an average of the dry and wet adiabatic gradients. Earth is about 50% covered by water clouds at any time. The H_2O abundance in the troposphere ranges from 1 to 4% and is highest near the equator and lowest near the poles. The H_2O concentration in tropospheric air decreases with altitude and roughly corresponds to 50% relative humidity at any level. The stratosphere contains much less water than the troposphere, about 2–7 ppmv. This is about the same as expected (5 ppmv) from the vapor pressure over water ice at 195 K, the temperature of the tropical tropopause. Some stratospheric water is mixed upward through the tropical tropopause while the rest is produced from CH_4 oxidation by OH radicals. Most of the water at Earth's surface is in the oceans, which are equivalent to a global layer about 2.7 km thick. There is about 270,000 times as much observable water on Earth as on Venus.

In contrast to Venus (and Mars), CO_2 is a trace gas in Earth's atmosphere with an abundance of ~ 387 ppmv. About 25% of this is anthropogenic and biological sources account for most of the rest. Volcanism is only a minor source of CO_2 in Earth's atmosphere. Most of the carbon at Earth's surface is in the crust (6×10^{19} kg), with carbonates making up 80% of this and organic carbon the remainder. Earth's crustal carbon reservoir is much larger than the oceanic (3.8×10^{16} kg), biospheric (3.7×10^{15} kg), or atmospheric (7.6×10^{14} kg) reservoirs.

Several of the reactive trace gases observed in Venus' atmosphere are also present in Earth's atmosphere, but at much lower abundances. The sources and sinks of these reactive trace gases are also generally different on Venus and Earth. For example, SO_2 has an abundance < 1 ppmv in the terrestrial troposphere and is mainly due to anthropogenic emissions and to a lesser extent volcanic outgassing. Carbonyl sulfide is present at about 0.5 ppbv in Earth's troposphere (versus ~ 4400 ppbv on Venus) and is mainly due to biogenic emissions (instead of volcanic outgassing and sulfide chemical weathering on Venus). Most of the sulfur at the surface of the Earth is in sedimentary deposits of gypsum $CaSO_4 \cdot 2H_2O$ (28%) and pyrite FeS_2 (57%), or as sulfate dissolved in the oceans (15%). Hydrogen chloride (~ 1 ppbv) and HF (~ 0.03 ppbv) are virtually absent from Earth's troposphere. Methyl chloride (CH_3Cl) present at ~ 0.5 ppbv and the chlorofluorocarbon (CFC) gases are the major Cl and F gases. The two major CFC gases are CF_2Cl_2 (~ 0.4 ppbv) and $CFCI_3$ (~ 0.2 ppbv). Methyl chloride results

from biogenic emissions but the CFC gases are produced industrially and have no natural sources. The atmospheric inventories of F and Cl are negligible in comparison to the oceanic and crustal inventories. About 75% of all Cl at Earth's surface is Cl^- dissolved in the oceans and essentially all F is found in the crust (Lodders and Fegley, 1997). However, the crustal (or oceanic) inventories of S, Cl, and F on Earth are much larger than the atmospheric inventories of these elements on Venus. Assuming that Venus and Earth have a similar bulk chemical composition, this suggests that significant amounts of S, Cl, and F remain in Venus' lithosphere instead of being completely degassed into its atmosphere.

The Earth's atmosphere contains over 10,000 times more O_2 than Venus' atmosphere and $\sim 15,000$ times more O_2 than the Martian atmosphere. Photosynthesis is the major source of O_2 in the terrestrial atmosphere and accounts for the large disparities between O_2 on Earth and on Venus and Mars.

The major differences between Venus' atmosphere and the terrestrial atmosphere are as follows:

1. Venus' atmosphere contains large amounts of C, S, Cl, and F relative to the atmospheric inventories on Earth. The high temperatures on Venus promote the outgassing of these rock-forming elements into its atmosphere.
2. The large amounts of CO_2 and SO_2 driven into Venus' atmosphere maintain a super-greenhouse effect and a surface temperature over 3 times higher than the blackbody temperature.
3. Venus' atmosphere is much drier than Earth's atmosphere. However the tiny amount of atmospheric water vapor on Venus also helps to maintain the super-greenhouse.
4. Venus' atmosphere contains only trace amounts of O_2 , which is the second most abundant gas on Earth because of the presence of life.

As mentioned earlier, Venus' lack of water is primarily responsible for all these differences.

Origin of Venus' volatile inventory

The Sun and all the planets in our solar system formed about 4.56 billion years ago from a cloud of gas and dust known as the solar nebula. The elemental abundances in the solar nebula were the same as those in the Sun when it formed and are known as solar system abundances (Lodders, 2003). Figure A45 shows a comparison of the abundances of chemically reactive volatile elements (e.g., H, C, N, S, Cl, F) and chemically inert volatile elements (Ne, Ar, Kr, Xe) on Venus and Earth relative to their solar system abundances. The volatile elements H, C, and N are plotted as H_2O , CO_2 , and N_2 in Figure A45, which are the major gases of these elements in the atmospheres of Venus and Earth. They are depleted relative to their solar system abundances because Venus and Earth captured only part of the solar system abundance of each volatile during their formation. However, the chemically reactive volatiles are not as depleted as the noble gases. For example, Venus contains about 10^{-9} of the Ne solar system abundance but has about 10^{-5} of the N solar system abundance. Nitrogen and neon have similar atomic weights (14.007 vs. 20.183) and have similar solar system abundances (1.95×10^6 atoms vs. 2.15×10^6 atoms). However, nitrogen forms minerals such as osbornite (TiN), sinoite ($\text{Si}_2\text{N}_2\text{O}$), and carlsbergite (CrN), while neon is inert and does not. Likewise Earth contains about 2×10^{-9} of the argon solar system abundance and about 7×10^{-5} of the sulfur solar system

abundance. Sulfur and argon also have similar atomic weights (32.06 vs. 36.32 for primordial argon) and similar solar system abundances (4.45×10^5 atoms vs. 1.02×10^5 atoms). Sulfur occurs in troilite (FeS) and other minerals, but argon does not form minerals. The larger depletions of noble gases and the smaller depletions of chemically reactive volatiles suggest that the atmospheres of Earth (e.g., Brown, 1949) and Venus primarily formed from volatile-bearing solids that outgassed during and after planetary accretion. The occurrence of volatile-bearing minerals in chondritic meteorites, which are relatively unaltered samples of nebular material, supports this argument.

Two observations suggest that Venus and Earth may have captured some nebular gas during their formation. Recent work on hafnium-tungsten (Hf–W) dating of meteorites indicates rapid accretion and early core formation for the terrestrial planets within the first 30 million years of solar system history (Yin et al., 2002; Kleine et al., 2002). In Cameron's (1995) model of the solar nebula, the loss of nebular gas, which is the last stage of nebular evolution, takes 3–30 million years. A possible implication of the Hf–W dating is that the terrestrial planets accreted in the presence of residual nebular gas and captured some of it. However, the nebular lifetime is uncertain and the recent Hf–W results are somewhat controversial. The second observation is that ^3He is currently degassing from the Earth's mantle. This discovery led to a large amount of work on the isotopic composition of other noble gases released from Earth's mantle. There is some evidence for degassing of Ne with solar isotopic ratios (primordial Ne), but there is little or no evidence for degassing of primordial Ar, Kr, or Xe from Earth's mantle (Ozima and Podosek, 2002). Pepin and Porcelli (2002) discuss the origin of noble gases on Venus, Earth, and Mars in some detail.

Dry versus wet accretion of Venus

Figure A45 graphically shows Venus' depletion in water relative to the Earth (about a factor of 270,000). As mentioned earlier, Venus may have formed "dry," or may have formed "wet" and subsequently lost most of its water. An initially "dry" Venus is predicted by the equilibrium condensation model. This model predicts the chemical composition of gas and grains in the solar nebula as a function of temperature and pressure, which vary as a function of radial distance from the Sun. The equilibrium condensation model predicts that Venus formed "dry" and that Earth formed "wet" because hydrous minerals were unstable where Venus formed but stable where Earth formed. Venus' meager water inventory is the result of cometary impacts over time (Lewis, 1974). The equilibrium condensation model explains the density difference between Venus and Earth, first order trends in planetary bulk compositions, and many chemical and mineralogical features of chondritic meteorites (Lewis and Prinn, 1984; Kerridge and Matthews, 1988).

However, persuasive arguments can be made against an initially "dry" Venus. Dynamical models of planetary accretion predict significant overlap of accretion zones for Venus and Earth (Weidenschilling, 1976). The overlap would lead to similar water inventories on the two planets. A second argument is that hydrous mineral formation is probably impossibly slow at the cooler temperatures where hydrous minerals are thermodynamically stable in the solar nebula (Fegley, 2000). This would lead to both planets accreting "dry" rock with water being supplied by subsequent impacts of icy planetesimals and comets

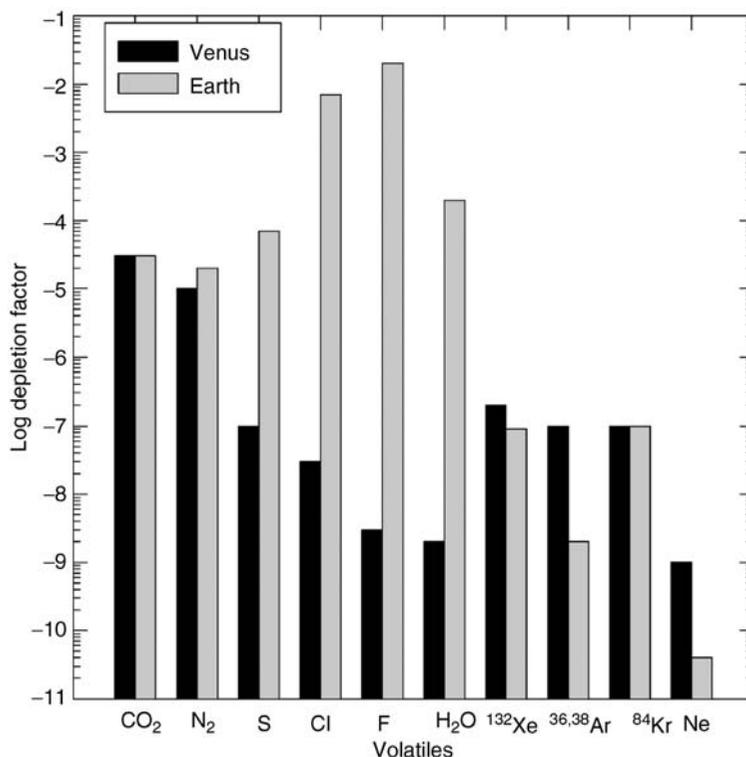

Figure A45 Depletions of chemically reactive volatiles and noble gases on Venus and Earth relative to their solar system abundances.

that are gravitationally scattered into the inner solar system by the outer planets.

We now consider the alternative that Venus formed “wet” and subsequently lost most of its water. Chondritic meteorites are often used as analogs for the types of material accreted by the terrestrial planets during their formation. Water contents of chondritic meteorites range from 9.5 to 10.8% (by mass) in the volatile-rich CM and CI carbonaceous chondrites, to 0.3–1.1% in the ordinary (H, L, LL) chondrites (Lodders and Fegley, 1998; Tables 16.10 and 16.11). For comparison, Earth’s hydrosphere corresponds to a water content of about 0.03%. As discussed elsewhere (Lodders and Fegley, 1997), Venus, Earth, and Mars each apparently formed from a mixture of chondritic material. In this case, formation of either an initially “moist” or “wet” Venus seems unavoidable. For example, the four-component meteorite model of Morgan and Anders (1980) predicts 0.03% water in Venus, which is comparable to Earth’s inventory.

The deuterium (D) to hydrogen (H) atomic ratio in Venusian water is 0.025 ± 0.005 , which is about 160 ± 32 times larger than the terrestrial D/H ratio of 1.558×10^{-4} in standard mean ocean water (SMOW). The high D/H ratio strongly suggests Venus originally had more H₂O (equivalent to 4–530 meters of liquid water) and lost most of it over time (Donahue et al., 1997). This interpretation assumes that Venusian water started with a D/H ratio like that of terrestrial ocean water. However, some chondritic meteorites, comets, and interplanetary dust particles have D/H ratios ranging up to 50 times the terrestrial value (Irvine et al., 2000; Table III). It is possible that Venus formed with a higher D/H ratio than the Earth. If so, Venus

may have had less water than if it formed with an Earth-like D/H ratio.

Even though the high D/H ratio is a good indicator, it is only indirect proof that Venus was initially “wet.” However, if Venus once had water, hydrous minerals, such as amphiboles, should have formed. Amphiboles are common on Earth and are found in metamorphic and igneous rocks. Experimental studies show that tremolite, one of the most common amphiboles, decomposes very slowly at Venus surface temperatures. Extrapolation of laboratory data shows that 50% decomposition of μm -size grains takes 2.7 billion years, and complete decomposition about 10 times longer. These data indicate tremolite and other amphiboles that formed on Venus during a wetter era in the past could still exist on Venus today and provide evidence that Venus was wet (Johnson and Fegley, 2003).

Venus’ accretionary atmosphere

The terrestrial planets probably formed by the accretion of smaller planetesimals (Wetherill, 1980). Impact devolatilization of sufficiently large planetesimals probably generated accretionary atmospheres containing N₂, CO₂, H₂O, and other volatiles once Venus (or Earth) reached about 10% of their present mass (Ahrens, 1993). Such accretionary atmospheres are called “steam” atmospheres, although H₂O is not necessarily the most abundant gas. Significant amounts of H₂, generated by the water gas reaction

or by the oxidation of Fe metal

to FeO-bearing minerals, may have been present in the “steam” atmospheres. Carbon, nitrogen, and sulfur gases such as CO_2 , CO , CH_4 , N_2 , NH_3 , SO_2 , H_2S , and OCS were probably also present in the “steam” atmospheres, with relative abundances dependent upon temperature, pressure, and oxidation state at a given time during planetary formation.

Matsui and Abe (1986) modeled the formation and properties of “steam” atmospheres on Venus and Earth. They found that accretion of planetesimals containing $\sim 0.1\%$ water, similar to that in some ordinary chondrites, led to development of a massive “steam” atmosphere on Venus. The greenhouse effect of this atmosphere trapped so much heat that Venus melted (at ~ 1500 K) once it reached about 40% of its current radius. The mass of Venus’ “steam” atmosphere reached about 10^{21} kg ($P \approx 100$ bar), comparable to that of Earth’s present hydrosphere, and was controlled by the solubility of water in molten silicate magma. However, Matsui and Abe’s (1986) conclusions are somewhat model dependent, and the existence and fate of a “steam” atmosphere on Venus remain unclear (Pollack, 1991).

After Venus had formed, its “steam” atmosphere may have rained out to form hot oceans or all the water may have remained in the atmosphere if the surface temperature remained above the critical point of water (647 K). Some of the water dissolved in the silicate magma may have crystallized as kaersutite, hornblende, or other igneous amphiboles. But, whether or not Venus ever had a “steam” atmosphere, the evolution of Venus’ water inventory is closely connected to the origin of the runaway greenhouse.

Origin of the runaway greenhouse and water loss

Models by Ingersoll (1969) and Rasool and deBergh (1970) qualitatively showed that Venus has a runaway greenhouse effect while Earth does not because Venus formed closer to the Sun. Once some H_2O or CO_2 was in Venus’ atmosphere, greenhouse warming led to sufficiently high surface temperatures to vaporize water and thermally decompose carbonates. Rasool and deBergh (1970) also suggest that reaction (1) and its analogs may have regulated the increasing CO_2 pressure as a function of temperature.

In both models, UV sunlight decomposed H_2O to its constituent elements with hydrogen loss to space. The hydrogen loss rates on Venus and Earth today (and presumably in the past) are controlled by the total H-atom mixing ratio ($f_{\Sigma\text{H}}$) at the homopause (above which diffusive separation of gases occurs)

$$f_{\Sigma\text{H}} = f_{\text{H}} + 2f_{\text{H}_2} + 2f_{\text{H}_2\text{O}} + f_{\text{HCl}} + f_{\text{HF}} \quad (5)$$

Venus’ hydrogen loss rate is currently $\sim 10^7$ H $\text{cm}^{-2} \text{s}^{-1}$, which could remove a global water layer only 21 cm thick over the age of the solar system. Loss rates $\sim 10^5$ times larger are required to remove an ocean’s worth of water in a geologically short time. These occur during hydrodynamic escape, which could have been driven by the significantly higher extreme UV flux that is expected to have been produced from the early Sun. A hydrodynamic flux of $\sim 10^{12}$ H $\text{cm}^{-2} \text{s}^{-1}$ could remove ~ 470 meters of water from Venus in 100 million years and produce the elevated D/H ratio observed on Venus today (e.g., Donahue et al., 1997).

However, astrophysical models predict that the early Sun’s visible solar flux was about 25–30% less than today. Because

of the lower solar flux, the runaway greenhouse (and water loss) may have happened some time after Venus formed, rather than right away (Pollack, 1991). Hydrodynamic escape of hydrogen is not viable once the solar extreme UV flux has declined. Instead, hydrogen loss occurs ~ 100 times slower via other non-thermal processes that remove much less water from Venus over time (~ 47 meters per 10^9 years). An initially “moist” Venus may be more likely than an initially “wet” Venus.

Huge amounts of residual O_2 are left after losing an ocean’s worth of hydrogen. For example, the loss of 2.7 km of water from Venus, equivalent to Earth’s oceans, would leave behind 1.1×10^{21} kg of O_2 , about 35 times the total amount of O_2 produced by photosynthesis on Earth over time. Loss of 470 meters of water leaves behind 1.9×10^{20} kg of O_2 , about 6 times Earth’s total photosynthetic oxygen. The disposal of so much oxygen is a formidable problem. One possibility is oxygen loss to space. This occurs on Venus today at a rate that would leave behind $\sim 30\%$ of the oxygen in water. However, if oxygen was not lost to space, all of it had to be consumed by chemical reactions.

On Earth about 96% of all O_2 produced over time was consumed by oxidation of reduced carbon, iron, and sulfur compounds and only 4% resides in the atmosphere. Currently, the major O_2 sinks on Earth are oxidation of organic carbon to CO_2 (1.6×10^{11} kg yr^{-1}), ferrous to ferric iron (4.7×10^{10} kg yr^{-1}), and sulfides to sulfate (6.2×10^{10} kg yr^{-1}), summing to 2.69×10^{11} kg $\text{O}_2 \text{ yr}^{-1}$ (Warneck, 1988). Oxidation of reduced carbon accreted by Venus plausibly happened during impact devolatilization. This leaves oxidation of reduced iron and sulfur in Venus’ lithosphere as possible O_2 sinks. The XRF elemental analyses of Venus’ surface found iron (8–9% “FeO”) and sulfur (0.9–4.7% SO_3), whose abundances are conventionally reported as oxides although their chemical form is unknown. The sulfur content of Venus’ lithosphere is probably closer to that in Earth’s mantle (0.04%) or oceanic crust (0.1%) than that found on the surface because reaction (2) adds sulfur by chemical weathering. If Venus’ lithosphere initially contained 10% “FeO,” which is oxidized to hematite (Fe_2O_3) or magnetite (Fe_3O_4), 1.9×10^{20} kg of O_2 would have to react with 0.5–0.8% of the lithosphere to be consumed. Removal of all this O_2 over 100 million years while water is lost requires a volcanic eruption rate of ~ 140 $\text{km}^3 \text{ yr}^{-1}$ to expose this much lithosphere to the atmosphere. For comparison, Earth’s volcanism rate is ~ 20 $\text{km}^3 \text{ yr}^{-1}$, and the estimated rate on Venus is $1 \text{ km}^3 \text{ yr}^{-1}$ (see below). A 100 million year removal rate also corresponds to a sink of $\sim 1.9 \times 10^{12}$ kg $\text{O}_2 \text{ yr}^{-1}$, which is ~ 7 times larger than the current O_2 loss rate on Earth. It is difficult to see how so much O_2 could be lost so rapidly on Venus or how so much lithosphere could be exposed so rapidly. It again seems that an initially “moist” Venus is more plausible than an initially “wet” Venus.

Volcanic outgassing and climate change

As mentioned earlier, CO_2 , SO_2 , and H_2O are the three most important greenhouse gases in Venus’ atmosphere. All three gases are common constituents of terrestrial volcanic gases and volcanism is a probable source for all three gases on Venus. Furthermore, all three gases are probably involved in atmosphere-lithosphere reactions on Venus. These and other arguments suggest that atmospheric chemistry and physics,

climate, and volcanism are closely linked on Venus (e.g., Bullock and Grinspoon, 2001).

The relative abundances of SO₂, OCS, H₂S, and elemental sulfur vapor (dominantly S₂) in Venusian volcanic gases are unknown. Sulfur dioxide is generally the major sulfur compound in basaltic volcanic gases on Earth, followed by H₂S, OCS, and elemental sulfur vapor. Venusian basalts probably erupt at higher or similar temperatures as terrestrial basalts. If Venusian volcanic gases are as oxidized as (or more oxidized than) terrestrial volcanic gases, SO₂ should be the major sulfur gas. More oxidized gases may also contain up to ~200 ppmv SO₃, which may provide an observational test for water loss and O₂ consumption on Venus. The large CO₂ and very low H₂O abundances in Venus' atmosphere imply that S₂ and OCS should be more abundant than H₂S in Venusian volcanic gases. For comparison, SO₂ and S₂ are the two major species in volcanic gases on Io, which has apparently lost all or most of its hydrogen and carbon.

As discussed earlier, reaction (2) would remove all SO₂ (and thus the sulfuric acid clouds) from Venus' atmosphere in ~1.9 million years in the absence of a volcanic source. Sulfur dioxide undergoes similar reactions with other calcium-bearing silicate minerals such as anorthite, diopside, and wollastonite, forming anhydrite (CaSO₄) by reactions analogous to equation 2. The measured Ca/S ratios are greater than unity at the *Venera 13*, *14*, and *Vega 2* sites. These ratios are larger than one, which is the expected value if all Ca were combined with S in anhydrite. Thus, loss of atmospheric SO₂ via chemical weathering of Ca-bearing minerals on Venus' surface is probably an ongoing process.

Maintenance of atmospheric SO₂ at current levels requires eruption of ~1 km³ yr⁻¹ of lava with the average composition of the *Venera 13*, *14*, and *Vega 2* landing sites. This volcanism rate is the same as the average rate of subaerial volcanism on Earth and is about 5% of the total volcanism rate of ~20 km³ yr⁻¹. The required sulfur eruption rate to maintain SO₂ on Venus at steady state is ~2.8 × 10¹⁰ kg yr⁻¹. This is similar to the SO₂ emission rates of 9 × 10⁹ kg yr⁻¹ (subaerial), 1.9 × 10¹⁰ kg yr⁻¹ (submarine), and 2.8 × 10¹⁰ kg yr⁻¹ (total) from terrestrial volcanism (Charlson et al., 1992).

Volcanism on Earth and on Io is episodic. By analogy, Venusian volcanism should be episodic, which may be one reason why active volcanism has not yet been seen on Venus. However, a volcanic source for SO₂ is required at present. What may happen if the volcanic source and anhydrite sink for SO₂ are not balanced? If less SO₂ is erupted than is lost by anhydrite formation, less SO₂ will be left in the atmosphere, less H₂SO₄ will be produced, and fewer clouds will form. Temperatures in Venus' atmosphere and at the surface may decrease because SO₂ as well as other volcanic volatiles such as CO₂ and H₂O are greenhouse gases, all of which are needed for the Venusian supergreenhouse state. As temperatures drop, the carbonates magnesite (MgCO₃) and dolomite (CaMg(CO₃)₂) may become stable and consume atmospheric CO₂ as they form. Conversely, if more SO₂ is erupted than is lost by anhydrite formation, more SO₂ will be added to the atmosphere, more H₂SO₄ will be produced, and more clouds will form. In this case, atmospheric and surface temperatures may rise as more greenhouse gases enter the atmosphere. Minerals now stable at 740 K on Venus' surface may decompose as temperatures increase, releasing more volatiles into the atmosphere (e.g., HCl, HF, elemental sulfur vapor). Some of these effects, which could operate in the future and may have done

so in the past, have been studied in climate models that incorporate variations of SO₂ and H₂O abundances on the clouds and temperatures on Venus (e.g., Bullock and Grinspoon, 2001). In particular, large temperature changes are predicted to result from the putative global resurfacing of Venus 500 ± 200 million years ago.

BANDED IRON FORMATIONS AND THE EARLY ATMOSPHERE

IRON FORMATIONS, a class of chemical sediments comparable to evaporites or phosphorites, occur on all continental cratons and represent the largest repositories of iron ever precipitated from Earth's hydrosphere (Trendall and Morris, 1983; Clout and Simonson, 2005). Iron formations reveal much about the composition of the atmosphere because of the redox sensitivity of iron in solution, and because of the dramatic change in the way iron was deposited through geologic time. The first-order observations are that Precambrian iron-rich sediments (known as *iron formations*) are generally cherty, thinly laminated (or banded), and widespread, whereas Phanerozoic iron-rich sediments (known as *IRONSTONES*) generally lack chert and are richer in aluminum (reflecting clastic contamination), not laminated, and smaller in areal extent. In order to make correct inferences about temporal changes in Earth's atmosphere, iron formations must first be understood as chemical sediments.

Sedimentary characteristics of iron formations

Many iron formations have well-preserved sedimentary features, which permit them to be subdivided into banded and granular varieties. *BANDED IRON FORMATIONS* (BIFs) are by far the more abundant of the two. The present minerals in the least-altered BIFs are remarkably fine-grained and uniform, and although recrystallized, it is likely they have been largely derived from the primary precipitates. Layers rich in iron and chert generally alternate on a scale of millimeters to centimeters (Figure B1a), and many BIFs exhibit cyclic alternations of iron-rich and iron-poor minerals or of BIF and fine shaly or volcanoclastic strata (Trendall and Blockley, 1970; Ewers and Morris, 1981; Beukes, 1984). Based on these characteristics, BIF minerals (or their precursors) are inferred to have formed in the water column and precipitated to the seafloor below storm wave base in waters that were not in direct connection with the atmosphere.

In contrast to BIFs, *GRANULAR IRON FORMATIONS* (GIFs) consist largely of well-sorted sand-size clasts referred to as "granules" that were transported in high-energy environments where ocean waters mixed much more freely with atmospheric gases. Most of the clasts appear to be reworked fragments of BIF precursor muds (Figure B1b) but some GIFs are also rich in concentrically laminated ooids that grew on the seafloor. GIFs have dune-scale cross-bedding that is more irregular than the banding of BIFs and shows complex paleocurrent patterns typical of shallow marine sands (Ojakangas, 1983; Simonson, 1985). Flat pebble conglomerates and stromatolites are locally abundant. GIFs also contain an abundance of intergranular cement that consists largely of void-filling chalcedony and drusy quartz (Simonson, 1987) and were emplaced so rapidly that some GIFs show virtually no compaction. The presence of gelatinous silica also led to the formation of intra- and intergranular syneresis cracks (Gross, 1972; Beukes, 1984). Early silica cementation helped to preserve primary iron-rich phases with minimal alteration, as well as some of the best early Precambrian microbiotas (Walter and Hofmann, 1983).

Mineralogically, iron formations consist of one or more iron-rich minerals admixed with quartz-rich layers interpreted as recrystallized cherts (Maliva et al., 2005). The main iron minerals fall into four groups that James (1954) defined as the "facies" of iron formation. His groups were oxide, silicate, carbonate, and sulfide, but most iron formations are hybrid mixtures with iron minerals from two or even three of these groups. In unaltered iron formations lacking clastic contamination, the dominant iron minerals are magnetite and hematite in the oxide facies; greenalite in the silicate facies; siderite, ankerite or ferroan dolomite in the carbonate facies; and pyrite in the sulfide facies. Detailed petrographic and isotopic studies of finely-laminated BIFs and GIFs rich in early cement suggest that chert, greenalite, siderite and hematite (or more poorly-ordered precursors of similar composition) are the minerals most likely to have formed as primary precipitates. All other phases are viewed as diagenetic or metamorphic overprints (Klein, 1983; Kaufman et al., 1990).

Temporal variation in stratigraphic and environmental patterns

Pure GIF (i.e., high-energy iron formation) rarely occurs in layers thicker than a few meters as it is usually interbedded with BIF on a scale of meters to tens of meters. In contrast, BIFs (i.e., low-energy iron formation) commonly contain no discernible GIF and range up to hundreds of meters in thickness. The lateral dimensions of iron formation likewise vary dramatically from thin layers sandwiched between other lithologies (e.g., volcanoclastic turbidites) to units hundreds of meters thick of nearly pure iron formation persisting laterally for hundreds of kilometers with little change (Trendall and Blockley, 1970; Beukes, 1983; Fralick and Barrett, 1995).

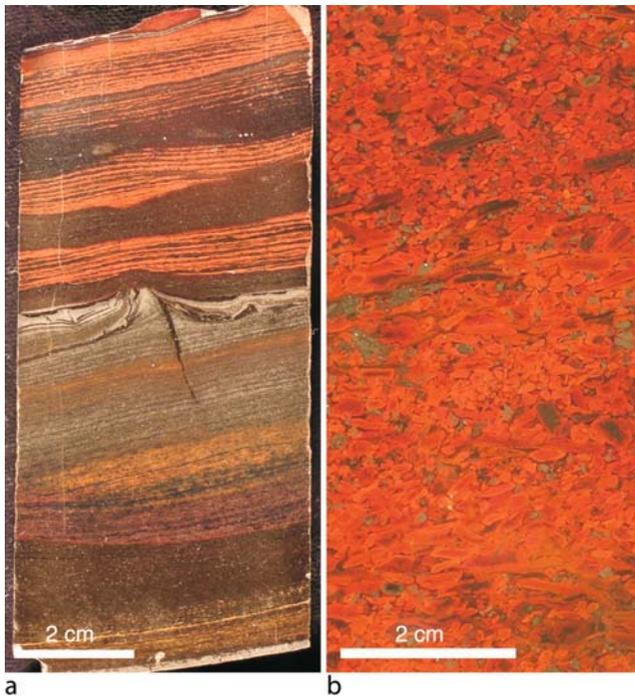

Figure B1 Sawed surfaces of iron formation samples. (a) Drill core of Dales Gorge banded iron formation (BIF, Hamersley Basin) consisting mainly of iron oxides (*silver to dark*) and hematitic chert (*reddish*). (b) Hand sample of granular iron formation from Sokoman Formation (GIF, New Quebec Orogen) consisting of unusually large intraclasts of hematitic chert and iron oxides; intergranular pores are filled with transparent chalcedonic cement.

The key to interpreting atmospheric evolution is to understand why the size, composition, and context of iron formations changed through time. Characterizing iron formations on their genetic associations as well as their sedimentary characteristics (i.e., BIF vs. GIF), Gross (1965, 1983) encapsulated the most important temporal changes by subdividing iron formations into two main categories. The category he called *Algoma-type iron formation* is a common component of Archean greenstone belts which range in age from ca. 2.7 Ga (billion years old) back to the oldest supracrustal rocks on Earth (Figure B2). By definition, Algoma-type iron formations are small and intimately associated with volcanic rocks. In addition, virtually all Algoma-type iron formations are BIFs (rather than GIFs), include significant thicknesses of all four of James' mineral facies, and are closely associated with deeper-water deposits consisting of volcanic rock, shale, and turbidites. The other category he called *Superior-type iron formation*, and these are much more massive accumulations of iron and silica that dominate the Neoproterozoic and Paleoproterozoic eras (about 2.7–1.8 Ga). Not only are Superior-type iron formations younger than most Algoma-type BIFs, they were deposited during marine transgressions on continental margins and therefore are thicker, laterally extensive, and generally associated with carbonate and siliciclastic strata (Simonson and Hassler, 1996). BIFs are the main constituent of many Superior-type iron formations, but many also contain substantial thicknesses of GIF. Moreover, Superior-type BIFs (like the Algoma-type iron formations) show the full spectrum of James' facies, whereas cherty Superior-type GIFs are rich in iron oxides and to a lesser extent iron silicates. Iron carbonates are scarce in GIFs with one notable exception, the Griquatown Iron Formation of South Africa (Beukes, 1984), which is one of the oldest of all Superior-type iron formations. In addition, BIF-rich Superior-type iron formations are associated with deep water shale and turbidites, whereas those with abundant GIFs are associated with shallow water deposits such as stromatolitic dolomites and quartzarenites (Simonson, 1985; Simonson and Hassler, 1996).

The distinction between Algoma- and Superior-type iron formations involves more than just a simple changeover at one point in time. For example, Algoma-type iron formations are not restricted to the Archean. Smaller iron-bearing volcanogenic deposits that meet the definition of Algoma-type BIFs persist into the later part of the Precambrian, and arguably even into the Phanerozoic. Moreover, Superior-type iron formations appear to be distributed unevenly in time between 2.7 and 1.8 Ga (Figure B2), possibly coinciding with discrete mantle plume events, which released voluminous iron through

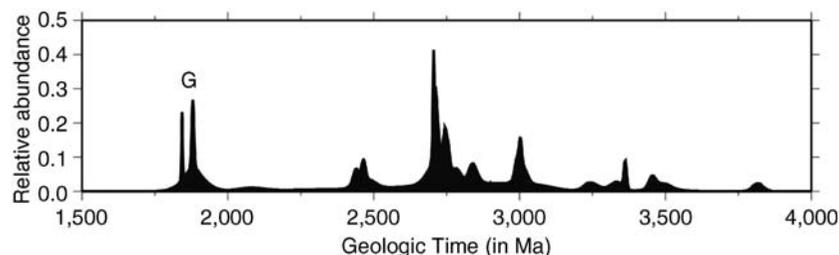

Figure B2 Time series of occurrences of iron formations in terms of numbers (but not sizes) through most of Precambrian calculated by summing Gaussian distributions of published age dates compiled by Isley and Abbott (1999); peaks under letter "G" include most of the GIFs; graph courtesy of Dr. Dallas Abbott.

hydrothermal activity (Isley and Abbott, 1999). It also appears that no BIFs were deposited during Earth's earliest glacial period (between 2.2 and 2.4 Ga) when continental glaciers and extensive sea ice covered the planet on at least three separate occasions. The deposition of large Superior-type iron formations ceased entirely around 1.8 Ga (Klein and Beukes, 1992; Simonson, 2003).

After a billion year hiatus, a remarkable, albeit brief, episode of global sedimentary iron accumulation took place in the Neoproterozoic. Iron-rich rocks that look much like BIF and meet the strict definition of iron formation were deposited in intimate association with glaciogenic sediments on several continents (Young, 1988; Derry et al., 1992). These late Precambrian iron formations tend to be richer in iron and have a simple mineralogy dominated by hematite, although both fine laminations similar to BIF and clastic textures similar to GIF are present locally (Klein and Ladeira, 2004). They also carry the geochemical signatures of a hydrothermal origin (Young, 1988; Klein and Beukes, 1993).

Implications for atmospheric history

The waxing and waning of iron formations early in Earth's long history must be linked to co-evolution of the atmosphere, hydrosphere, biosphere, and lithosphere. The sedimentary characteristics summarized above make it clear that iron formations were primary precipitates deposited mostly in open marine settings (Beukes, 1983; Ojakangas, 1983; Simonson, 1985). Cloud (1973) first suggested that dissolved ferrous iron was ubiquitous in the early ocean and that iron formations formed where photosynthesizing microbes produced free oxygen, causing iron oxides to precipitate. This hypothesis was elegant for its time, but it cannot explain the diversity of iron minerals in iron formations, nor the fact that contemporaneous carbonate sediments are depleted in iron relative to Phanerozoic carbonates (Veizer et al., 1990, 1992). To accommodate these observations, new theories evolved.

Most researchers now believe that large-scale hydrothermal activity and a stratified world ocean were important factors in the deposition of large iron formations (Klein and Beukes, 1992; Isley and Abbott, 1999). All iron formations record geochemical signatures of hydrothermal sources, and iron-rich plumes were probably capable of traveling from deep-sea sources to distant depocenters, provided that the early oceans were stratified (Isley, 1995). The need for a stratified water column mainly stems from the fact that, even though normal marine surface waters were clearly not well oxygenated in the early Precambrian, they were still too oxic to carry much dissolved ferrous iron (Trendall, 2002). Given a world ocean with a surface layer lacking dissolved iron, a deep reservoir of ferrous iron, and high concentrations of silica throughout, precipitating iron oxides and silicates such as hematite and greenalite (or suitable precursors) along a chemocline between the water masses presents no problem. Petrographic and isotopic observations also require primary precipitation of siderite (Kaufman et al., 1990; Kaufman, 1996). We attribute the siderite to a rain of calcium carbonate from shallow water environments that was dissolved as it encountered deeper and more acidic hydrothermal solutions rich in ferrous iron, as sideritic carbonate is notably less soluble than its calcium-rich counterpart (Kaufman, 1999). Exsolution or uptake of CO₂ (and iron)-rich hydrothermal solutions along a chemocline between reduced and oxidized water masses would have had a similar effect. Anomalously high variability in the isotopic composition of iron in

iron formations has been attributed to microbial involvement in their precipitation (Beard et al., 1999), but inorganic causes have also been proposed (Rouxel et al., 2005). This scenario of precipitate raining down from a chemocline explains why iron formations occurred in many different tectonic settings, associated with diverse rock types (Gross, 1983; Fralick and Barrett, 1995), and how iron accumulated essentially undiluted by other types of clastic and/or chemical sediment.

The transition from small Algoma-type to large Superior-type iron formations in the Neoproterozoic is generally attributed to the first appearance of extensive continental shelf environments rather than atmospheric evolution. Superior-type iron formations appeared at the same time and in the same basins as the first laterally extensive stable shelf deposits, e.g., platform carbonates (Grotzinger, 1994). The areal expansion of continental shelves offered larger, more uniform repositories than volcanic terrains, and presumably reflected a Neoproterozoic surge in the growth of continental crust and associated rise in sea levels (Lowe, 1992; Groves et al., 2005). "Cratonization" of shields was a highly diachronous process (Eriksson and Donaldson, 1986), which could account for the deposition of large iron formations on different continents at different times.

In contrast, the abrupt disappearance of iron formations around 1.8 billion years ago is generally attributed to a rise in the oxygen content of the atmosphere (e.g., figure 6 in Canfield, 2005). The key to terminating iron formations was to reduce the mobility of dissolved iron in the deep ocean. Although attributed to oxygenation, the first dramatic rise in atmospheric oxygen appears to have taken place much earlier, at around 2.4 Ga (Canfield, 2005). This event is generally associated with early Paleoproterozoic glaciation and the first strongly positive carbon isotope excursion recorded in marine carbonates (Bekker et al., 2001). Such excursions are indicative of the burial of a higher proportion of reduced carbon, so oxidants (like O₂) could have built up in the atmosphere at the time. Notably, the last of the Paleoproterozoic $\delta^{13}\text{C}$ excursions took place some 200–300 million years *before* iron formation deposition ended around 1.8 Ga. Given the lack of an oxidative signal, some now favor an alternative model of BIF cessation invoking increased levels of dissolved sulfide to limit iron solubility in the deep mid-Proterozoic ocean (Anbar and Knoll, 2002; Arnold et al., 2004). Whatever the change was, it clearly prevented the deep ocean from storing and transporting dissolved iron over long distances, thereby severing the connection between seafloor hydrothermal systems and continental shelf environments and putting a stop to the deposition of iron formations.

The temporal changes in Superior-type iron formations may also reflect changes in Earth's atmosphere. Most notably, the fact that the last Superior-type iron formations, the ones formed just before their abrupt disappearance around 1.8 Ga, show the greatest abundance of both GIF (Figure B2) and oxide minerals may reflect increasing concentrations of oxygen in the ocean's surface layer. Moreover, large iron formations occurred before and after, but not during, the 200 million year interval of Paleoproterozoic glaciation. Such variations are likely to record Neoproterozoic to Paleoproterozoic oscillations in both hydrothermal inputs and atmospheric oxygenation. These may have been coupled in the world ocean through the photosynthetic production of oxygen, which is stimulated by the availability of soluble iron, a known biolimiting nutrient (Coale et al., 1996). The recurrence of iron formation and iron-cemented glacial diamictites near the end of the Proterozoic suggests a brief return of localized oceanic anoxia, similarly associated with tectonic

rifting and hydrothermal delivery of iron to the oceans (Asmerom et al., 1991). Insofar as long-term nutrient-driven cycles of primary productivity may have drawn down greenhouse gases (Kaufman et al., 1997), the Neoproterozoic return of BIFs may have contributed to the widespread low latitude "snowball Earth" glaciations (Hoffman et al., 1998).

BASAL ICE

Basal ice is the ice close to the base of a glacier or ice sheet that has been affected by processes operating at the glacier bed (Hubbard and Sharp, 1989; Knight, 1997). Most of the ice in glaciers and ice sheets is formed by the accumulation of snow at the glacier surface, but basal ice is created, or substantially modified, by processes at the bed. Basal ice provides information about processes that operate in the inaccessible subglacial zone, it influences glacier dynamics, it contributes directly to glacier sedimentation, and it represents a barrier to the downward extension of the climate record to the bottom of deep ice cores. The presence of debris in the basal ice, and the processes by which it is entrained and released, are crucial to processes of glacial erosion and deposition. The basal layer is fundamental to realistically formulated models of ice sheet behavior and of the development of glacial landscapes.

Basal ice may be several tens of meters thick and comprises a variety of facies of ice and debris. Ice may be entrained from beneath the glacier, or may be derived from the glacier surface but modified by thermal, strain, and hydraulic conditions close to the bed. The characteristics of the basal ice vary widely between sites because of varying glaciological controls on basal ice formation and survival. The chemistry, physical structure, and debris content of the basal ice are different from the englacial ice above because of its interaction with the bed, and the high debris content of the basal ice affects its rheological properties and its geomorphic potential. Two key issues in the description and interpretation of the basal layer are the processes by which the ice is formed and the processes by which rock debris from the bed is entrained into the ice. Processes by which basal ice can be formed can be divided into: (a) formation and accretion of new ice at the base of the glacier and (b) metamorphic alteration of existing ice close to the bed. Entrainment of debris at the bed occurs by a variety of processes including regelation, congelation, flow of water through the vein system, shearing, and folding. The basal layer is accessible via boreholes drilled through the glacier to the bed in subglacial cavities and locations where it is exposed at the

glacier margin. Debris from the basal ice is a major source of material for glacial sedimentation, and the characteristics of the basal ice, and hence former subglacial conditions, can be reconstructed from the characteristics of basal ice debris in glacial deposits (Knight et al., 2000).

BEACHROCK

Occurrence and sedimentology

Beachrock comprises sediments deposited in the intertidal zone on the beach face, beach berm, upper shoreface, and on tidal flats that have been cemented in situ to form an indurated sedimentary rock. Beachrock outcrops are ubiquitous along modern tropical and subtropical shorelines bounded by 35° N and 35° S (Scoffin and Stoddart, 1983) (Figure B3). Beachrock forms pavements and can comprise sand to shingle size clasts forming a sandstone or conglomerate, but predominantly comprises carbonate sands. The physical sedimentology of beachrock is similar to that for cay sandstone that forms in the supratidal zone (Kuenen, 1950), submerged dune calcarenite and emerged reef rock (Hopley, 1986), although the characteristic cements of each of these rock types are distinguishable. The internal stratigraphy of beach and upper shoreface deposits is preserved during the formation of beachrock, and is often recognized by seaward dipping planar beds outcropping on the beach. Beachrock is generally friable to brittle and the outer surface is case hardened (Scoffin and Stoddart, 1983). It is subject to mechanical, biological and chemical erosion following exhumation.

Beachrock cementation: mineralogy and origin

Beach sand grain or shingle clasts are cemented by aragonite or magnesium-calcite in a marine-phreatic environment. Depending upon location, beach sands or shingle are cemented within an intertidal sediment package, through physicochemical precipitation of calcium carbonate (Ginsberg, 1953), microbial activity (Webb et al., 1999), or a combination of both. The physicochemical precipitation of carbonate cement results from the evaporation of seawater and seaward-flowing groundwaters within the beach deposits, and by CO₂ degassing of this water through wave agitation and tidal pumping (Hanor, 1978; Meyers, 1986), particularly on windward beaches (Gischler and Lomando, 1997). The form of the cement is characteristic of the diagenetic environment and includes: (a) isopachous fringes of needle cement (usually aragonite), (b) micritic, peloidal and bladed cement (often magnesium-calcite; Gischler and

Figure B3 Late Holocene beachrock outcrop on south coast Upolu Island, Samoa, following beach erosion (photograph, Ian D. Goodwin).

Lomando, 1997) in marine-phreatic (below the water table) environments where water fills the pore spaces between grains, and (c) microcrystalline rinds, laminated crusts, and needle fiber cements in meteoric-vadose (above the water table) environments where the pore spaces are filled with cement (Gischler and Lomando, 1997).

Beachrock as an indicator of former sea level

Emerged or submerged beachrock has been used in many studies as an indicator of former sea level (Hopley, 1986; Pirazzoli, 1996). Specific examples are the Bahamas (Kindler and Bain, 1993), South Africa (Cooper, 1991), and Bangladesh (Chowdhury et al., 1995). However, the application of beachrock outcrops as an indicator of former sea level requires caution (Hopley, 1986). The water level control on the upper level of cementation must be identified with respect to Mean High Water Spring Tide and Highest Astronomical Tide. The mineralogy, form and fabric of the cements must be determined and the diagenetic environment identified as marine-phreatic. The beachrock stratigraphy should be horizontal and dipping seaward. The stratigraphic relationships to overlying dune calcarenites and to coral reef below the beachrock support the reconstruction of former sea level. Dating the age of beachrock deposition has been problematic, although modern radiometric techniques using micro-samples such as accelerator mass spectrometry or thermal ionizing mass spectrometry allow the dating of cements or microfossils embedded within the beachrock. Whilst the use of beachrock as a sea level indicator has not been routine in studies, its ubiquitous nature is important in paleoenvironmental reconstructions. Since beachrock forms within the phreatic zone of beach deposits, its exposure on the surface of modern beaches is indicative of recent beach erosion on many of the Earth's tropical and subtropical beaches.

BEETLES AS QUATERNARY AND LATE TERTIARY CLIMATE INDICATORS

Insect remains are particularly abundant in freshwater sediments that have remained waterlogged since their deposition. Most of the remains are of beetles (Coleoptera) because of their

robust exoskeletons, but many other orders of insect are also preserved. Beetle species from the Quaternary and late Tertiary can be shown to be identical to their present day representatives. Most past assemblages of beetles can be shown to resemble modern communities closely. It can therefore be safely assumed that physiological stability accompanied their demonstrable morphological constancy. Thus, paleoecological and paleoclimatic inferences can be made on the basis of the past presence of particular beetle species. Many beetle species have changed their geographical ranges by thousands of kilometers even within the limited timespan of the last glacial/interglacial cycle. For instance the most abundant dung beetle in the British Isles during the middle Weichselian (Wisconsin) glaciation is now restricted to the high plateau of Tibet.

Quantification of climatic (particularly thermal) parameters may be made from these range changes. In the past, climatic interpretations were based on the overlap of the modern geographical ranges of species or the fit of the distributional margins to some isotherm, thereby inferring the paleoclimate (Coope, 1959). This method has problems that arise from the vagaries of space and time that determine geographical distributions; a species may not fulfill its total range potential for reasons other than climate.

To avoid these geographical problems, the distribution of a species can be plotted on a climate-space chart, where the mean temperature of the warmest month (TMax) is plotted on the x-axis and the difference between the mean temperature of the warmest and coldest months (TRange) on the y-axis. These figures are measured in meteorological stations. These coordinates subsume most of the important thermal constraints that determine the gross distribution of a beetle species. Assuming a simple sinusoidal relationship between the mean monthly temperatures, it is then a simple matter to infer the mean temperature of the coldest month (TMin) or any other mean monthly temperature. In this way, a ragged geographical distribution map frequently condenses into a compact grouping (Coope, 1986) and new occurrences of a species often fall within the body of the group. When plotted in terms of geographical space, new records often involve repeated redrawing of the distribution maps. Once a temperature envelope has been constructed for each species, it is much more stable and can be stored electronically in a database. As of 2003, the database included 436 species.

In order to obtain figures that are independent of those derived from the plant data, only carnivorous or scavenging species were used in these paleoclimatic calculations. Quantitative climatic estimates were made by overlapping the thermal envelopes for each species in a fossil assemblage and determining values from the coordinates of the area of greatest of mutual overlap (usually 100%). This method has been termed the mutual climatic range (MCR) method (Atkinson et al., 1987). In order to check the effectiveness of this method, present day beetle assemblages from a geographically widespread area of Eurasia were treated in the same way as fossil assemblages and the reconstructed thermal regime was compared with that measured at nearby meteorological stations. The correspondence between the MCR estimates and the measured values were generally very close but there was a slight tendency for MCR to over-estimate both summer and winter temperatures at "cold" sites. An equation has been devised that may be applied to the raw MCR data to correct this minor deviation (Coope et al., 1998).

Quantitative estimates of the thermal paleoclimate of both glacial and interglacials using the MCR method on sub-fossil beetle assemblages have now become standard practice in

Britain. The results are not always compatible with the traditional paleoclimatic interpretation of the paleobotanical (chiefly pollen analytical) records. Thus, the climates of treeless interstadials can at times be shown to be temperate and oceanic, rather than indicative of tundra coldness (Coope et al., 1997; Coope, 2000). During the late glacial period, the climate of Britain warmed to present-day levels at the beginning of the Bølling-Allerød Interstadial before there was any response from the trees. The beetles show that this climatic warming from glacial to interglacial conditions took place within the timespan of one human lifetime. The Younger Dryas cold period saw a return to fully glacial conditions. During "cold" periods, the climate of the British Isles was often of Siberian continentality with mean July temperatures at or below 10 °C and mean January/February temperatures at or below -15 °C. (Coope, 2002).

Recently the MCR method has been applied to Quaternary beetle assemblages from North America (Elias, 2000). There the record has been extended back to the latest Miocene faunas, where the presence of extant beetle species has permitted valid paleoclimatic interpretations to be made (Elias and Matthews, 2002).

BERYLLIUM-10

Beryllium is a lithophile element concentrated in the residual phases of magmatic systems. Due to its special properties as a metal (stiffness, light weight, dimensional stability), it is used in high-tech applications. Several radioactive isotopes exist beside the stable isotope of mass 9. However, only ^7Be and ^{10}Be have half-lives longer than a few seconds (Table B1).

^{10}Be production

^{10}Be is produced almost exclusively by the interaction of galactic cosmic rays with the atmosphere and other matter on the Earth's surface. In the atmosphere, neutron-induced spallation reactions with nitrogen contribute 75% of the total mean global production rate of $0.018 \text{ atoms cm}^{-2} \text{ s}^{-1}$ (Masarik and Beer, 1999). The production rate is variable in space and time. The magnetic fields originating from the Sun and Earth reduce the intensity of the galactic cosmic rays approaching the atmosphere from space.

At the Earth's surface, oxygen is the main target element in matter from which ^{10}Be is produced. The production rate is lower than in the atmosphere due to the attenuation of cosmic rays crossing the atmosphere. It decreases exponentially with increasing depth.

Temporal variability of ^{10}Be production can be caused by:

1. Supernova explosions within our galaxy that are in close proximity to Earth and enhance the galactic cosmic ray flux.
2. Solar wind streaming out of the Sun's coronal holes and affecting the propagation of cosmic ray particles through the heliosphere. High solar activity means strong shielding and low production rate. This effect is latitude dependent (Figure B4).
3. The geomagnetic field preventing cosmic ray particles with too low a rigidity (momentum per charge) entering the Earth's atmosphere.

Figure B5 shows the dependence of the mean global ^{10}Be production rate (in relative units) on solar activity, expressed by the solar activity parameter Φ , and on the geomagnetic dipole field, expressed in units relative to the present field. The range between low production (high solar activity, strong magnetic field) and high production (low solar activity, no geomagnetic field) is almost one order of magnitude.

Other production mechanisms beside spallation, such as neutron activation of ^9Be , are not important and in most cases can be neglected.

The ^{10}Be system

After it is produced in the atmosphere, ^{10}Be becomes attached to aerosols and follows their pathways. Within 1–2 years, ^{10}Be is removed from the atmosphere, mainly by wet precipitation. After deposition, several different processes are responsible for further transport and dispersion of ^{10}Be (McHargue and Damon, 1991). Figure B6 shows a schematic overview of the

main reservoirs and the corresponding ^{10}Be fluxes. The given numbers are still preliminary and to be used with caution.

Some reservoirs have residence times of many centuries or millennia. If ^{10}Be is stored in a reservoir in a stratigraphically undisturbed manner, this reservoir can be considered to be an archive. Provided a time scale is available, archives become the basis for the reconstruction of the history of production and transport of ^{10}Be . In contrast to ^{14}C , which is homogeneously mixed with ^{12}C within the carbon cycle, ^{10}Be and ^9Be are only partly mixed and therefore the isotopic $^{10}\text{Be}/^9\text{Be}$ ratio is only of limited value.

Applications

The range of applications of ^{10}Be depends strongly on the sensitivity of the analytical measuring technique. ^{10}Be was first detected by decay counting in a deep-sea sediment (Arnold, 1956). Due to the long half-life of ^{10}Be , decay counting is not very sensitive. The development of accelerator mass spectrometry (AMS) increased the detection limit by about 6 orders of magnitude, which opened up a large variety of new

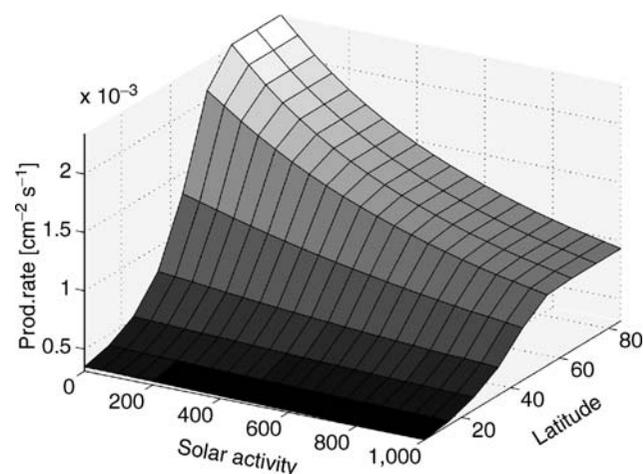

Figure B4 Dependence of the ^{10}Be production rate on latitude and solar activity.

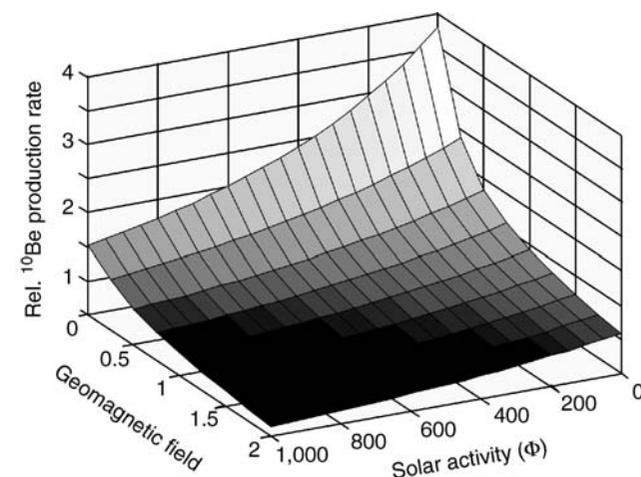

Figure B5 Dependence of the ^{10}Be production rate on solar activity (Φ) and magnetic field strength.

Table B1 Half-lives of ^7Be and ^{10}Be

	$T_{1/2}$	Product
^7Be	53.4 d	^7Li
^{10}Be	$1.51 \pm 0.06 \text{ My}$	^{10}B

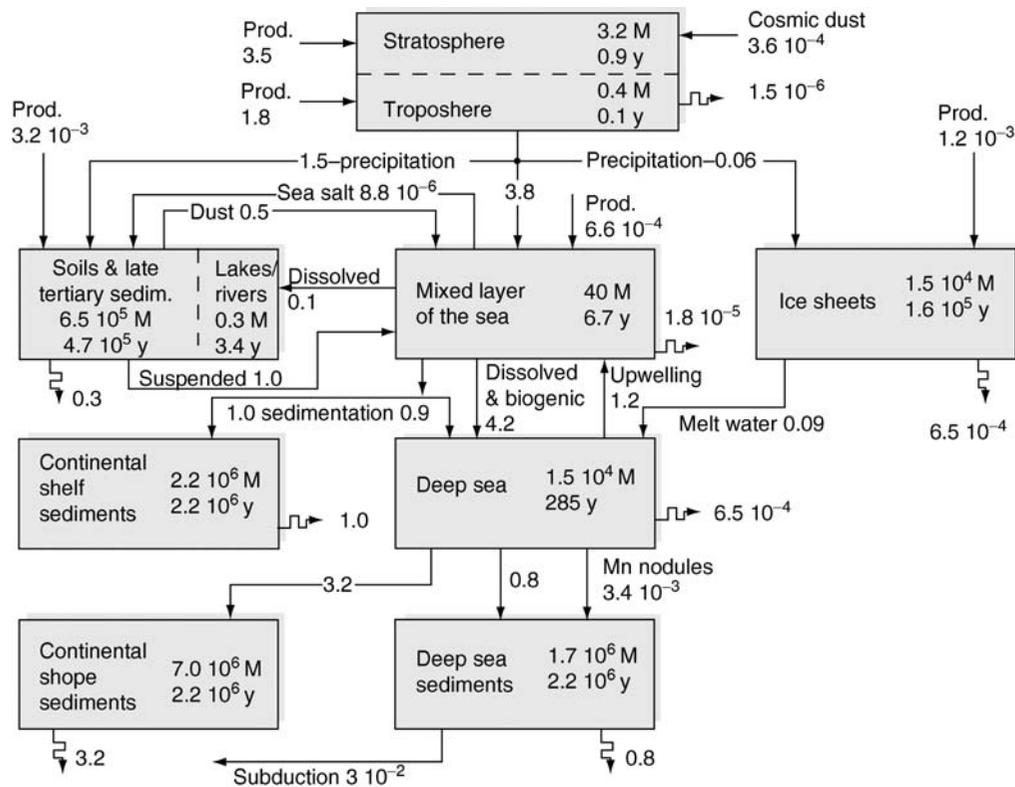

Figure B6 The ^{10}Be system. The inventories of the reservoirs are given in moles and the fluxes between the reservoirs in moles per year. (Modified after McHargue and Damon, 1991).

applications (Lal, 2000). The applications can be divided into three categories, related to production, transport and dating:

Production

All the applications in this category are based on the fact that changes in cosmic ray intensity or in the energy spectrum lead to changes in the production rate of ^{10}Be . So far, no significant fluctuations in the galactic cosmic rays outside the heliosphere have been detected. However, a supernova explosion in our galaxy could significantly increase the cosmic ray intensity.

The solar modulation effect offers the unique opportunity to trace solar activity back in time over many millennia and discover cycles and periods of reduced (e.g., Maunder Minimum) or enhanced activity. Satellite-based measurements show that solar irradiance (solar constant) and solar activity are related. This opens up the possibility of using a ^{10}Be record to estimate the effect of solar variability on the climate and establishing a long-term solar forcing function (Beer et al., 2000).

Using the known relationship between ^{10}Be production rate and the geomagnetic field (Figure B5), the field intensity can be reconstructed. Results from ice cores clearly show magnetic excursions such as the Laschamp event 40,000 years ago. ^{10}Be records from sediments can also be used but are more difficult to interpret.

Transport

All the different processes shown in Figure B6 can potentially be studied using ^{10}Be as a tracer. A short summary of some typical applications is given in the following.

Mixing within the atmosphere and exchange between stratosphere and troposphere occurs on short time scales of weeks to 1–2 years that can be investigated by using the $^{10}\text{Be}/^{7}\text{Be}$ ratio.

^{10}Be deposited on land becomes adsorbed to particles depending on the pH. In arid areas such as deserts, some of the fine dust particles are picked up and transported over long distances to other areas, forming loess deposits. Their accumulation rate can be derived from the total ^{10}Be flux, composed of the eolian and the local atmospheric components. In humid areas, soil erosion removes some of the deposited ^{10}Be . The erosion rate can be derived by analyzing either the total inventory of ^{10}Be or the ^{10}Be depth profile. ^{10}Be transport in aquatic systems occurs in either soluble form or bound to organic matter with too low a density to sediment. The insoluble part of ^{10}Be entering the oceans is finally scavenged into the sediments. The sediment is transported slowly with the oceanic plates, and at the continental margin a small part may become subducted and incorporated into the magma of a volcano.

Dating

An important aspect of ^{10}Be and other radionuclides is dating. There are different ways to use ^{10}Be as a dating tool: (a) characteristic features such as peaks caused by geomagnetic excursions (e.g., Laschamp event, 40,000 BP) or periods of reduced solar activity can be used as time markers to synchronize different records; (b) The decreasing concentration of ^{10}Be with increasing depth in a sediment can be attributed to the radioactive decay, which reveals an age scale; (c) A rock or mineral (e.g., quartz) that is shielded by ice, water or other matter basically contains

no ^{10}Be . If the shielding is removed and the rock is exposed to cosmic rays, ^{10}Be production occurs. From this known production rate and the measured ^{10}Be concentration, the exposure time can be calculated, assuming a certain erosion rate of the rock surface. Combining several different cosmogenic radionuclides enables determination of both the exposure age and the erosion rate (Bierman, 1994).

BINGE-PURGE CYCLES OF ICE SHEET DYNAMICS

Background

Binge-purge cycles of ice sheets are based on a hypothesis that ice sheets may exhibit short periods of enhanced ice flow (the purge phase) followed by longer spells of much slower flow (the binge phase). This behavior is thought to be controlled by internal ice sheet dynamics and, hence, may occur under stable environmental conditions. The main application of this hypothesis has been to the Laurentide Ice Sheet, which lay across much of North America during the last ice age (e.g., Siebert, 2001).

Binge-purge cycles and the Laurentide ice sheet

Marine sedimentological investigations have revealed a series of ice rafted debris deposits across the North Atlantic, corresponding to the 7,000 year periodic production of huge volumes of icebergs, named Heinrich layers (Heinrich, 1988; Bond et al., 1992). The cause of Heinrich layers is still debated. However, a commonly held view is that they were formed by periodic unstable flow of the Laurentide Ice Sheet during the last glaciation; the so-called “binge-purge” theory (MacAyeal, 1993a, b). The explanation of this theory is as follows (Figure B7). From a relatively stable configuration, the ice sheet slowly builds up over an essentially frozen base (the binge phase). Heat supplied to the ice sheet base is, initially, from geothermal sources, which have a background value of around 50 mW m^{-2} . The ice sheet becomes larger and subglacial temperatures rise as a consequence of: (a) extra insulation from the cold air on the

ice surface and (b) extra heating induced by the deformation of ice, which is proportional to ice thickness to the power 4. The heat supplied through ice deformation to the ice base enhances that from the Earth such that the total heat received at the ice sheet base is significantly greater than the background geothermal value (up to twice as much). Eventually the basal temperatures reach the pressure melting value that initiates rapid basal motion (the purge phase). As the ice base becomes wet, subglacial sliding and the deformation of subglacial sediments can occur, which may contribute even more heat, from friction, to the ice base. For the Laurentide Ice Sheet, during the purge, ice is lost through iceberg calving, and the ice sheet thins as a consequence. Much of the ice is drained through a single outlet, the Hudson Strait, which becomes the focal point for iceberg release to the North Atlantic. The drainage of so much ice depletes the reserves in the parent ice sheet and it becomes thinner. As it does so, heat is lost from the ice sheet base (i.e., the insulating effect of the ice cover is reduced) and, eventually the ice becomes refrozen to the base, at which time the flux of ice to the ice margin is decreased. The end of the purge phase results in the reduction of ice passing into the Hudson Strait and the shutdown of iceberg calving. Once enhanced ice velocities have been curtailed, the cycle of binge-purge is completed, and re-growth occurs as the first stage of the purge phase.

Modeling binge-purge cycles in ice sheets

The binge-purge of an ice sheet (with implication to the Laurentide Ice Sheet) was modeled by MacAyeal (1993a, b) by considering heat conduction within and beneath an ice sheet and initial thermal conditions in accord with atmospheric temperature. The results of the numerical analysis showed that binge-purge oscillations had a cycle of around 7,260 years duration, a remarkably similar periodicity to that measured from IRD in the North Atlantic. The purge (surging) phase was predicted to last for only a short time (around 700 years).

While MacAyeal's model was original, it lacked a detailed analysis of the interplay between ice dynamics and the thermal regime. To solve this, Payne (1995) and Payne and Donglemans (1997) showed how the build-up and decay of ice sheets strongly controls the subglacial thermal regime. Under relatively stable external forcing conditions, an ice sheet may oscillate between periods of ice growth, when the ice is cold-based, and ice decay caused by the attainment of warm-based thermal conditions and the consequent initiation of rapid basal motion. By utilizing a thermo-coupled time-dependent ice sheet model, Payne (1995) highlighted the importance of basal sliding to the oscillatory behavior of ice sheets. In his model, Payne showed how the accumulation rate of ice governed the periodicity of ice sheet oscillations. For low accumulation rates, such as those experienced over the Laurentide Ice Sheet, periods of between 6,000 and 7,000 years were predicted, in support of MacAyeal's earlier work.

Binge-purge cycles and iceberg rafted debris

One problem associated with the notion of binge-purge oscillations being responsible for Heinrich layers is the method of entrainment of material within the ice sheet during the surge phase, when most icebergs are produced. The problem is that a surge-type situation will involve the ice sheet being effectively decoupled from the glacier bed, which may not allow the take-up of material into the basal ice layers. However, Alley and MacAyeal (1994) established a method that allows both

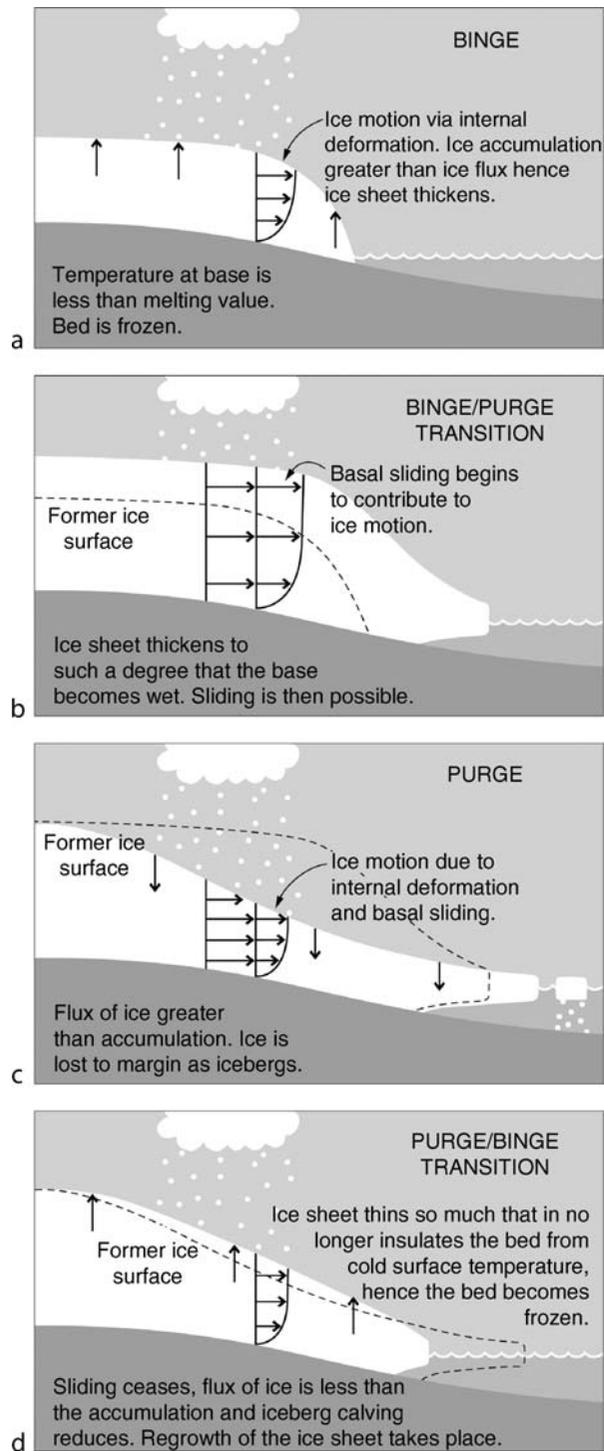

Figure B7 Binge-purge cycles of an ice sheet. (a) The binge phase. Ice sheet growth occurs as a result of ice accumulation exceeding the flux of ice to the margin. Basal temperatures are cold as the only heat supply is from geothermal sources. (b) The binge/purge transition. As ice sheet growth continues, the base of the ice sheet warms due to enhanced heating from ice deformation and extra insulation from the ice above, until a critical threshold is reached at which point the base becomes wet. (c) The purge phase. Once the subglacial conditions are warm, basal sliding takes place (and this supplies more heat to the ice

entrainment and surging to take place, which results in the production of sediment-laden icebergs. The model assumes that the start of the purge phase involves enough frictional heat to melt the ice base, lubricating the sediments and causing them to deform. As this happens, however, the ice stream begins to thin, which results in colder temperatures at the ice base and so water and sediment freeze onto the base of the ice stream. Beneath the refrozen basal ice the sediment is still warm and water-saturated, however, and so the ice stream remains active and fast flowing. When all the water-soaked sediment has frozen onto the ice stream base it becomes “cold-based” and the purge phase ends. This soft-bed model produces, in theory, a volume of sediment within the ice sheet that is larger than required to account for the Heinrich layers. However, a hard-bed model would produce far less. So, the presence of both hard and soft bed conditions would seem to make the model fit the measurements. Although this model remains unproven, Alley and MacAyeal (1994) suggest a number of good reasons as to why alternative entrainment mechanisms are less likely. For example, if the process of sediment entrainment was through ice-tectonics such as folding and cavitation, a rate of uptake of material far in excess of that calculated and measured in modern ice sheets and glaciers would be required to form the Heinrich layers. Further, a pressure-induced basal freezing process results in 2 orders of magnitude less sediment than is required. Therefore, the soft-bed freezing model appears a likely mechanism to explain the incorporation of material into the ice sheet during the latter period of the binge-purge cycle.

Dowdeswell et al. (1995) revealed that the thickness distributions of Heinrich layers one and two (at 14.5 ka and 21.1 ka) are similar. This similarity suggests that the volume and size of icebergs responsible for their formation, the proportion of sediment within these icebergs and the ocean currents were similar on both occasions. In addition, Dowdeswell et al. (1999) showed that there appeared to be a lack of correlation between Heinrich events and IRD features from the Fennoscandian Ice Sheet. This suggests that the cause of Heinrich events was particular to the Laurentide Ice Sheet, which reduces the likelihood of a climate-induced mechanism that would affect all ice sheets in the Northern Hemisphere. Thus, there seems to be a balance of sedimentary data in support of the oscillatory binge-purge internal ice sheet dynamics mechanism for Heinrich layers. Indeed, MacAyeal (1993a) demonstrated through numerical modeling that climate-induced changes would not result in periodic ice sheet variations as temperature perturbations are attenuated with depth in an ice sheet.

Binge-purge cycles and climate change

Although MacAyeal (1993a) showed it unlikely that Heinrich layers are caused by climate change, he also predicted that the product of the Laurentide Ice Sheet binge-purge cycle, namely a huge release of icebergs to the North Atlantic, would have forced climate change. MacAyeal (1993b) calculated that an ice sheet with a surface area of 10,000,000 km² would

base), which leads to more ice transported to the margin than is replaced by falling snow and, hence, the ice sheet thins. (d) The purge/binge transition. As the ice sheet thins, the insulation effect of the ice diminishes and the base becomes cold. Once freezing conditions are reintroduced, sliding is no longer possible and the purge phase ends. As the accumulation of ice is once again greater than the flux of ice, the ice sheet begins to thicken and the binge phase begins again.

produce about 1,250,000 km³ of icebergs. As these icebergs melted, the freshwater produced may have been large enough to slow the thermohaline-driven ocean-circulation. Thus, heat transport northward from the mid-Atlantic would have been reduced, lowering ocean and air temperatures in the North Atlantic and surrounding regions.

The interplay between ice dynamics and ice-sheet thermal regime, as hypothesized for the Laurentide Ice Sheet, is relevant to contemporary ice masses. In particular, the possibility that ice sheets can undergo rapid change as a consequence of their interior dynamics rather than through external forcing has caused some to speculate about the stability of the West Antarctic Ice Sheet.

BOLIDE IMPACTS AND CLIMATE

The coincidence of a large asteroid or comet (bolide) impact with the mass extinction of life that occurred at the Cretaceous/Tertiary (K/T) boundary (65 million years ago) suggests that the extinctions were caused by climatic and environmental changes triggered by the impact event (Alvarez et al., 1980; Toon et al., 1997). A number of possible mechanisms of impact-induced climatic change have been proposed, including the direct effects of: atmospheric dust produced by the impact;

soot from wildfires triggered by the initial blast and by ejecta re-entering the atmosphere; water vapor injected into the upper atmosphere by oceanic impacts; the creation of NO and HNO₃ acid rain; sulfuric acid aerosols derived from anhydrite deposits in the target rocks; and carbon dioxide released from limestone in the target. Indirect effects on climate could come from major perturbations of the global carbon and sulfur cycles generated by the mass extinctions, and related ecological perturbations (Rampino, 1995; Toon et al., 1997).

Effects of a global dust cloud

Alvarez et al. (1980) originally suggested that the large amount of fine ejecta distributed worldwide by the K/T boundary impact would have created a dense global atmospheric dust cloud. They proposed that the darkness and short-term surface cooling beneath such a cloud led to cessation of photosynthesis and frigid conditions (impact winter), resulting in the observed mass extinctions. Calculations and experiments suggest that even a few months of such darkness would have been sufficient to produce the severe extinction seen among photosynthetic plankton at the K/T boundary. This would have led to a collapse of marine and terrestrial food chains.

The energy release of a 10 km diameter asteroid (such as the object that hit the Earth 65 million years ago) traveling at about 20 km s⁻¹ is estimated to be equivalent to the explosion of 10⁸ Mt of TNT. In such an impact, it is estimated that more than 10¹⁹ g of excavated rock and vaporized asteroid could be lofted to high altitude. Most of the ejecta would be in the form of relatively large particles (0.1–1 mm in diameter) with an atmospheric residence time of a few hours to a few days. Toon et al. (1997) calculated that a mass equal to about 30% of the bolide mass (0.1% of the pulverized ejecta) reaches the stratosphere as sub-micron dust with a residence time of a few months. For a 10¹⁸ g impactor, this atmospheric dust load, roughly equal to about 3 × 10¹⁶ g, would produce a very high atmospheric optical depth of up to 10³–10⁴, and consequent reduced atmospheric transmission of solar radiation. Impacts with energies greater than 5 × 10⁶ Mt would lower light levels below those required for photosynthesis, and impacts larger than 10⁷ Mt could lead to light levels well below those needed for human vision (Figure B8).

Study of the climatic effects of a dense impact dust cloud using a one-dimensional model of aerosol physics and a one-dimensional radiative/convective climate model suggested that light levels would have remained too low for visibility for up to 6 months, and too low for photosynthesis for up to 1 year after the impact. Calculations of surface cooling showed decreases in continental temperatures to below freezing for up to 2 years, whereas ocean-surface temperatures fell only a few degrees C (Figure B9; Toon et al., 1997).

Possible changes in atmospheric thermal structure were also investigated. In normal conditions, solar energy is absorbed by the ground, and the infrared emission back to space comes largely from the upper troposphere. At times of heavy dust loading, however, both the level of solar energy deposition and the infrared emission level of the atmosphere are controlled by the dust, and both lie within the stratosphere. Earth's surface no longer receives any solar radiation, and has a net energy deficit. Under these conditions, one-dimensional models predict land-surface temperature decreases of about 30 °C in the first 1–2 months after impact of a 10 km diameter body (Figure B9).

Covey et al. (1994) utilized a more sophisticated three-dimensional global climate model (GCM) to study the effects

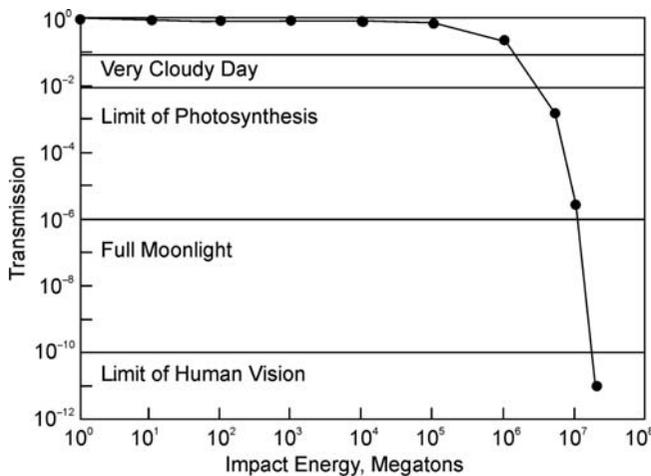

Figure B8 Estimate of the reduction in light transmission through the atmosphere as a result of submicron dust in clouds from impacts of various sizes (in megatons of TNT equivalent) (after Toon et al., 1997).

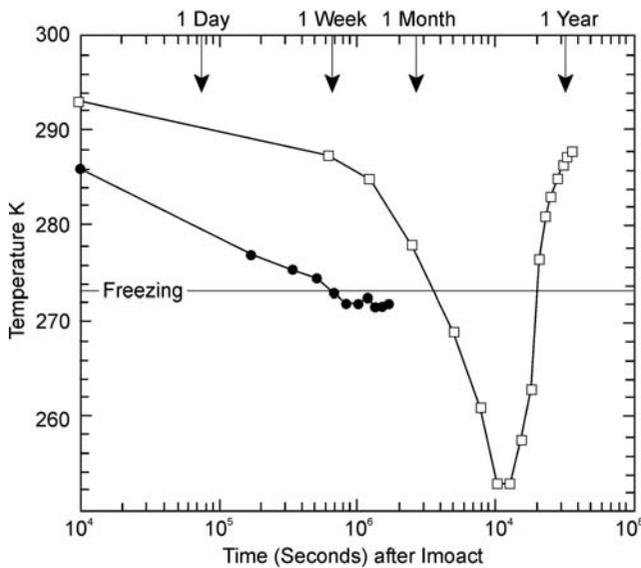

Figure B9 Estimates of the global cooling resulting from the fine dust produced by the impact of a 10 km diameter asteroid using the 1-D radiative convective model (*open squares*) of Toon et al. (1997) and the 3-D Global Climate Model (*filled diamonds*) of Covey et al. (1994).

of an impact-induced global dust cloud on climate. For a dust-loading equivalent to an optical depth (τ) of 10^4 (decaying to $\tau = 1$ after 400 days) after a 10 km diameter impact (in May of the model year), land-surface temperatures fell below freezing in less than a week (decreases of about 15°C), with partial recovery as summer approached in the Northern Hemisphere (Figure B9). Significant cooling was maintained for a year despite the gradual removal of the dust. Land-surface cooling was somewhat mitigated by the heat capacity of the oceans, and by atmospheric circulation patterns (created by the dust cloud) that transported additional heat from the oceans to land areas. In this simulation, however, fixed sea-surface temperatures somewhat exaggerated the oceanic heat reservoir.

GCM studies also suggest an almost complete collapse of the global hydrologic cycle after the modeled impact, with world-wide drought. The GCM model results indicated that impacts of smaller objects (approximately 1 km diameter asteroids or 10^6 Mt impacts) could cause less severe, but still quite significant drops in temperature (about 5°C) over the continents within 20 days of impact. Such rapid and severe decreases in temperatures could have devastated global vegetation.

By contrast, Pope (2002) proposed that most of the globally distributed ejecta from the K/T event were deposited as condensation droplets from the impact vapor plume. He estimated that less than 10^{12} kg of the distal ejecta was sub-micrometer dust. This smaller amount of dust would be insufficient by 2 or 3 orders of magnitude to cause a shutdown of photosynthesis, and would have had much smaller climatic effects (but see Kring and Durda, 2002).

Effects of injection of water vapor into the atmosphere

In the case of an oceanic impact, water would probably comprise a significant fraction of the ejecta lofted to high altitudes. For a 10 km impactor hitting the ocean, it is estimated that the expansion of the impact-related steam bubble would drive a plume of mixed impactor vapor, debris, and water vapor more than a hundred kilometers above Earth's surface. Condensation of the cloud of water vapor and meteoroid vapor could produce a combination of dust and ice particles in the upper atmosphere. McKay and Thomas (1982) considered the consequences of enhanced water vapor concentrations on the middle atmosphere (50–100 km) chemistry and heat budget. They estimated that the increased mixing ratio of hydrogen would have caused a decrease in ozone concentration above 60 km. The ozone reduction would lead to a lowering of the average height of the mesopause, and lowering of average temperature. These conditions were predicted to produce a long-lived (possibly 10^5 – 10^6 years) global layer of mesospheric ice clouds.

An increase in global albedo of up to several percent was predicted, but the net climatic effect (cooling or warming) would depend upon how much infrared radiation from below is also trapped by the clouds. This is a function of the mean size of the ice crystals in the clouds. The size of the dust and ice grains produced in the atmosphere is also critical to the mean lifetime of the dust and ice clouds – if the grains are large, rapid fallout would occur, and long-term darkness and climatic effects would be less likely. A measure of the initial grain-size distribution of material in the K/T boundary fallout layer would help in constraining these effects.

The water vapor would have locally supersaturated the stratosphere, and thus much of the vapor might have rapidly re-condensed and precipitated out of the atmosphere. If the coagulation time of the water vapor was similar to that of the dust as calculated by Toon et al. (1997), then most of the water would have left the atmosphere within weeks to months. However, during this time, an enhanced greenhouse effect and reduction of stratospheric ozone could have caused sudden global heating. A permanent increase in stratospheric water vapor by a factor of 25 would lead to an 8°C increase in average global surface temperatures.

Effects of the formation of NO_x and acid rain

The shock waves from the K/T impact and the transfer of energy from the fine ejecta to the atmosphere ($\sim 40\%$ of the energy transferred to the atmosphere) would have heated the

global atmosphere. Calculations suggest that, for a large 10^7 – 10^8 Mt impact, this could have produced an immediate heat pulse with a global average temperature increase of $\geq 15^\circ\text{C}$, and ocean-surface temperature increases of about 5°C (Toon et al., 1997).

The high-temperature shock waves produced by the passage of the impactor through the atmosphere and interaction of the high velocity plume of ejecta with the atmosphere could have created large amounts of NO (Toon et al., 1997), estimated to be as high as 3×10^{17} mol of NO, corresponding to $>0.2\%$ NO by volume. This amount of NO_x is enough to poison plants and animals, but it could have also produced destructive nitric acid rain with a pH of about 1. About 3×10^{14} mol of HNO_3 could lower the pH of ocean surface water sufficiently to dissolve calcite.

The large amount of fixed nitrogen deposited on Earth's surface after an impact might have denitrified to produce N_2O and NO. Smog reactions, involving the oxidation of CH_4 produced by anaerobically decaying organic matter, might then have led to significant amounts of ozone in the troposphere. Production of N_2O (along with CO_2 , HNO_3 and CH_4) could have resulted in an enhanced greenhouse effect over the approximately 150-year lifetime of N_2O in the atmosphere. The N_2O could have also interacted with the stratospheric ozone layer, depleting it within a decade.

In other studies, a much smaller total NO production (about 10^{14} mol) from a 10 km diameter impactor (10^8 Mt) was calculated. In these models, most of the global NO production came not from the initial shock wave or plume, but from the dispersed ejecta re-entering Earth's atmosphere.

According to some calculations, larger yields of NO would accompany only relatively rare grazing impacts. Oblique impact of a 10 km object with a velocity of 20 km s^{-1} , impacting at 10° to the horizontal, could ricochet many 0.1–1 km fragments at hypervelocity, producing a global swarm of Tunguska-scale events. Nitrate production from such a swarm could greatly exceed that of a single vertical impactor. Energy partitioned to the target apparently increases for impact angles between 45° and 15° , increasing the ability of the impact to vaporize potentially volatile targets.

Effects of global wildfires

The immediate creation of a large, heated mass of low-density air with peak temperatures of more than 20,000 K at the impact site and the intense heat emitted globally by impact ejecta re-entering the atmosphere are calculated to ignite combustible material and to create widespread wildfires (Melosh et al., 1990). Vegetation killed by the lack of sunlight and the abrupt cooling would have provided abundant fuel for the wildfires.

Large amounts of soot were discovered at the K/T boundary (estimated at $>5 \times 10^{16}$ g worldwide), which supports the burning of a significant fraction of the terrestrial biomass (Wolbach et al., 1988). This amount of soot in the atmosphere would have yielded a soot optical depth of about 10^3 , capable of causing climatic effects similar to those of the fine dust produced by the impact. The soot produced by the fires would have added to the opacity of the atmosphere, exacerbating the scenario of darkness and cooling following an impact.

Calculations suggest that such forest fires could have produced more than 10^{19} g of CO_2 , 10^{18} g of CO, 10^{17} g of CH_4 , and 10^{16} g of N_2O , in addition to reactive hydrocarbons and

oxides of nitrogen ($\text{NO} + \text{NO}_2$). This might have led to an intense photochemical smog, and a short-term increase in the greenhouse effect estimated to produce a global warming of roughly 10°C (Toon et al., 1997).

Effects of impacts on targets containing carbonates or sulfates

The target material of the impact can be important in terms of climatic impact. For example, impact of a 10 km diameter asteroid into thick carbonate deposits (like those at the Chicxulub Crater) might have released 10^3 – 10^4 Gigatons (10^{12} tons) of CO_2 that could have increased atmospheric carbon dioxide levels by factors of 2–10. This increase in CO_2 could have caused a rise in global temperatures of about 2 – 8°C , for 10^4 – 10^5 years after the impact.

The K/T impact site at Chicxulub was also underlain by thick Cretaceous evaporites including anhydrite (CaSO_4), and some K/T impact glasses are rich in calcium and contain up to 1 wt% SO_3 . Estimates of the increase in atmospheric SO_2 derived from degassing of deposits of anhydrite at the impact site range from about 10^{17} – 10^{19} g (independent of the sulfur released by the asteroid itself; Pierazzo et al., 1998). This can be compared with the 10^{13} g of SO_2 produced by the 1991 Pinatubo eruption or the 10^{15} g of SO_2 released by the Toba eruption (73,000 years ago), the largest volcanic eruption of the last few hundred thousand years. The formation of sulfuric acid aerosols from the large release of SO_2 by the Chicxulub impact would have sufficed to cause significant reduction of sunlight and global cooling after the dissipation of the short-lived dust/soot cloud. Estimates of cooling range from 5 to 31°C for as long as a decade, and even longer if ocean-temperature feedbacks come into play. The sulfuric acid fallout could have equaled or exceeded that proposed for the nitric acid produced by the impact.

Climatic changes from perturbations of biogeochemical cycles

The K/T boundary is marked by a major perturbation of the global carbon cycle, including severe reduction in pelagic carbonate deposition, decrease in biomass and oceanic productivity, and changes in organic carbon deposition (Kasting et al., 1986; Caldeira and Rampino, 1993). The primary source of alkalinity (excess positive charge) to the oceans is dissolved Ca and Mg derived from the chemical weathering of carbonate and silicate rocks. The two major sinks for alkalinity and carbon in the oceans are the deposition of shallow-water carbonate sediments, and the accumulation of deep-water carbonates derived from the calcareous tests of pelagic plankton.

A major disruption of the pelagic alkalinity and carbon sinks may have occurred in the aftermath of the mass extinction, with reduction in populations of calcareous plankton at the K/T boundary. The reduction of ocean primary productivity – the so-called “Strangelove Ocean” interval – lasted perhaps as long as 500,000 years (Caldeira and Rampino, 1993).

Kasting et al. (1986) performed model calculations with a two-box ocean model of the carbon-cycle perturbations that might accompany a large impact. They investigated the suggestion that an impact event would cause ocean surface waters to become under-saturated with respect to calcium carbonate, and hence lead to the extinction of calcareous organisms. This situation could also delay the recovery of calcareous plankton during the Strangelove Ocean period.

Global darkening could have killed off most of the existing phytoplankton within several weeks to months, while deposition of atmospheric NO_x created in the impact would have lowered the pH of ocean surface waters and released CO₂ into the atmosphere. However, model results indicated that mixing would have limited acidification of ocean surface waters to about 20 years or less. Kasting et al. (1986) also looked at the direct input of atmospheric CO₂ from a comet or from oxidation of terrestrial and marine organic matter. The net results might have been a greenhouse effect raising temperatures by several degrees, and perhaps a surface ocean uninhabitable by calcareous organisms for a couple of decades, but the model runs also suggested that the surface waters would not have remained corrosive for long, and thus could not have led to the Strangelove Ocean conditions of decreased carbonate productivity.

DMS reduction and climatic warming

Marine phytoplankton release dimethyl sulfide (DMS) gas, which oxidizes to form sulfuric acid aerosol that is the precursor for cloud condensation nuclei (CCN) over the oceans. The extinction of most marine calcareous phytoplankton at the K/T boundary would have drastically reduced output of DMS, and thus CCN and marine cloud coverage. Reduction of global cloud albedo would have led to a rapid warming of the global climate.

Rampino and Volk (1988) used model results that showed the effect of variations in CCN number density upon cloud albedo and climate. For a DMS reduction of ~80%, global temperature was predicted to rise by more than 6°C, and by nearly 10°C when the DMS was reduced by 90%. Even a 50% reduction in DMS should have produced a significant global warming of 3–4°C. The thermal mass and mixing structure of the ocean could have delayed the full surface warming by several 1,000 years.

Climate changes at the K/T boundary

Since many of the theoretical studies of impact processes predict significant climatic changes, it is worthwhile to ask if any clear evidence of such climate changes can be discerned in paleoclimatic data from the K/T boundary. For most paleoclimatic records, a brief “impact winter” would be impossible to resolve with present techniques. Paleobotanical evidence from western North America, however, has been interpreted by Wolfe (1991) as indicating a brief summer freeze (a temperature decrease of 25–30°C for less than 2 months). Leaf studies from the same area suggested a marked longer-term increase in temperature of 10°C that persisted for 500,000–1 million years after the impact (Wolfe, 1990).

Paleotemperatures based on oxygen-isotope studies suggest a very brief cooling at the K/T boundary, followed by a warming that lasted at least a few 1,000 years. Several analyses suggest a possible dramatic warming of ocean surface waters by as much as 10–12°C and bottom waters by 5°C. By contrast, some oxygen-isotope studies have reported “cold snaps” in the aftermath of the K/T impact event with 4–5°C regional coolings lasting from 5,000 to 10,000 years. These apparent climatic fluctuations following the K-T extinction event suggest that the paleotemperature data are unreliable, or that there was a basic instability in the post-impact climate regime (Rampino, 1995).

Galeotti et al. (2004) presented records of dinoflagellate cysts and benthic foraminifera across the K/T boundary at

El Kef, Tunisia. These records show a brief 20,000–40,000 year expansion of species from the Boreal Bio Province into the warmer western Tethys. This could have been caused by the formation of a large volume of cold surface waters during the K/T impact winter that later sank into the deeper ocean. Ocean-atmosphere modeling experiments provide support for such a prolonged cooling phase from the formation of a mass of cold sinking water.

Climate changes at times of other impacts

Little information exists as to climatic changes related to other known and well-dated Phanerozoic impacts (Rampino and Haggety, 1994), although these were all smaller in size than the Chicxulub event. The late Eocene Chesapeake Bay (90 km diameter) and Popigai (100 km diameter) impact craters (~35.7 million years ago) are probably related to a comet shower that lasted about 2.5 million years (Farley et al., 1998). This interval is marked by stepwise extinction of planktonic foraminifera (Hut et al., 1987), and a shift in species assemblage of calcareous nannoplankton (Monechi et al., 2000). In the well-studied Massignano Section in Italy, the iridium anomaly and shocked quartz most likely associated with the Popigai impact seem to be followed by a warming episode and a subsequent slight cooling episode that occurred about 60,000 years after the impact event (Coccioni et al., 2000). The relatively long duration of the environmental perturbation that followed the impact event(s) suggests feedback mechanisms that sustained the initial impact induced changes. The impacts may have accelerated global cooling (Vonhof et al., 2000). The major cooling and period of ice growth in the earliest Oligocene, however, followed the impacts/comet shower by about 2 million years.

Very little additional data exists as to the effects of impacts on climate. A possible impact shower in the Late Devonian that produced several layers of glassy microtektites (in Belgium and China) may be associated with a global climate cooling (see Rampino, 1995), but a cause-and-effect relationship is not clear.

BØLLING-ALLERØD INTERSTADIAL

Introduction

The Bølling-Allerød interstadial is the initial warm phase during the Weichselian late glacial that is followed by the cold Younger Dryas stadial.

The Weichselian late glacial, often referred to as *last glacial-interglacial transition* or *last termination* (ca. 13,000–10,000 ¹⁴C yr BP), was a period of rapid climate change. The late glacial is classically sub-divided into a series of stadials named after the occurrence of the characteristic arctic-alpine plant species *Dryas octopetala*, separated by interstadials named after the type localities Bølling and Allerød in Denmark. The biostratigraphic sub-division has been extensively used in north-west Europe, usually in a chronostratigraphic sense, and is still widely used globally.

History

Hartz and Milthers (1901) showed that, based on deposits in a clay-pit near Allerød (Denmark), a climatic warming had occurred during the late glacial. Between clay layers containing mountain avens (*Dryas octopetala*) and reindeer fossils, an organic layer containing birch (*Betula*) and elk fossils was present, indicating a change from tundra to a more forested environment followed by a return to tundra. Based on palynology, Jessen (1935) was able to define three subsequent pollen zones: Early Dryas (I), Allerød (II), and Late Dryas (III). This subdivision was further refined by Iversen (1942), who added another interstadial phase that supposedly occurred before the Allerød and was first described in Bølling Sø (Denmark).

The palynological sub-division of the Weichselian late glacial established by Jessen (1935) and Iversen (1942) was introduced into The Netherlands by van der Hammen, who recognized the Bølling and Allerød oscillations, separated by the Dryas stadials in a site named Hijkermeer. The interstadial deposits were characterized by a higher content of organics in comparison with the stadial deposits. Van der Hammen (1951) went on to demonstrate a similar vegetation development at different locations in The Netherlands. Since then, hundreds of pollen diagrams from late glacial deposits have been constructed using van der Hammen's scheme (Hoek, 1997).

Bio- and chronostratigraphy

Unfortunately, the boundaries of similar biostratigraphical zones defined in different regions are in most cases diachronous due to differences in vegetation response to changes in climate. This makes the use of the biostratigraphic zones defined in Scandinavia problematic outside this region. Furthermore, there are problems that can be regarded as inconsistencies in biostratigraphic definition. In northwestern Germany especially, an additional interstadial called Meiendorf is recognized, which correlates with the Bølling interstadial, while the term Bølling is used for the first part of the Allerød interstadial (Litt and Stebich, 1999). The discrepancy between the definition of Bølling and Allerød is mainly the result of a difference of opinion about the correlation with the section at Bølling Sø, first studied by Iversen (1942). In Britain, it is often difficult to recognize stadial conditions separating the individual interstadial phases (Lowe and Gray, 1980). Terms such as late glacial interstadial or Windermere interstadial have been used for the Bølling-Allerød interstadial complex. These examples all point towards the problems of transferring the biostratigraphic zonation scheme from one region to another. A detailed discussion regarding this issue is presented by de Klerk (2004).

With the introduction of the radiocarbon dating method, biostratigraphic correlation became less important and pollen diagrams were considered more frequently in a chronological context. Moreover, the terminology that was originally developed for biostratigraphical zones (Bølling, Allerød, etc.) has been used in a chronostratigraphic sense (Mangerud et al., 1974). Since then, the terms Bølling and Allerød have been connected worldwide to the time period between 13,000 and 11,000 yr BP, as defined by Mangerud et al. (1974). This chronological definition was, however, initially based on the radiocarbon-dated biostratigraphic zone boundaries from southern Scandinavia. Above this, the Mangerud et al. (1974) scheme has been constructed using bulk radiocarbon dates and was constructed when reservoir ages and radiocarbon-plateaux were not yet known (Wohlfarth, 1996). If the chronostratigraphic scheme is compared to the ¹⁴C-dated

biostratigraphy in The Netherlands, for instance, which is based on over 250 dates (Hoek, 1997), all zone boundaries appear to have different ages. The most striking differences can be seen in the ages for the start of the Bølling biozone or chronozone (Table B2).

Climate changes during the Bølling-Allerød interstadial

Although lithological and botanical evidence shows that strong environmental changes occurred during the late glacial period, it is ambiguous to translate these signals directly into climate. The AP (arboreal pollen) percentage was long considered as a temperature proxy. Based on the palynological records, in which the AP percentage increased during the course of the Bølling-Allerød interstadial, it was concluded that the warmest part of the late glacial fell towards the end of the Allerød interstadial, just before the Younger Dryas stadial.

It appears that this classical interpretation of late glacial vegetation and climate development leads to a different picture than

the records obtained from, for instance, the Greenland ice cores (Johnsen et al., 1992; Grootes et al., 1993) and Coleoptera studies (Atkinson et al., 1987; Coope et al., 1998). Both oxygen isotopes and fossil Coleoptera are considered to reflect changes in temperature almost instantaneously, while vegetation responds more slowly, due to migration lags in particular. Temperature reconstructions based on isotopes and Coleoptera reach their highest values early in the late glacial. This implies that the warmest phase must have occurred during the Bølling, followed by a step-wise cooling during the Allerød (Figure B10).

Recent developments

Stuiver et al. (1995) presented a comparison between European pollen zone boundaries and the GISP2 $\delta^{18}O$ climate transitions, but only at a low resolution. It is apparent from these and from other data that the use of different timescales has impeded more precise correlation between ice core and terrestrial records.

Table B2 Chronostratigraphy of the late glacial based on ^{14}C dated biozone-boundaries in The Netherlands (after Hoek, 1997) compared with the classical Stratigraphy of Norden by Mangerud et al. (1974)

The Netherlands		Stratigraphy of Norden	
^{14}C age BP	biozone	chronozone	^{14}C age BP
	HOLOCENE	FLANDRIAN	
10,150	Late Dryas	Younger Dryas	10,000
10,950	<i>Pinus</i>	Allerød	11,000
11,250	Allerød		
	<i>Betula</i>		
11,900	Earlier Dryas	Older Dryas	11,800
12,100	Bølling	Bølling	12,000
12,450	Earliest Dryas		
12,900	PLENIGLACIAL	MIDDLE WEICHSELIAN	13,000

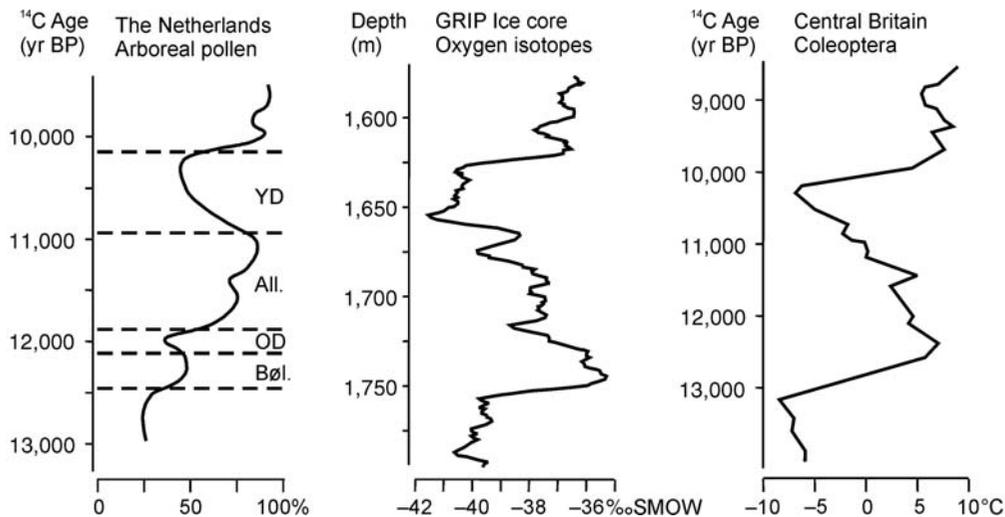

Figure B10 Comparison between the Bølling-Allerød interstadial, as recognized in the pollen record from the Netherlands (after Hoek, 1997), oxygen isotopes from the Greenland ice-core GRIP (Johnsen et al., 1992) and temperature reconstructions based on Coleoptera from Britain (Atkinson et al., 1987).

As described above, the application of biostratigraphic terminology to records from different regions and different sources may easily cause correlation problems. Therefore, the INTIMATE group of the INQUA Palaeoclimate Commission developed an event stratigraphy for the North Atlantic region, based on the stratotype of the GRIP ice-core record (Björck et al., 1998). This scheme defines a series of stadials and interstadials for the period 23.0–11.5 ice-core yrs BP, based on marked oxygen isotope variations in the GRIP ice core. Within Greenland interstadial 1, a subdivision is made into three warmer episodes GI-1a, 1c and 1e with intervening colder periods GI-1b and 1d (Figure B11). The INTIMATE event stratigraphy scheme has not been proposed as a replacement of the existing stratigraphic schemes, but as a *standard* against which to compare regional stratigraphic schemes including terms such as the Bølling-Allerød interstadial. Furthermore, the event stratigraphy is supposed to serve as a basis for establishing the synchronicity (or asynchronicity) of comparable events or sequences of events throughout the North Atlantic region (Lowe et al., 2001).

In the Swiss Alps, for instance, oxygen isotope analysis on calcareous lake deposits shows a strong correspondence to the Greenland ice-core records (Lotter et al., 1992). The same patterns have been recognized in lake deposits from

The Netherlands (Hoek and Bohncke, 2001), and central North America (Yu and Eicher, 1998), indicating a common temperature influence during the last glacial-interglacial transition in the Atlantic region.

The adoption of the Greenland ice-core record as the stratotype for the last glacial-interglacial transition, and thus as the standard chronology against which to compare the timing of regional events, has certain advantages over the use of the traditional scheme of Mangerud et al. (1974). The ice cores record the sequence of events at the highest available temporal resolution (potentially definable to sub-annual variations) and the chronologies derived from them, although not free of problems, are less problematic than radiocarbon dates, especially because several of the key transitions lie within radiocarbon plateaux (Stuiver et al., 1998).

It is to be expected that the term Bølling-Allerød interstadial will continue to be used, in particular for the warm phase during the Weichselian late glacial in northwest Europe. The ongoing effort in establishing the precise timing of climate changes during the last glacial-interglacial transition will hopefully provide the precise chronological framework with which to correlate other regional stratigraphies with each other and with the Greenland ice cores.

Wim Z. Hoek

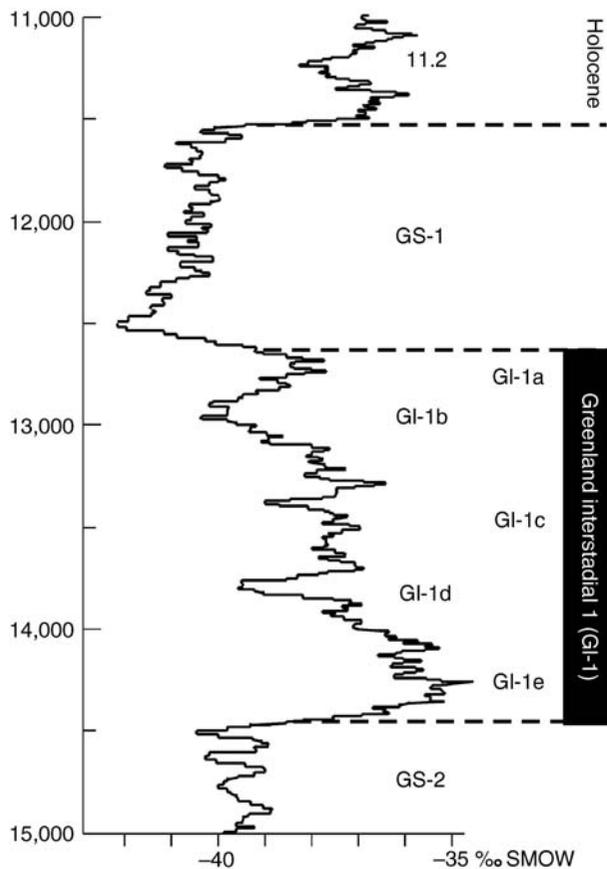

Figure B11 Stratigraphic position of Greenland interstadial 1 (GI-1) in the GRIP oxygen isotope record, corresponding to the Bølling-Allerød interstadial; age is in GRIP ice-core yrs BP. Within the Greenland interstadial, warm (GI-a,c,e) and cold (GI-b,d) events are given according to Björck et al. (1998).

BOREHOLE CLIMATOLOGY

Introduction

Past ground temperatures can be estimated by analyzing perturbations to the quasi-steady state equilibrium geothermal profile in the uppermost kilometer of the Earth's crust. In fact, it has been customary to eliminate the effects of known climatic events (mainly the last glacial termination) from the temperature profiles, in order to determine the internal heat output, an important quantity for the understanding of our planet's dynamics. Widespread concern about global warming and temperature changes during the last century prompted many in the geothermal community to reexamine the data for evidence of more recent temperature changes. Not surprisingly, we are finding coherent and systematic temperature perturbation patterns. What had previously been considered noise is now appearing to be a rich signal of local and regional climate change.

Consider the Earth's crust in thermal equilibrium. A temperature-depth profile starts at the surface at the mean-annual ground temperature and increases steadily with depth (Figure B12a). If the temperature at the upper boundary of the body is increased, additional heat propagates into the body causing an corresponding increase in temperature just below the surface (Figure B12b). The depth to which equilibrium temperatures are perturbed in a given time is governed by the thermal diffusivity of the body. For typical rocks, a thermal front (i.e., 5% change) propagates to about 16 m in one year, 50 m in 10 years, 160 m in 100 years,

and 500 m in 1,000 years. Thus the Earth's ground temperature history over the last millennium is captured in the uppermost kilometer of the crust. The depth of a temperature perturbation is related to the timing of surface changes. The shape of the perturbation reveals details of the surface temperature history. Positive and negative subsurface temperature anomalies are associated with ground surface warming and cooling respectively. The magnitude of surface temperature excursions that caused the subsurface anomalies is usually inferred directly by data inversion (Beltrami et al., 1997).

Although proxy indicators such as tree rings and oxygen isotope data are very useful as climatic indicators, they are not directly related to temperature at the Earth's surface. On the other hand, geothermal data are a direct reflection of the energy balance at the surface (Huang et al., 2000; Beltrami, 2002a,b). However, the heat conduction process acts as a low pass filter and smoothes the ground surface temperature perturbation as it propagates into the subsurface. As a result, geothermal data are useful to reconstruct the past climate through the last millennium, but with a resolution that decreases significantly in time.

Analyzes of geothermal data from the last century have revealed warming of between 2–4 °C in Alaska (Lachenbruch and Marshall, 1986), between 1–2 °C in eastern and central Canada (Beltrami and Mareschal, 1991; Beltrami and Mareschal, 1992; Shen and Beck, 1992; Beltrami et al., 2003), less than 1 °C in Utah (Chisholm and Chapman, 1992), etc. About half of this warming in Canada appears to be a recovery from a colder period that may be associated with the Little Ice Age, also documented from geothermal data in Europe (Grove, 1988).

Theory

One of the fundamental assumptions required for the reconstruction of ground temperature histories from geothermal data and eventually past climatic change is that the heat transfer regime within the ground be conductive (Beltrami, 2001a,b). In an ideal perfectly conductive soil, variations of surface temperature are propagated into the ground according to the heat conduction equation (Carslaw and Jaeger, 1959):

$$\frac{\partial T}{\partial z} = \kappa \frac{\partial^2 T}{\partial z^2}, \quad (1)$$

where κ is the thermal diffusivity of the rock controlling the rate of heat propagation into the solid as a response to temperature variations with time, T is temperature, and z is depth. The use of a one-dimensional equation is valid if long term surface temperature changes have a wavelength much larger than the depth to which they penetrate (usually less than 1 km).

In a source-free half space, the equilibrium heat-flow is constant and it is evaluated in the deeper part of the temperature profile least affected by the recent surface temperature changes. Following standard methods (Bullard, 1939), the equilibrium temperature is continued upward by assuming constant gradient over intervals of constant conductivity. The perturbation is determined as the difference between the measured temperature and the upward continuation of the deep temperature profile. The area between these curves represents the net heat absorbed by the ground, and the shape of the perturbation, if heat generation is ignored, is determined by the thermal history of the surface.

$$T(z) = T_0 + q_0 R(z) + T_i(z); \quad (2)$$

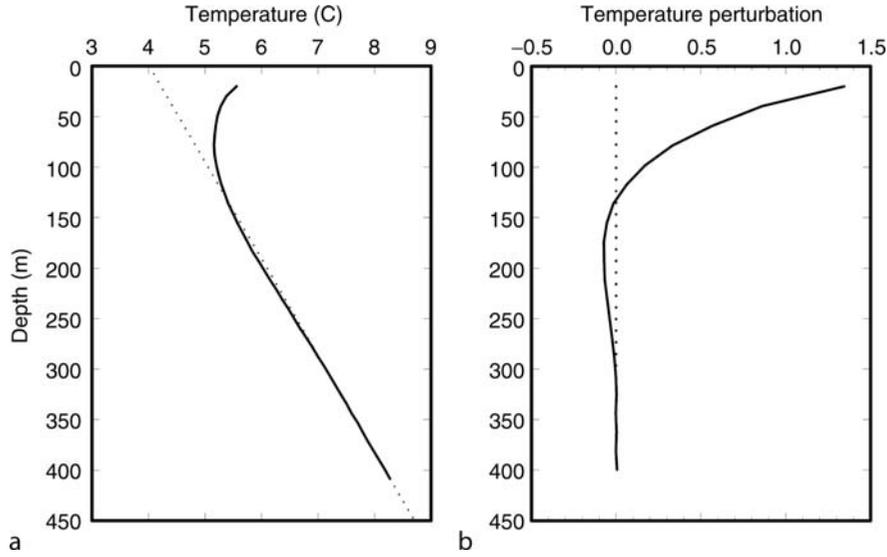

Figure B12 (a) Typical measured temperature-depth profile (solid line). The dashed line represents a background thermal profile least affected by recent climate change. (b) Temperature anomaly for the log shown at an expanded scale. Perturbation is calculated as the difference between measured temperature and background temperature for corresponding depths.

where $T(z)$ is the temperature at depth z , T_0 is the equilibrium ground surface temperature (in the deepest part of the borehole, the temperature is not affected by the changes of surface temperature: when $z \rightarrow \infty$, $T = T_0$, $t > 0$), q_0 is the equilibrium surface heat flow density, $R(z)$ is the thermal resistance, and $T_i(z)$ is the temperature perturbation arising from the time varying surface temperature.

For a one step change in ground surface temperature at time t before present ($\Delta T = T_s - T_0$), the temperature perturbation at depth z is given by (Carslaw and Jaeger, 1959):

$$T_i(z) = \Delta T \operatorname{erfc}\left(\frac{z}{2\sqrt{\kappa t}}\right), \quad (3)$$

where $\sqrt{\kappa t}$ is the characteristic thermal diffusion depth and erfc is the complementary error function.

Short period variations are attenuated rapidly with depth such that the ground surface temperature history can be approximated by the averaged surface temperature over a series of time intervals of equal duration.

For a model consisting of a series of step temperature changes, the temperature at depth z , Eqs. (2) and (3) yield:

$$T(z) = T_0 + q_0 R(z) + \sum_{k=1}^K T_k \left[\operatorname{erfc}\left(\frac{z}{2\sqrt{\kappa t_k}}\right) - \operatorname{erfc}\left(\frac{z}{2\sqrt{\kappa t_{k-1}}}\right) \right] \quad (4)$$

which is valid at each depth where data exist, becoming a system of linear equations that can be expressed as:

$$\Theta_j = A_{jl} X_l, \quad (5)$$

where Θ_j is a column vector containing the j -values of temperature measured at depth z_j , corrected for heat production between surface and depth z_j when necessary; X_l is a column vector containing the model parameters: $k+2$ unknowns (T_0 , q_0 , T_1 , ..., T_k); A_{jl} is a $(j \cdot l)$ matrix that contains 1 in the first

column, the thermal resistance to depth z_j , $R(z_j)$, in the second column and the difference between complementary error functions at times t_{k-1} and t_k for depth z_j in columns 3 to $k+2$.

$$\begin{pmatrix} T_1 \\ T_2 \\ \vdots \\ T_j \end{pmatrix} = \begin{pmatrix} 1 & R_1 & A_{1,3} & A_{1,4} & \dots & A_{1,k+2} \\ 1 & R_2 & A_{2,3} & A_{2,4} & \dots & A_{2,k+2} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & R_j & A_{j,3} & A_{j,4} & \dots & A_{j,k+2} \end{pmatrix} \begin{pmatrix} T_0 \\ q_0 \\ T_1 \\ \vdots \\ T_k \end{pmatrix}, \quad (6)$$

$$A_{j,k+2} = \operatorname{erfc}\left(\frac{z_j}{2\sqrt{\kappa t_k}}\right) - \operatorname{erfc}\left(\frac{z_j}{2\sqrt{\kappa t_{k-1}}}\right) \quad (7)$$

This yields an under-determined system of linear equations that can be solved by singular value decomposition (SVD) (Lanczos, 1961; Jackson, 1972; Menke, 1989).

The model parameters can be written explicitly as:

$$X_l = \Theta_j \left(\frac{v_{lr} u_{rj}}{\lambda_{(r)}} \right) \quad (8)$$

with $r = 1, \dots, R$, $l = 1, \dots, M$, and $j = 1, \dots, N$. The summation is performed over repeated indices, and R is the rank of the matrix, M is the number of model parameters, and N is the number of data.

Equation (8) shows that any error in the data will be multiplied by $1/\lambda_{(r)}$ and will be amplified for the very small singular values. So, it is necessary to eliminate the singular values that are smaller than a cutoff value. The singular value decomposition selects the linear combination of model parameters that is best constrained by the data.

The model resolution matrix, \mathbf{R} , relates the parameters of an arbitrary model to the parameters that would be obtained by inversion of the corresponding data: $\mathbf{R} = \mathbf{V}\mathbf{V}^T$, $\mathbf{T}^{\text{est}} = \mathbf{R}\mathbf{T}^{\text{true}}$. The data resolution matrix, \mathbf{Q} , relates the observed data to those data that the inverted model parameters would produce: $\mathbf{Q} = \mathbf{U}\mathbf{U}^T$, $\Theta^{\text{pred}} = \mathbf{Q}\Theta^{\text{true}}$.

Energy balance at the earth's surface

There has been little work to infer variations of surface heat fluxes from geothermal data. Beltrami et al. (2000) estimated, using an analytical approximation, the average heat flux into the ground during the last 1,000 years, over a large region from eastern and central Canada. Results indicated average heat flux increases of 17.0 mWm^{-2} and 74.0 mWm^{-2} since 1,765 and in the last 100 years, respectively. They also identified a cold period between 1,500 and 1,800, indicated by a negative subsurface temperature anomaly.

More recently, singular value decomposition inversion was used to reconstruct surface heat flux histories from the heat flux anomalies detected in the subsurface (Beltrami, 2001a). In the Earth, the heat flux at any depth, ignoring the heat production, can be expressed as the sum of the quasi steady-state geothermal heat flux, q_{eq} , and the transient component, $\Delta q_0(z, t)$:

$$q(z, t) = q_{eq} + \Delta q_0(z, t) \quad (9)$$

If the surface heat flux history is modeled by a series of step heat flux changes at the surface, the heat flux at the depth z is given by:

$$q_t(z) = q_{eq} + \sum_{k=1}^K q_k \left[\text{erfc} \left(\frac{z}{2\sqrt{\kappa t_k}} \right) - \text{erfc} \left(\frac{z}{2\sqrt{\kappa t_{k-1}}} \right) \right] \quad (10)$$

$$q_0(t) = q_k; \quad t_{k-1} \leq t \leq t_k; \quad k = 1, \dots, K; \quad t_0 = 0 \quad (11)$$

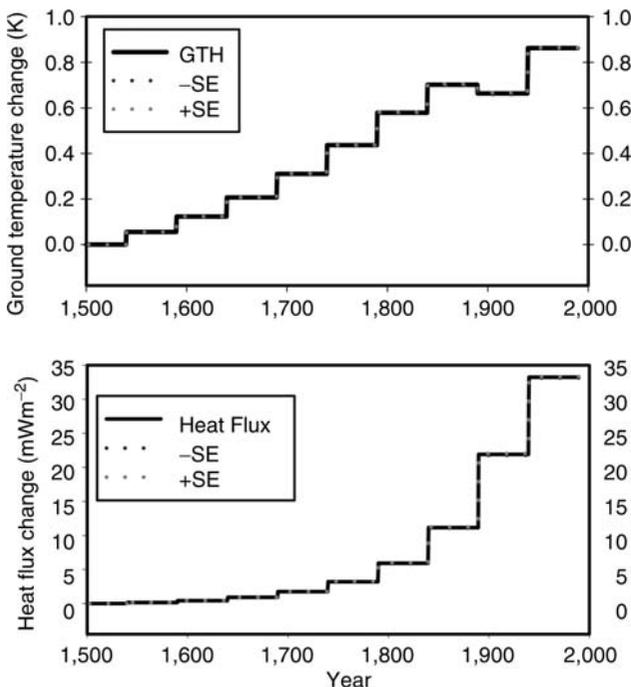

Figure B13 (a) Global mean ground surface temperature history (GSTH) from borehole temperature data. The dotted lines represent the stability of the GSTH for a data noise level of 0.02° K . (b) Global mean surface heat flux history (SHFH) for the same data set. The global SHFH describes the energy balance history at the Earth's surface for the last 500 years.

The system of linear equations can be resolved by singular value decomposition inversion in a similar fashion as for the ground surface temperature reconstruction.

An analytical estimate of the heat flux history from geothermal data (Beltrami et al., 2000), used an approximation based on fractional calculus (Wang and Brass, 1999). An equivalent expression for the heat flux history for a semi-infinite, homogeneous medium subjected to a series of sudden changes of surface temperature at any time between $[t_s, t]$, where t is the time at the moment of observation and t_s is time before present, is given by:

$$q_l = \frac{2\lambda}{\sqrt{\Delta t \kappa \pi}} \sum_{k=l+1}^N [(T_k - T_{k+1})(\sqrt{k-l} - \sqrt{k-l+1})] \quad (12)$$

Equation (12) is general and can be applicable to any time series at any time scale as long as the initial surface heat flux is zero, to avoid error accumulation in time (Beltrami, 2001b).

Observational results of Levitus et al. (2001) showed an increase in observed ocean heat content of $18.2 \times 10^{22} \text{ J}$ (over the past half-century) and an increase in atmospheric heat content $6.6 \times 10^{21} \text{ J}$, while the heat gained by the cryosphere is around $8.1 \times 10^{21} \text{ J}$. From the analysis of geothermal data Beltrami et al. (2002) estimated the heat gained by the lithosphere during the last half-century as $9.1 \times 10^{21} \text{ J}$. Recent inversion of the same data set yielded $7.1 \times 10^{21} \text{ J}$ for the heat absorbed during the same time period (Beltrami, 2002a) (Figure B13). These results are consistent with the idea that the observed warming of the Earth during the last fifty years has been global and affects all climate system components. Further information on the latest developments in borehole climatology can be found in Gonzalez-Rouco et al., 2008.

C

CARBON CYCLE

Historical background of the carbon cycle

The discovery that plants use carbon dioxide for growth in sunlight and return it to the atmosphere in darkness must have been the first scientific observation of part of the carbon cycle. The discovery of carbon dioxide as a gas that forms by fermentation and burning of charcoal, under the name of *spiritus silvestris*, is attributed to Jan Baptista (or Baptist) van Helmont, a man of medicine, alchemy, and early chemistry in the then Spanish Netherlands, in the first half of the 1600s (e.g., Graham, 1974). Presentation of the first general scheme of the carbon and nitrogen cycles was attributed to the French chemist, Jean Baptiste André Dumas, in 1841 (Rankama and Sahama, 1950, p. 535). Dumas (1842) described the cycle of CO₂ consumption and production by respiration, pointing to the sources of “carbonic acid” in the air and soil where it forms from decomposition of manure or organic fertilizers. He also pointed out that the Earth’s primordial atmosphere must have contained all the carbon dioxide and nitrogen that has been taken up by living organisms.

As to the geochemical cycles, in 1875, several chapters on the cycles of chemical elements appeared in a book on Earth history by Friedrich Mohr, a professor at the University of Bonn, with one short chapter on the carbon cycle among them (Mohr, 1875, pp. 397–398). The role of carbon dioxide as a gas warming the atmosphere, in addition to the similar role of water vapor that was known earlier, was demonstrated by Arrhenius (1896). The formation of organic matter from carbon dioxide and water under the action of light, the process known as photosynthesis, has been studied since the later part of the 1700s, when molecular oxygen was discovered to be part of the process and carbon dioxide was identified as a component of air. Short histories of successive discoveries in photosynthesis since the late 1,700s to the twentieth century have been published by several authors (Gaffron, 1964; Meyer, 1964, p. 21; Bassham, 1974; Whitmarsh and Govindjee, 1995). By the 1920s, the cycles of the chemical elements that are involved in biological processes – carbon, nitrogen, and phosphorus – and that are also transported between

soil, crustal rocks, atmosphere, land and ocean waters, and the Earth’s interior were sufficiently well recognized. Alfred Lotka’s book, *Elements of Physical Biology*, published in 1925, includes chapters on the cycles of carbon dioxide, nitrogen, and phosphorus that present a modern treatment of what are today called the biogeochemical cycles (Lotka, 1925). The term biogeochemical reflects the fact that biological, physical, and chemical processes play important roles and interact with each other in the carbon cycle. By 1950, the geochemical cycles of elements in the Earth’s interior and on its surface became textbook material, with the variable degree of detail in each cycle reflecting the knowledge of the reservoir contents and inter-reservoir fluxes at the time (Rankama and Sahama, 1950). Subsequent decades produced the knowledge we have today of the different chemical forms of carbon in the different compartments of the Earth, their abundances, and flows, all of which make the global biogeochemical cycle of carbon.

Structure of the carbon cycle

Geochemical or biogeochemical cycles of chemical elements are usually represented by environmental reservoirs and material flows or fluxes connecting them to each other. The structure of the global carbon cycle is shown in Figure C1 and the masses of carbon in the main environmental reservoirs are summarized in Table C1. The inventory of the reservoirs represents the geologic near-Recent, with atmospheric carbon given as the pre-industrial concentration of CO₂. Estimates of carbon masses in other reservoirs are subject to variable and greater uncertainties. The mass of carbon in land plants has been variably reported in the range of ±15–20% of the value given in Table C1, 700 Gt C (1 gigaton or 1 Gt = 10¹⁵ g). Large variations in the estimated global mass of peat and soil humus have also been reported in the literature. Thus, the numbers in Table C1 should be viewed as estimates for geologically recent time, and it should be kept in mind that the masses of carbon in the individual reservoirs have varied considerably throughout the Earth’s history. The carbon cycle is usually divided into a deeper part, called the *endogenic cycle*, and the *exogenic cycle* that includes the surface reservoirs of the sediments, oceanic and continental waters, land and aquatic biomass, soils, and the atmosphere.

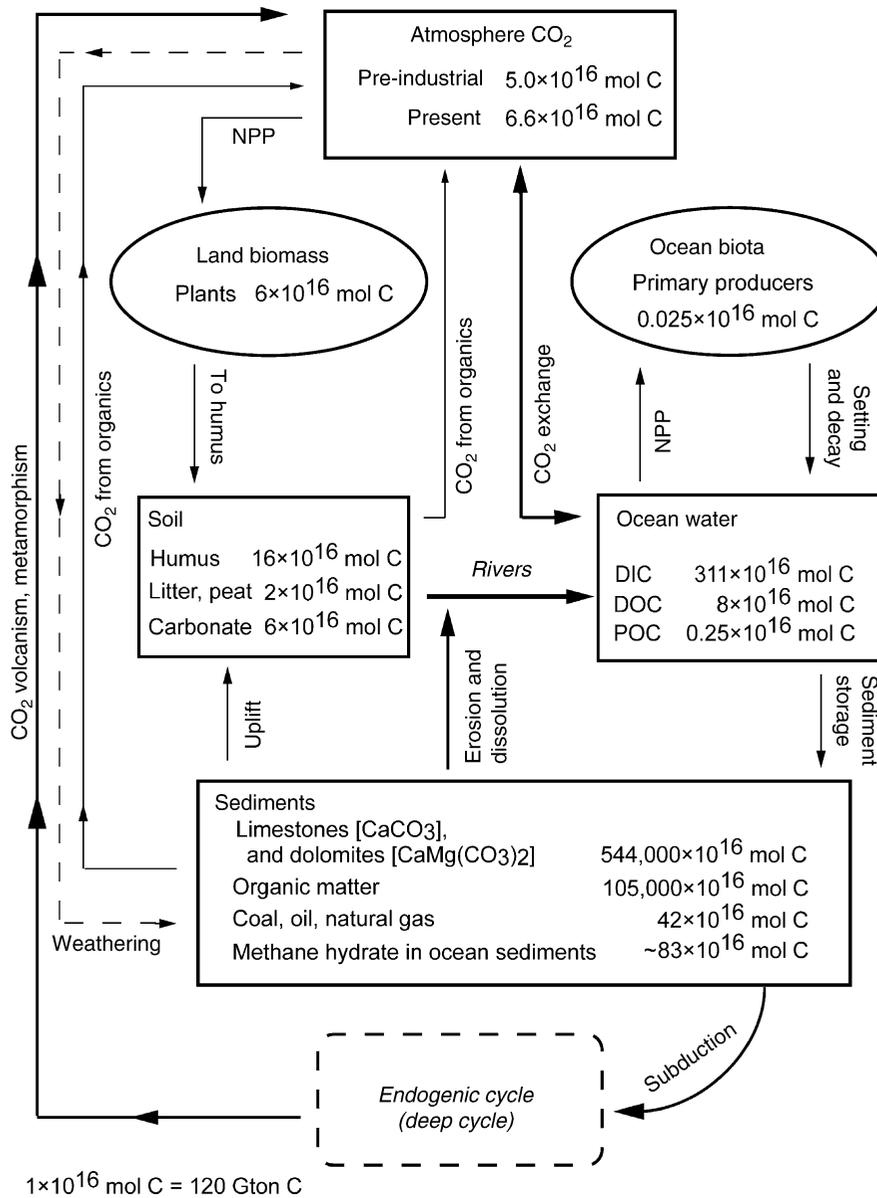

Figure C1 Global biogeochemical cycle of carbon. Reservoirs on the Earth surface represent the exogenic cycle. Masses of the major reservoirs given in Table C1. Mass units: 1 mol C = 12.011 g C or 1×10^{16} mol C = 120 Gt C. From Mackenzie and Lerman (2006).

The biggest reservoir of carbon near the Earth's surface lies in past and present oceanic sediments. These include carbonate rocks that comprise limestones, consisting mostly of the mineral calcite (CaCO₃), and dolomite rocks made predominantly of the mineral dolomite (CaMg(CO₃)₂); younger unconsolidated carbonate sediments on the ocean floor, composed to a large extent of skeletal remains of marine organisms; and organic matter in sediments that consists of many different organic compounds containing reduced carbon. Inorganic, oxidized carbon in carbonates accounts for about 84% of the sedimentary carbon mass, and the remaining 16% are in reduced organic matter. Both inorganic (oxidized) and organic (reduced) carbon, occurring in carbonate rocks and organic matter, make only 3.7 wt.-% of all the sediment preserved in the geologic record.

The planetary average abundance of carbon in the Earth as a whole is not well constrained because its abundance in the lower mantle and core is not well known, but its abundance in the Earth's mantle is much lower than in the sediments, 0.008–0.015 wt.-%.

Oxidized carbon is the most abundant form at the Earth's surface where it occurs as carbon dioxide gas, dissolved carbonate and bicarbonate ions, and carbonate ions in sedimentary minerals. In addition to carbonate minerals, pure elemental carbon occurs in nature in two minerals, diamond and graphite. Diamonds are a product of high temperature and pressure associated with explosive volcanic rocks called kimberlites and lamproites that formed in the mantle. Graphite deposits occur in different forms: hydrothermal veins in igneous rocks where

Table C1 Carbon masses in the major environmental reservoirs. From data in Li (2001), Mackenzie (2002), Ver et al. (1999), and Walker (1977). Units: 1 mol C = 12.011 g C

Reservoir	Mass of carbon	
	In grams C	In moles C
Atmosphere		
CO ₂ (at pre-industrial 280 ppmv)	5.94×10^{17}	4.95×10^{16}
CO (present)	1.24×10^{15}	4.42×10^{13}
CH ₄ (present)	4.82×10^{15}	3.01×10^{14}
Ocean		
Dissolved inorganic (DIC)	3.74×10^{19}	3.11×10^{18}
Dissolved organic (DOC)	1×10^{18}	8.33×10^{16}
Particulate organic (POC)	3×10^{16}	2.50×10^{15}
Ocean biota	3×10^{15}	2.50×10^{14}
Land biota		
Phytomass	7×10^{17}	5.83×10^{16}
Bacteria and fungi	3×10^{15}	2.50×10^{14}
Animals	$1 \text{ to } 2 \times 10^{15}$	1.25×10^{14}
Land		
Soil humus	1.5×10^{18}	1.25×10^{17}
Reactive fraction of humus		2×10^{16}
Dead organic matter, litter, peat	2.5×10^{17}	2.08×10^{16}
Inorganic soil (CaCO ₃)	7.2×10^{17}	6×10^{16}
Sediments		
Carbonates	6.53×10^{22}	5.44×10^{21}
Organic matter	1.25×10^{22}	1.05×10^{21}
Continental crust (layer 30 km thick)	2.58×10^{21}	2.14×10^{20}
Oceanic crust (layer 6.5 km thick)	9.20×10^{20}	7.66×10^{19}
Upper mantle (layer from 30 to 700 km)	$(8.9 \text{ to } 16.6) \times 10^{22}$	$\sim 1.1 \times 10^{21}$

crystalline graphite precipitated from hot fluids, thermally metamorphosed coal, and metamorphic rocks originally rich in organic matter. Another form of carbon occurring in igneous rocks is carbonatite, a rock made mostly of calcite, dolomite, and iron-containing dolomite (ankerite). Carbonatites are believed to form in the mantle, at high pressures of CO₂, and extrude as volcanic rocks or intrude into the upper lithosphere at the later stages of magmatic differentiation. The occurrence of carbonatites is limited to small areas at about 330 locations (Barker, 1997), and their total mass is very small in comparison to the sedimentary limestones and dolomites.

On Earth, the biological origin of organic matter is indicated by the abundance ratio of the two stable isotopes of carbon, ¹³C/¹²C: this ratio is lower in biologically-produced organic matter than in the source of CO₂ used in chemosynthesis or photosynthesis. However, organic compounds of non-biological origin occur in a class of meteorites known as chondrites, among which carbonaceous chondrites contain between 0.26 and 3.5 wt.-% carbon in organic compounds coexisting with aluminosilicate minerals. This abundance of organic carbon in extraterrestrial materials may be compared with its abundance of about 0.75 wt.-% in the entire preserved mass of sediments on Earth. Fossil fuels – coal, petroleum, and hydrocarbon gases – represent a very small part of the global reservoir of sedimentary organic matter (Figure C1). Known reserves of fossil fuels (coal, petroleum, and natural gas), recoverable with present-day technology, are estimated at about 800 Gt C or 7×10^{16} mol C. Estimates of total fossil fuel reserves are about 5,000 Gt C and, additionally, 10,000 Gt C in methane-hydrate deposits on the ocean floor and in the tundra, estimated within a range of a factor of 10 smaller or greater (Kvenvolden, 1988; Kvenvolden and Lorenson, 2001). These masses of fuel reserves and methane

hydrates make about 0.1 wt.-% of sedimentary organic carbon (Figure C1). The mass of atmospheric carbon dioxide would more than double if the known fossil fuels of 800 Gt C were burned to their commercial exhaustion and there were no removal of carbon dioxide from the atmosphere. A much greater potential increase in atmospheric carbon dioxide is indicated by the amounts of the estimated fuel reserves and methane hydrate.

The mass of carbon stored over the geologic history of the Earth in sedimentary limestones, dolomites, and undecomposed organic matter exceeds by a very large factor, about 100,000 the mass of carbon in atmospheric CO₂ at the present time.

Next in size is the carbon reservoir of the oceans or, more generally, of the oceanic and continental surface and ground waters that comprise most of the hydrosphere. The main form of carbon in the global water reservoir is dissolved carbon dioxide and its ionic species, and the generally less abundant dissolved organic carbon from incomplete decomposition of living and dead organic matter. These dissolved forms of carbon are usually denoted DIC, for dissolved inorganic carbon, and DOC, for dissolved organic carbon. Dissolved inorganic carbon (DIC) includes three aqueous species – CO₂, HCO₃⁻, CO₃²⁻ – and, to a lesser degree, their complexes with metal ions in solution. On the other hand, dissolved organic carbon includes a great variety of organic compounds ranging in molecular weight from light, simple organic acids to much heavier and structurally more complex species. Besides the dissolved forms of carbon, there are particles containing both inorganic and organic carbon in continental and ocean waters. Particulate inorganic carbon or PIC is mostly the grains of eroded carbonate rocks and skeletons of calcareous organisms formed in surface waters that sink to the ocean floor. Its organic counterpart, particulate organic carbon or POC, consists of undecomposed cells, products of metabolic excretion by zooplankton (fecal pellets), soft parts of dead organisms and organic matter adsorbed on mineral-particle surfaces such as clays.

The total mass of carbon in the global oceans, consisting mostly of DIC, is about 60 times greater than its atmospheric mass (Table C1). The greater mass of DIC in the ocean becomes either a source or sink of atmospheric carbon dioxide, depending on environmental conditions (Sect. *Running of the carbon cycle*).

In the atmosphere, carbon dioxide is the most abundant of the carbon-containing gases. At present, it forms a volume fraction 3.85×10^{-4} or 385 ppmv¹ of the atmosphere, increasing at a rate of approximately 1.5 ppmv per year. Other gases, such as methane (CH₄) from natural sources or agricultural activities, carbon monoxide (CO) and volatile organic compounds mainly from industrial activities, and the most recent emissions of the various chloro-fluoro-carbon compounds (CFCs) used as refrigerant and spray-propellant gases are believed to have a potentially much greater effect on atmospheric temperature, stratospheric and tropospheric ozone, and climate, despite their occurrences at concentrations much lower than those of atmospheric CO₂.

In the biosphere, land plants represent a major part of the carbon in living organic matter. This very large and diversified group includes predominantly photosynthetic plants ranging in

¹ppmv is parts per million by volume. In the atmosphere that is a mixture of ideal gases at the total pressure $P = 1$ atm, concentrations of individual gases in units of ppmv are also their partial pressures in units of 10^{-6} atm. CO₂ at a concentration of 370 ppmv has a partial pressure 3.70×10^{-4} atm.

size from short-lived unicellular organisms to trees whose lifetimes average several decades. Forests are the main reservoir of biotic carbon on land. In the ocean, most of the photosynthesizing organisms live in the upper layer of the oceans where sufficient light is available, called the euphotic zone, of an average thickness of 50 m, ranging up to about 200 m in very clear water. These free-floating organisms are the phytoplankton, and at least one group of the phytoplankton (coccolithophorids) are important producers of calcium carbonate shells that have made up a major part of the ocean-floor carbonate sediments since the middle of the Mesozoic Era. Additional aquatic photosynthesizers include the great variety of algae and bigger plants rooted to the bottom, known as macrophytes. The oceanic phytoplankton makes only a small fraction, about 0.5%, of carbon in the global biota. However, oceanic plants have a much shorter life cycle, about 20 days–1 month, than the land plants that turn carbon over approximately every 10 years. These differences account for the fact that flows of carbon through the land and oceanic phytomass are not too different (Table C4).

Carbon on the primordial earth

The Earth's history in its early stages went from the formation of the planet by accretion of a cloud of solid particles and gases to its partial melting after accretion, which resulted in the structural separation of its major units – the inner and outer core, the mantle and the lithosphere, and the crust. After the formation of the Earth nearly 4.55 billion years ago, a long period of some 650–800 million years preceded the appearance of life, the first fossil records of which are dated at 3.75–3.9 billion yr before present (Mojzsis et al., 1996; Rosing, 1999). This time of prebiotic Earth, known in the geologic time scale as the Hadean Eon, was a long period of environmental conditions very different from those of later time, when photosynthetic organisms emerged and modified greatly the Earth's surface environment. In this early, prebiotic stage of Earth history, when the temperatures near the Earth surface were considerably higher than at present, possibly near the 1,000 °C of silicate melts, the lighter chemical constituents of the Earth were separated or degassed from the solids and melt, forming the fluid layer of the primordial atmosphere. These volatile constituents became the major components of the outer shell of the Earth that comprises its atmosphere, hydrosphere, biosphere, and sediments.

The chemical elements and their compounds that escaped from the molten or solid Earth interior by degassing and made the primordial atmosphere are known as the *volatiles* (Rubey, 1951) or *hyperfusibles* (Poldervaart, 1955), mainly water

(H₂O), carbon (C), nitrogen (N), sulfur (S), and chlorine (Cl), as listed in Table C2. Rubey (1951, 1955) and later investigators who studied the balance of the volatiles at the Earth's surface demonstrated that their complete inventory includes some of the same constituents that had been added to the Earth's surface by the weathering of igneous rocks and, in general, by transfer of materials from the lithosphere to the oceans and sediments. These amounts are small fractions of the total masses of volatiles and the difference between the total and those derived from igneous rocks is known as *excess volatiles*. The masses of H₂O, C, N, S, and Cl in the present-day Earth's surface environment are approximately the masses of the volatiles on the primordial Earth that became incorporated in the differentiated outer shells of the cooler, later Earth. Water is the most abundant volatile and its mass exceeds the masses of other volatiles by a factor of 30–300. The individual estimates of H₂O and N, shown in Table C2, agree within 10–15%, but there is a much greater variation among the estimates of C, Cl, and S, attributable probably to the differences in the estimated masses of sedimentary rock salt, sulfates, sulfides, and the organic and inorganic carbon reservoirs. The view that most of the volatiles on the Earth's surface had been released from the mantle by degassing rather than remaining on the surface from an early stage of planetary accretion has been discussed by several authors (Rubey, 1951; Walker, 1977; Li, 2000). Degassing was probably not uniform and for such volatiles as carbon dioxide, water and perhaps sulfur, large fractions may still remain in Earth's upper mantle and possibly deeper in its interior.

The five primordial volatile gases were likely to have been H₂O (v), CO₂, N₂, HCl, and H₂S, although a number of authors have argued for different species of carbon, nitrogen, and sulfur as components of the primordial atmosphere: methane (CH₄) instead of carbon dioxide (CO₂), ammonia (NH₃) instead of molecular nitrogen (N₂), and sulfur dioxide (SO₂) instead of the reduced form of hydrogen sulfide (H₂S). Concerning the main chemical form of carbon in the early atmosphere, CO₂ rather than CH₄ is a thermodynamically stable species in the presence of even very low concentrations of oxygen gas (O₂), such as might have existed in contact with magmatic silicate melts. For the five volatiles to exist in a gaseous state, the temperature of the atmosphere should have been sufficiently high to prevent their condensation. Of the five, the highest critical temperature is that of H₂O, 374 °C, and this may be taken as a representative temperature of that stage of the early Earth before the volatiles began to condense to liquid water and form an aqueous solution of reactive and nonreactive gases. Although the time sequence and rate of Earth's cooling, the formation of the early oceans, and the reactions between minerals and water that led to the

Table C2 Volatiles in primordial Earth's surface environment (masses in grams of chemical species shown)

^aFrom data in Li (2001) and other sources.

accumulation of dissolved solids in ocean water are known very incompletely, the prebiotic atmosphere and ocean likely evolved in three stages:

- (1) A hot atmosphere where the five volatiles could occur as gases.
- (2) A cooler atmosphere after the water has condensed and accumulated as a liquid on the Earth's surface, and hydrogen chloride and hydrogen sulfide were removed from the atmosphere by reactions with crustal rocks and transport of the reaction products to the primordial ocean.
- (3) An atmosphere where carbon dioxide and nitrogen remained the two main constituents, and CO₂ also dissolved in the primordial hydrosphere and reacted with crustal rocks.

After the Earth's surface had cooled, and HCl and H₂S were removed from the atmosphere by dissolution in the early hydrosphere and chemical reactions with crustal rocks, the two remaining main constituents of the atmosphere were CO₂ and N₂. Chemical neutralization of the chloride-ion from HCl and the sulfate-ion from the oxidized H₂S by reactions with silicate rocks would have added metal cations that doubled the salt content of the primordial ocean relative to the present-day value (70–80 g kg⁻¹ as compared to 35 g kg⁻¹ now). At a limiting, hypothetical case of no removal of CO₂ and N₂ from the atmosphere, the atmosphere would have been almost pure carbon dioxide at a concentration 97.4 vol.-% CO₂ with 2.6 vol.-% N₂ (the C and N masses of total volatiles given in the last column of Table C2 correspond to 6.481×10^{21} mol CO₂ and 0.175×10^{21} mol N₂). The combined mass of CO₂ and N₂ in this atmosphere, covering the Earth surface of 510×10^6 km², would have generated an atmospheric pressure of about 56 bar.

At a surface temperature of the Earth near 25–35 °C, about 25% of the CO₂ could dissolve in ocean water, with around 75% remaining in the atmosphere. Because N₂ gas at these temperatures is much less soluble in water than CO₂, the remaining atmosphere would have been 96.6 vol.-% CO₂ and 3.4 vol.-% N₂, with a total atmospheric pressure of about 40 bar. Dissolution of a large mass of CO₂ in the primordial hydrosphere would have resulted in very high concentrations of DIC in water, about 1 mol C kg⁻¹, in comparison to the present-day concentration in ocean water of about 2×10^{-3} mol C kg⁻¹. Because DIC reacts with Ca²⁺-ions in solution, making CaCO₃ as calcite and/or aragonite (Reaction (8) below), the solubility of CaCO₃ and the capacity of the solution to remain supersaturated with respect to these minerals place a limit on the mass of CO₂ and calcium that can remain in solution. For the removal of most CO₂ from the primordial atmosphere, a mass of CaCO₃ comparable to its present mass preserved in sediments might have formed during the first several hundred million years of Earth's prebiotic history. The higher concentrations of CO₂ in the primordial atmosphere, at the time when the solar luminosity was some 25–30% lower than at present, might have been responsible for the warming of the Earth's surface that kept it above freezing temperatures and enabled the emergence of life. (See *Archean environments; Atmospheric evolution, Earth; Faint young Sun Paradox*, this volume).

Running of the carbon cycle

The starting point of the carbon cycle is the Earth's mantle, from where it was degassed with other volatile elements in the early stage of the formation of the Earth. The processes of material exchange between the mantle and the Earth's surface belong in the endogenic cycle that operates on a much

longer time scale (10⁸–10⁹ years) and they are much slower than those among the surface reservoirs (Figure C1).

CO₂ in the atmosphere dissolves in rain, on land, and in ocean surface waters. It is also taken out of the atmosphere and surface waters by photosynthesizing organisms. Residues of living plants in part decompose to CO₂ and organic acids, and in part they become organic matter of soils and sediments. The solution of CO₂ in fresh water is mildly acidic and together with dissolved organic acids reacts with crystalline rocks of the continental crust, causing mineral dissolution and release of such major constituents of river waters as the metals sodium, magnesium, potassium, and calcium. Metal ions in rivers (Na⁺, K⁺, Mg²⁺, and Ca²⁺), balanced to a large degree by negatively-charged bicarbonate (HCO₃⁻) ions, are transported to the ocean. The calcium carbonate minerals, calcite and aragonite – both chemically the same (CaCO₃), but differing in their crystal structure – form in the ocean either as skeletons secreted by marine organisms that range in size from microscopic algae to large mollusks and corals, or by inorganic precipitation. Calcites containing up to about 15 mol-% Mg are formed by some groups of calcareous algae in shallow-water sections of the ocean. This calcium carbonate accumulates over large areas of the ocean floor in the form of settling shells of phytoplankton and zooplankton or in structures built of algae and corals, called reefs, in the shallower parts of the coastal zones. Aragonite and calcites rich in magnesium do not last long in the geologic record and they are transformed to calcite by recrystallization and/or dissolution and reprecipitation. Dolomite accounts for approximately 40% of the carbonate rock mass of the Phanerozoic Eon, the last 540 million years, but it is much less abundant, about 15%, in the carbonates of the younger Tertiary (Wilkinson and Algeo, 1989). At present, the formation of dolomite is much more restricted as, for example, in the highly saline coastal playas in the Persian Gulf.

In the present-day ocean, both the photosynthetically produced organic matter and calcium carbonate in surface waters have their own subcycles. As organic matter settles into the deeper ocean, it undergoes oxidation that returns CO₂ to ocean water (see *Carbon dioxide, dissolved (ocean)*). This process is also known as the biological pump. Some of the respired CO₂ is transported back to the surface layer by water mixing, but some of it is used in dissolution of CaCO₃ that rains down from the surface. An increase in concentration of dissolved CO₂ makes seawater more acidic and brings it to a level of undersaturation with respect to calcite and aragonite. Both of these minerals dissolve in the deep ocean, and their rates of dissolution are sufficiently fast to return most of the CaCO₃ to ocean water. Preservation of CaCO₃ in ocean-floor sediments is limited in the present-day ocean to depths smaller than approximately 3,500–4,000 m, which is a combined effect of a higher concentration of dissolved carbon dioxide that lowers the CO₃²⁻-ion concentration, an increase in the solubility of calcite with an increasing pressure, and a faster dissolution rate in a solution that is farther away from saturation with respect to the mineral. Over geologically long periods, much of the oceanic CaCO₃ was preserved in sediments that became the sedimentary cover of the present-day continents and some of it was transported into the mantle by the process of seafloor spreading and subduction of their margins in ocean trenches. This subduction process is part of the endogenic cycle (Figure C1) that breaks down CaCO₃ at high temperatures in the mantle and returns CO₂ to the surface, mostly in gases emitted by continental and oceanic volcanoes. The isotopic

composition of carbon in CO₂ in some of the volcanic emissions suggests that it is a mixture of carbon originally from the mantle and carbon from the Earth's surface.

The organic matter of terrestrial plants becomes incorporated in soils, where it is known as humus (a mixture of complex organic humic and fulvic acids), and the residues of fresh-water and oceanic plants are buried in sediments. Some of this organic matter decomposes more slowly, producing CO₂ and organic acids. The nutrient elements nitrogen and phosphorus return to soil water, where they become available once more for new plant growth. However, some fraction of this organic matter resists decomposition. This fraction becomes nearly permanently buried. Because land is at a higher elevation than the ocean surface, there is a continuous transport of running water carrying dissolved material and solid particles eroded from rocks, soils, and terrestrial organic matter to the ocean. Particles containing organic carbon (POC) are brought to the ocean where some of the POC decomposes. CO₂ thus produced by decomposition of terrestrial organic matter is added to CO₂ already present in ocean water.

In the ocean, atmospheric CO₂ dissolves in the surface water layer, a few hundred meters thick, which is well mixed by winds, and there it is used in photosynthetic production of organic matter, in addition to the production of calcium carbonate. The exchange of CO₂ between surface ocean water and the atmosphere depends on such factors as the mass of CO₂ in the atmosphere; temperature, salinity, and chemical composition of ocean water; the production and respiration of organic matter; and precipitation and dissolution of calcium carbonate minerals. For example, greater biological production of organic matter and its storage in sediments removes carbon dioxide from the atmosphere-ocean system; weathering of old organic matter in oceanic sediments exposed on land returns carbon dioxide to the atmosphere; and formation of calcium carbonate and its deposition in sediments removes carbon from the atmosphere-ocean system, yet it also changes the relative abundances of the three dissolved species of inorganic carbon in ocean water (CO₂, HCO₃⁻, and CO₃²⁻) and by this it affects the air-sea CO₂ exchange.

Net removal of carbon from ocean water by sedimentation of undecomposed organic matter and calcium carbonate must be balanced by inputs of carbon from other sources. One obvious but limited source is dissolution of atmospheric CO₂ in ocean water. Another important source is oxidation of carbon in organic matter that was eroded from older sediments on land and that was transported to the ocean. As atmospheric CO₂ is the source both of organic matter stored on land and in oceanic sediments, and the atmosphere and ocean water lose CO₂ by the formation of CaCO₃ and its storage in sediments, this CO₂ source would have been exhausted rapidly if it were not replenished. Replenishment comes from oxidation of old organic matter that is disseminated in sediments and more concentrated in black shales. Tectonic processes that cause uplift of continental masses and mountain building expose these older sediments to the atmosphere and to weathering and erosion on the Earth's surface, thereby providing input of CO₂ to the atmosphere. Volcanic emissions also add or, in part, return CO₂ to the atmosphere.

Main driving processes

Deep carbon cycle

Carbon dioxide is emitted from the Earth mantle through subaerial volcanism, in the spreading zones and ridges on the ocean floor, and from magmatic plumes and hot spots. The occurrence

of this chemically oxidized form of carbon in magmatic emissions indicates that CO₂ is not just a product of carbon oxidation at the Earth's surface but has a much longer geologic history on our planet. This view is consistent with the chemical thermodynamic properties of carbon and oxygen that tend to combine and form carbon dioxide, as in the reaction:

Over a wide range of temperatures, from those at the Earth's surface to those of molten silicate melts, chemical equilibrium in Reaction (1) is strongly shifted to the right, producing very high ratios of CO₂ to O₂. At the relatively low temperature of the Earth's surface, many processes represented by Reaction (1) do not go spontaneously from the left to the right, but carbon can exist metastably in contact with the oxidizing atmosphere for a very long time. Common examples of such occurrences are the pure forms of elemental carbon graphite and diamond; less pure forms, such as the coal varieties anthracite, and lignite; and fossilized organic compounds, such as amber.

A shorthand notation of the endogenic cycle of carbon is the chemical reaction between calcium carbonate carried into the mantle by tectonic plate subduction and silica, which produces calcium silicate minerals and carbon dioxide:

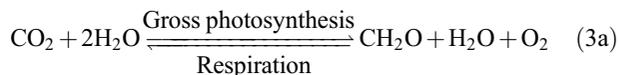

The reaction is generally known as the Urey reaction (Urey, 1952, pp. 148 and ff.), although J.J. Ebelmen was credited with introducing it much earlier, in 1845 (Berner and Maasch, 1996). In Reaction (2), CaSiO₃ represents various calcium silicate minerals that occur in igneous and metamorphic rocks. SiO₂ occurs either in the melt or in igneous rocks that can react with calcium carbonate. Reaction (2), going from left to right, describes the conversions of carbonates to calcium silicate and production of carbon dioxide during metamorphism. The reverse reaction, from right to left, represents chemical weathering of silicates in the continental crust by reactions with CO₂, and the final product CaCO₃. This omits intermediate reactions that involve Ca²⁺, HCO₃⁻, and CO₃²⁻ ions in aqueous solution.

Photosynthesis and respiration

Carbon is the main constituent of life on Earth. The main process that converts carbon dioxide into the organic molecules in cells of living plants is known as photosynthesis. Photosynthesis involves the chemical reduction of carbon, using the energy of sunlight to make organic matter in plants; the subsequent decomposition of organic matter is oxidation of carbon, also known as respiration or mineralization. These reactions are summarized in Reaction (3).

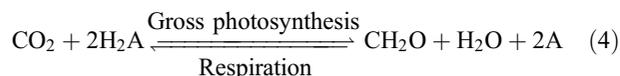

The respiration of organic matter is a process driven by bacteria that utilize the energy stored in CH₂O for their own metabolism. The common form of photosynthesis is the reaction between carbon dioxide and water that produces organic matter and free oxygen gas:

or, in a shorter form

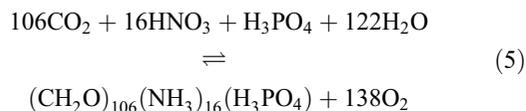

More generally, photosynthesis includes H_2A as a chemical compound where reduced A^{2-} transfers four electrons to oxidized carbon in CO_2 , to form organic matter of composition CH_2O and liberate $2A$ (Reaction (4)). Hydrogen sulfide, H_2S , is such an H_2A compound utilized by some photosynthetic sulfur-oxidizing bacteria:

The difference between gross photosynthetic production and respiration is net primary production, denoted NPP and usually given in units of carbon mass stored in living biomass in a unit of time (for example, mol C yr⁻¹). Reactions (3) and (4) are also often written with all the reactants and products multiplied by 6, giving the composition of organic matter as $C_6H_{12}O_6$, analogous to the sugar glucose. Organic matter produced by photosynthesis stores 470–490 kilojoules or 112–117 kilocalories of energy per 1 mole of carbon (1 mol C = 12.011 g C; 1 kcal = 4.184 kJ). When organic matter is oxidized, energy is released.

In photosynthesis, free molecular oxygen (O_2) is produced from water. Respiration generally oxidizes less reduced carbon than that produced by photosynthesis, which results in some surplus CH_2O and O_2 . This imbalance between photosynthesis and respiration has been of major importance to life on Earth because it enabled accumulation of molecular oxygen in the atmosphere and storage of organic matter in sediments over a period of perhaps the last 2 billion years or about one-half of the Earth's age of 4.6 billion years.

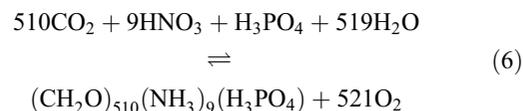

In addition to carbon, photosynthesizing organisms need nitrogen, phosphorus, sulfur, and trace elements. Mean atomic proportions of carbon, nitrogen, and phosphorus in photosynthesizing planktonic organisms are C:N:P = 106:16:1. The consistency and limited variability of this ratio, originally described by Redfield et al. (1963) and called the Redfield ratio since then, extend to oceanic zooplankton and to the plankton of continental waters. Oceanic phytoplankton uses nitrogen in the form of dissolved nitrate ions, NO_3^- , and phosphorus in the form of one of the dissolved phosphate ions, mostly HPO_4^{2-} . In solution, where the positively and negatively charged ions must balance, nitrogen and phosphorus used in the photosynthetic reaction can be written as neutral acid molecules, HNO_3 and H_3PO_4 , instead of the equivalent ($NO_3^- + H^+$) and ($HPO_4^{2-} + 2H^+$). The photosynthetic reaction of aquatic photosynthesis, similar to Reaction (4), is:

In Reaction (5), both carbon in CO_2 and nitrogen in NO_3^- are reduced, and the mass of oxygen produced is greater than the mass of carbon fixed in organic matter. In the absence of nitrate, ammonia (NH_3 or $NH_4^+ + OH^-$) may be utilized at least by some of the phytoplankton species, and organic matter of the same composition would be produced by a reaction with $16NH_3$ instead of $16NO_3^- + 16H^+$, then producing $106O_2$.

The Redfield ratio for land plants is less well constrained than for the aquatic phytoplankton, and C:N:P atomic ratios for land plants have been reported in a wide range from about 510:9:1 to 2057:17:1. Land plants are more efficient photosynthesizers

than marine organisms because they fix more carbon and produce more oxygen for each atom of phosphorus consumed. Higher land plants emerged in the Devonian Period that lasted from about 365 to 410 Ma ago. For a plant of C:N:P atomic ratio 510:9:1, the photosynthesis reaction based on carbon dioxide, nitrate, and phosphate, similar to Reaction (5), produces organic matter and oxygen in the following proportions:

In both Reactions (5) and (6), respiration or mineralization of organic matter is the reverse reaction (from right to left) that also consumes oxygen, but releases nitrogen and phosphorus to the environment, where they become available for new biological production. This recycling of nutrient nitrogen and, in particular, phosphorus is of major importance to biological productivity because the ultimate source of most phosphorus is in much slower leaching or dissolution from crustal rocks (see *Phosphorus cycle*).

Carbon in the atmosphere and hydrosphere

In an atmosphere containing oxygen, carbon dioxide is the only chemically stable form of carbon. More reduced carbon gases, such as carbon monoxide (CO), methane (CH_4), and volatile hydrocarbons are eventually oxidized to CO_2 . Carbon dioxide dissolved in water reacts to produce bicarbonate and carbonate ions:

An increase in concentration or partial pressure of CO_2 in the atmosphere results in its higher concentration in solution at equilibrium, and this further reduces the concentration of the carbonate ions and changes the relative proportions of the dissolved inorganic carbon species:

A higher CO_2 concentration can make the solution undersaturated with respect to $CaCO_3$ and cause dissolution, as shown in the following reaction going from the right to the left:

Reaction (8), proceeding from left to right, represents the formation of calcium carbonate minerals. As the bicarbonate ion, HCO_3^- , is the main species of DIC in ocean water and continental freshwaters, its reaction with Ca^{2+} removes 1 mole of carbon into sediments and produces 1 mole of CO_2 thereby restoring the balance of the carbonate species.

Dissolution of calcium carbonate by reaction with dissolved CO_2 represents the process of chemical weathering of limestones and silicate rocks on land, where they are exposed to atmospheric precipitation and groundwater containing elevated concentrations of CO_2 from respiration of organic matter in soils. The reaction of CO_2 with water that produces the bicarbonate and carbonate ions, the reactions of the latter with calcium, and the relatively low solubility of $CaCO_3$ minerals at the Earth's surface conditions are the factors behind the abundance of limestones and dolomites that once formed as oceanic sediments and became part of the continental crust and land surface.

Isotopic fractionation

In photosynthesis, plants use the lighter carbon isotope, ^{12}C , in preference to the heavier isotope, ^{13}C . This biological fractionation is a non-equilibrium process and results in marine and most terrestrial organic matter having a lower $^{13}\text{C}/^{12}\text{C}$ ratio than the atmospheric source. This difference, expressed as $\delta^{13}\text{C}$ (‰) (see *Carbon isotopes, stable*), amounts to organic matter being about 20–25‰ lighter than the value of $\delta^{13}\text{C} = -7\%$ of CO_2 in the present-day atmosphere. The land plants in the metabolic group C_3 that accounts for 85–95% of the present-day plant species, have an average $\delta^{13}\text{C} \approx -27\%$, with a range from -21 to -35% (O’Leary, 1988). A group of geologically younger land plants, the C_4 plants, is characterized by a smaller isotopic fractionation, -9 to -20% , with an average $\delta^{13}\text{C} \approx -13\%$. This metabolic pathway is only several million years old and it is believed to have evolved in response to lower atmospheric CO_2 concentrations. The third and smallest metabolic group, the CAM (crassulacean acid metabolism) plants, has carbon isotope fractionation values that extend from those of the C_3 to C_4 plants. In the ocean, the spread of $\delta^{13}\text{C}$ values for different groups of planktonic and benthic plants is considerable: -10 to -22% for algae and macrophytic plants, and -18 to -31% for plankton. Values of -20 to -21% are considered a representative average for marine plankton.

In the system of CO_2 gas, DIC, and CaCO_3 (calcite), isotopic fractionation at equilibrium between pairs of species is considerably smaller than in biological processes, as shown by the fractionation values in Table C3.

Equilibrium fractionation factor, α , is usually written in the δ notation of the two species exchanging their ^{13}C and ^{12}C . For the exchange between aqueous HCO_3^- and gaseous CO_2 the fractionation factor is, with the δ values taken as fractions:

$$\alpha_{\text{HCO}_3^-(\text{aq})-\text{CO}_2(\text{g})} = \frac{(^{13}\text{C}/^{12}\text{C})_{\text{aq}}}{(^{13}\text{C}/^{12}\text{C})_{\text{g}}} = \frac{1 + \delta^{13}\text{C}_{\text{aq}}}{1 + \delta^{13}\text{C}_{\text{g}}} \quad (9)$$

It should be noted that in the preceding notation the fractionation factor α is the quotient of the isotopic ratio in the aqueous phase to the ratio in the gaseous phase. As long as δ is much smaller than 1 and α is close to 1, the approximations $\ln(1 + \delta) \approx \delta$ and $\ln \alpha \approx \alpha - 1$ are used in Equation (9), giving logarithmic and linear forms of α :

$$\ln \alpha_{\text{HCO}_3^-(\text{aq})-\text{CO}_2(\text{g})} = \delta^{13}\text{C}_{\text{aq}} - \delta^{13}\text{C}_{\text{g}} \quad (10a)$$

or

$$\alpha_{\text{HCO}_3^-(\text{aq})-\text{CO}_2(\text{g})} - 1 = \delta^{13}\text{C}_{\text{aq}} - \delta^{13}\text{C}_{\text{g}} \\ = 9.6\text{‰}_{00} \text{ to } 7.9\text{‰}_{00} \quad (10b)$$

The preceding shows that the equilibrium fractionation is the difference between the $\delta^{13}\text{C}$ values of the two species. The bicarbonate ion in solution, as the main species of DIC, is isotopically heavier than CO_2 gas by 7.9‰ (at 25°C) to 9.6‰ (at 5°C) (Table C3). Isotopic fractionation of carbon between calcite and the bicarbonate ion in solution, as in Reaction (8), is small at Earth surface temperatures, where the $\delta^{13}\text{C}$ of calcite differs from HCO_3^- by -0.1 to $+0.9\%$ (Table C3). For this reason, changes in the isotopic composition of carbon in limestones through geologic time, such as those shown in Figure C2a, are considered as representative of the isotopic composition of DIC in ocean water, from which the rates of biological production and storage of organic carbon are estimated for different geologic periods.

Carbon fluxes

On the Earth’s surface with a climate and vegetation cover similar to those of pre-industrial times, the biggest carbon fluxes are those of net primary production (NPP) on land and in the ocean (Table C4). In Recent time, NPP on land recycles atmospheric CO_2 every 9 years:

$$\text{Recycling time} = \frac{\text{CO}_2 \text{ mass}}{\text{NPP}} \\ = \frac{4.95 \times 10^{16} \text{ mol C}}{5.25 \times 10^{15} \text{ mol C yr}^{-1}} = 9.4 \text{ yr}$$

Residence time of carbon in the individual reservoirs is a measure of the carbon cycle dynamics. Changes in reservoir sizes and fluxes in the geologic past produced great changes in the residence times of carbon in the different reservoirs. In particular, changes in atmospheric carbon dioxide and density of vegetation cover of land, discussed in the next section, were likely to result in changes in the residence times. The near-Recent mean residence time of carbon in land vegetation, from

Table C3 $^{13}\text{C}/^{12}\text{C}$ equilibrium fractionation between species shown as 1 and 2 in gaseous phase (g), aqueous solution (aq), and calcite (cal). Notation of the fractionation factor α_{12} is given in Equations (9)–(10). Temperature T is in Kelvin

No.	Species and phase		$\ln \alpha_{12}$ or $\alpha_{12} - 1$, as shown	T range (°C)	$(\alpha_{12} - 1) \times 10^3$ (‰)

^bUplift assumed as balanced by subduction of ocean floor over geologically long periods (Mackenzie, 2002, p. 178).

the data in Tables C1 and C4, is about 11 years. Greater land coverage by either forests or grasses would lead to considerably longer or shorter, respectively, residence times of carbon in land phytomass. Recycling time by oceanic phytomass is about 0.06 yr or 20 days.

Volatilization of carbon from soil humus is due to respiration or mineralization of the reactive fraction of humus (15–20% of total). This implies a faster recycling of soil organic matter than may be suggested by the size of the whole reservoir.

The ratio of mean carbon fluxes of carbonate and organic carbon (carbonate/organic) in long-term storage or burial in sediments is 3.6–5.6, comparable to the mass ratio of 5.2 in sedimentary reservoirs (Tables C1 and C4). However, the rivers transport much more organic carbon relative to DIC, with the DIC to organic carbon ratio between about 1 and 1.8 (Table C4). This indicates that the rate of organic matter recycling in sediments is considerably faster than that of carbonates on a geologically long timescale.

Carbon trends through time

Sedimentary mass records

Preservation of sediments is subject to recycling, a process in which materials are eroded and dissolved, the products transported to the ocean where deposition or new mineral formation occurs, and ultimately the materials are reincorporated in the continental sediment cover or crystalline crust, through continental accretion and/or the endogenic cycle. As a result, the older the sediment, the less is preserved. Furthermore, most older sediments of the Early Proterozoic and Archean Eons, older than about 2 billion years (2 Ga), have been metamorphosed, and it is difficult to estimate the original proportions of the different sediment types in metamorphic rocks.

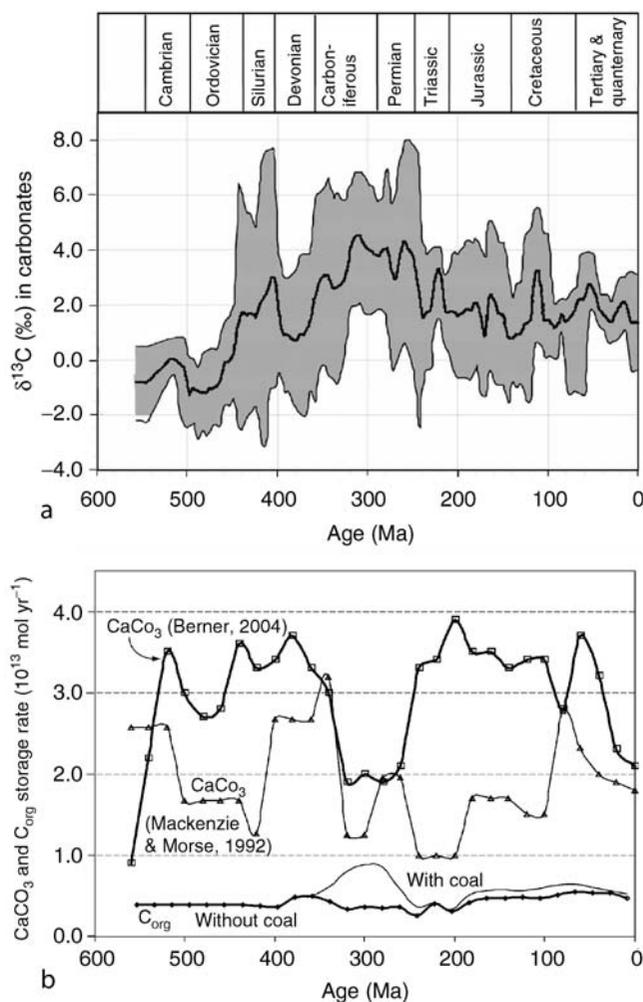

Figure C2 (a) Distribution of $\delta^{13}\text{C}$ in the shells of biogenic calcite during the Phanerozoic, based on approximately 4,500 samples. The black line is a running mean and the shaded area includes the 95% confidence limit about the mean (from Veizer et al., 1999). The base of the Phanerozoic Eon is the base of the Cambrian Period, 542 Ma BP, as given by the International Commission on Stratigraphy 2004. (b) Calculated CaCO_3 and organic carbon storage rates (accumulation rates) during the Phanerozoic (from data of Berner and Canfield, 1989; Mackenzie and Morse, 1992; Robert A. Berner, Yale University, personal communication, 2004).

The rates of carbonate storage during the last 550 Ma (Figure C2b) vary by about 50% from the mean, depending on the data source, but they show a decline from the higher values of the past to recent values. Organic carbon shows an increase in the storage rate around 300 Ma before present due to massive accumulation of coal in the Carboniferous Period. Variations in the rates of organic carbon storage result in variations of the rates of oxygen production, as shown in Reactions (3b), (5), and (6), with more oxygen generated when more photosynthetically produced organic carbon is sequestered.

A record of isotopic composition of organic carbon and carbonate carbon since the Late Proterozoic time, about 780 Ma ago, is shown in Figures C2a and C3. In general, an increase in the values of $\delta^{13}\text{C}_{\text{carb}}$ is accounted for by a greater rate of

storage of organic matter that incorporates ^{12}C in preference to ^{13}C . The fluctuating increase in $\delta^{13}\text{C}_{\text{carb}}$ during the earlier part of the Paleozoic Era, from 500 to 300 Ma ago, probably indicates long-term expansion of marine biological production and emergence of higher land plants in the Devonian Period, between about 400 and 360 Ma ago (see also *Carbon isotope variations over geologic time*). The magnitude of isotopic fractionation due to biological production and storage of organic carbon is the difference between the $\delta^{13}\text{C}$ values in carbonates (taken as representing the DIC isotopic composition in ocean water, Figure C2a) and organic carbon (Figure C3c; see preceding section on *Isotopic fractionation*).

The fractionation factor (ϵ , in ‰) varied within a range of 28–33‰ during the Paleozoic Era, from about 540 to 245 Ma. Departures outside this range, in geologically earlier and later periods may represent, at least to some extent, evolutionary changes in the oceanic and terrestrial biotas. In Late Proterozoic time, older than 540 Ma, large variations in the isotopic values of organic and carbonate carbon (Figure C3a, b) may correspond to the times of three major glaciations that occurred between 800 and 600 Ma ago, when rates of storage of organic carbon might have been relatively low (Hayes et al., 1999, p. 111). A decline in $\delta^{13}\text{C}_{\text{carb}}$ since the beginning of the Cenozoic Era about 65 Ma ago (Figures C2a and 3b) is usually attributed to the rise in the elevation of land and emergence of the major mountain terrains, such as the Alps and the Himalayas, which exposed more of the old organic carbon from shales to weathering, thereby adding more ^{13}C -depleted carbon to the oceans. However, the reasons behind a decrease in biological fractionation during the same period are not altogether clear.

As sedimentary carbonates and organic matter account for most carbon on the Earth's surface (Table C1), the isotopic

composition of these two reservoirs has been used to estimate their mass fractions in the sedimentary record. Because carbon on the Earth's surface ultimately originated in the mantle, $\delta^{13}\text{C}$ of the mantle should equal the mean $\delta^{13}\text{C}$ of the two major surface reservoirs (sedimentary carbonates and organic carbon). Thus, the isotopic composition balance requires that

$$\delta^{13}\text{C}_{\text{mean}} = f\delta^{13}\text{C}_{\text{carb}} + (1 - f)\delta^{13}\text{C}_{\text{org}} \quad (11)$$

where f is the mass fraction of carbonate carbon and $1 - f$ is the mass fraction of organic carbon in sediments. The mean $\delta^{13}\text{C}$ for mantle and surface carbon lies in the range of $-5 \pm 2\text{‰}$, the organic carbon reservoir in the Phanerozoic is about -28‰ , and the carbonate carbon is between $+1$ and $+2\text{‰}$ (Figure C3a, b). These values of $\delta^{13}\text{C}$, used in Equation (11), give the fraction of organic carbon in sediments, $1 - f = 0.15$ to 0.29 . The value given in Table C1 is 0.16.

Atmospheric CO_2

The latest major period of the Earth's history, the Phanerozoic Eon, covers approximately the last 550 Ma when such major evolutionary events occurred as the emergence of large vascular land plants and different groups of CaCO_3 -secreting organisms in the ocean. The biosphere and the global carbon cycle most likely affected one another interactively throughout the Earth's history, when atmospheric CO_2 undoubtedly played a major role in both because of the properties of the atmosphere. Apart from its interactions with the biosphere, atmospheric CO_2 is variably controlled by the major tectonic processes of the formation of the new ocean floor at the oceanic spreading zones, subduction of oceanic sediments, and emission of CO_2 from the deeper parts of the Earth by volcanism and

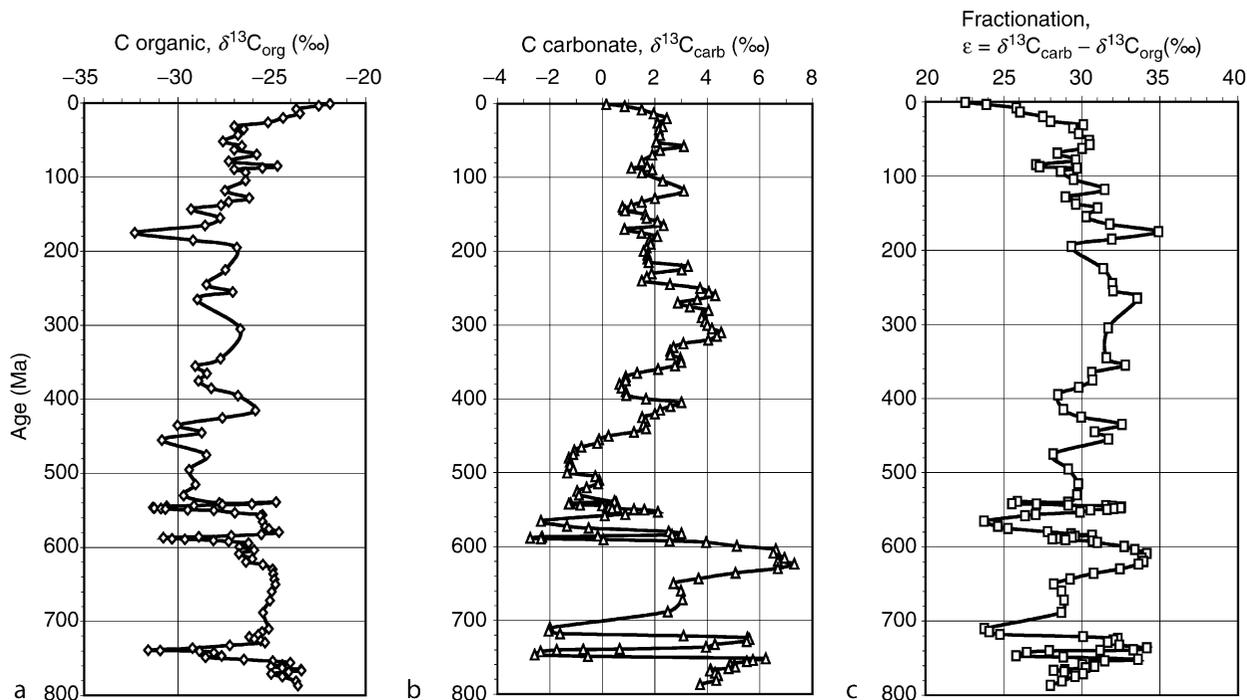

Figure C3 Carbon isotopic composition ($\delta^{13}\text{C}$, in ‰) in the Late Proterozoic (age > 570 Ma) and Phanerozoic time of (a) organic matter and (b) carbonates. (c) Fractionation between carbonate and organic carbon, ϵ in ‰ (from Hayes et al., 1999, and data provided by John M. Hayes, Woods Hole Oceanographic Institution, June 2003).

metamorphic processes. Furthermore, the rates of weathering on land, transport of weathered materials to the ocean, and sedimentary storage of organic matter and carbonates are all parts of the carbon cycle that involve the atmospheric CO₂ reservoir.

Atmospheric CO₂ underwent great changes in concentration during the Phanerozoic, as shown in Figure C4. Relative to its pre-industrial concentration of about 300 ppmv, CO₂ atmospheric levels might have been 15–25 times higher in the Early Paleozoic time, before a decline began about 380 Ma ago due to emergence of large vascular land plants. The high atmospheric CO₂ concentrations at that time might have been comparable to those of modern soils that contain about 30 times more CO₂ in their pore space than the atmosphere, due to the respiration or oxidation of organic matter. The calculated CO₂ curve, and its upper and lower limits of estimated error (e.g., Berner and Kothavala, 2001), is based on a geochemical model of the carbon cycle in a system of land-ocean-atmosphere reservoirs, and it includes numerous processes that affect weathering, biological production, and storage of reduced and oxidized carbon in sediments.

Among such processes are the increase in solar luminosity during the Phanerozoic, changes in the area and elevation of the global land mass, changes in the abundance of gymnosperm and angiosperm plants, water runoff from land, temperature, volcanic activity, and interactions among these processes. The low CO₂ values between about 380 and 280 Ma reflect the emergence of land plants in the Devonian and storage of coal in the Carboniferous Period. The higher values in the Mesozoic Era, from about 240 to 100 Ma, reflect a low relief of land and relatively low rate of utilization of atmospheric CO₂ in the weathering of continental rocks and old sediments. Thereafter, from the beginning of the Tertiary, the tectonically-driven rise of land resulted in higher weathering rates and a decline of atmospheric CO₂.

The variations in shallow ocean temperature and atmospheric CO₂ content during Phanerozoic time may be contrasted with those of the last 18,000 years, since the Last Glacial Maximum to the beginning of industrial time about 200 years ago and to the present. Since the Last Glacial Maximum, global mean temperature increased from about 9 °C to

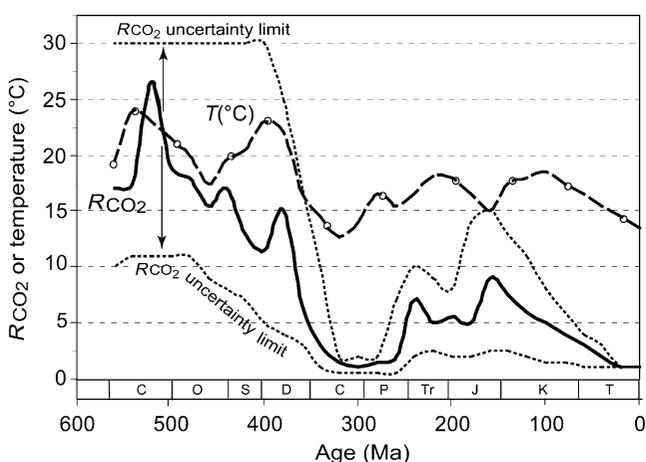

Figure C4 Calculated ratio of atmospheric CO₂ to the Holocene Epoch value taken as 300 ppmv (R_{CO_2}) and shallow ocean temperatures (from data of Berner and Kothavala, 2001, and Wallmann, 2004, as plotted in Locklair and Lerman, 2005).

15 °C and CO₂ from about 185 to 280 ppmv at the beginning of industrial time, indicating a change in R_{CO_2} from 0.66 to 1. Since 1861 to 2000, mean global temperature of the Earth's surface has increased further by about 0.7 °C and atmospheric CO₂ has risen by a factor of 1.33 since pre-industrial time. Concern is focused on the continued increase of atmospheric CO₂ due to burning of fossil fuels and human practices of land use, and the possible release of methane from the methane-hydrates due to warming (Figure C1). The rise in atmospheric carbon dioxide since the Last Glacial Maximum, and especially the last century, has not been countered by a greater biological production of organic carbon and, importantly, its sequestration in sediments that provide, together with mineral weathering, a powerful geological buffer of the carbon cycle.

CARBON DIOXIDE AND METHANE, QUATERNARY VARIATIONS

Introduction

A straightforward method to reconstruct variations of atmospheric greenhouse gas concentrations during the past few hundred thousand years is the analysis of air enclosed in bubbles of suitable polar ice. For polar ice to be suitable, the possibility of any influence of melt water must be excluded, which is the case for very cold regions in the center of the Antarctic and the Greenland Ice Sheet, in part. Such ice is formed by the compaction of snow and firn by a dry sintering process. Atmospheric air is gradually enclosed in bubbles at the transition from firn to ice, typically 70–120 m below the surface. If the age of air in ice is defined as the time since its separation from the free atmosphere, it is clear that it is younger than the surrounding ice (defined as the time since deposition as snow). The age difference varies between a few decades for high accumulation rate sites and up to 5 millennia or more for low accumulation rate sites. For a given drilling site, the age difference generally varies with depth due to variations of temperature and accumulation rates in the past.

The gradual enclosure of air in bubbles also implies that air of an ice sample does not have a well-defined age but has a certain age distribution, depending on temperature and accumulation rate. This limits the possible time resolution of greenhouse gas records to a few years for high accumulation rate sites and more than a century for low accumulation rate sites. The air is well preserved in the bubbles. Diffusion of gases in cold ice is low. However, chemical reactions with impurities cannot be excluded, even in very cold ice.

The main foci of analyses of air samples extracted from air bubbles are the concentrations of the greenhouse gases CO₂ and CH₄, together with N₂O and the O₂/N₂ ratio. The isotopic composition of the gases is also of interest, especially in finding possible causes of observed variations. In the following description, only variations of the atmospheric concentration of the important greenhouse gases CO₂ and CH₄ will be discussed.

Records measured along the Antarctic Vostok (78° 28' S, 106° 48' E) core go back to 420,000 yrBP (Petit et al., 1999) and those from the recently drilled Dome C (75° 06' S, 123° 21' E) core date back to 740,000 yrBP (EPICA members, 2004). More detailed records are available for the last glacial epoch, the transition from the last glacial epoch to the Holocene, the Holocene and the last millennium. All these time intervals are discussed in separate sections.

Atmospheric CO₂ and CH₄ concentrations are relatively constant globally at any given time due to a short global mixing time. However, small CH₄ concentration differences between Greenland and Antarctica allow a rough estimate of the latitudinal distribution of CH₄ sources during different climatic epochs.

Analytical methods

To measure the CO₂ and CH₄ concentration of air enclosed in air bubbles of polar ice samples, the air has first to be extracted and then measured in a second step. For the extraction of air for CO₂ measurements, most laboratories use a dry extraction method to avoid any contamination with CO₂ that could be produced by the interaction of carbonates with water. Air

bubbles are opened mechanically by cracking, milling or grating ice samples at low temperature. For CH₄ measurements, air is removed by wet or dry extraction. In a typical wet extraction, ice is melted in an evacuated container and after all ice has melted, the sample is frozen very slowly from the bottom again to expel any air dissolved in the meltwater.

The CO₂ concentration in the air is measured by gas chromatography or by laser absorption spectroscopy. For the second method, a tunable infrared laser (wavelength about 4.23 μm) is tuned several times over the absorption line of a vibration-rotation transition of the CO₂ molecule. The CH₄ concentration is generally measured by gas chromatography. Measurement by laser absorption spectroscopy is possible but has not been used for routine measurements yet.

The minimal sample size for a single CO₂ measurement is 12 g ice; for a single CH₄ measurement, about 40 g ice is needed. Certain laboratories are using larger sample sizes but perform multiple analyses on the extracted air sample.

Reliability of CO₂ and CH₄ data from ice cores

The reproducibility of CO₂ measurements in air of polar ice samples is on the order of 1.5 ppmv. Results from direct atmospheric measurements of several ice cores that have an overlapping time period are in good agreement. However, this is no guarantee that the air in bubbles of older ice has exactly the composition of atmospheric air at the time of ice formation. CO₂ could be produced very slowly by carbonate-acid reactions or oxidation of organic material, or CO₂ dissolved or enclosed in micro bubbles in snowflakes could diffuse slowly into air bubbles. Only air from normal size bubbles and clathrates are extracted by dry extraction methods. The agreement of results for ice cores from various drill sites with different impurity concentrations show that the effect would be small, but cannot be excluded. For inland sites from Antarctica, it can be concluded that such artifacts are smaller than 5 ppmv.

The reproducibility of CH₄ measurements is about 10 ppbv. CH₄ is much less soluble in water than CO₂, but still twice as soluble as N₂. Therefore, it cannot be expected that analyses

of ice from locations with a mean temperature above -20°C will provide reliable results. Methane results are certainly less affected by chemical reaction between impurities in the ice, but a small production of CH₄ by chemical reactions or by biological activity cannot be excluded (Sowers, 2001).

Variations of atmospheric CO₂ and CH₄ concentrations during the past 650,000 years

Figure C5 shows variations of atmospheric CO₂ and CH₄ concentrations during the past 650,000 years compared with the Antarctic temperature derived from δD records. The CO₂ and CH₄ concentrations are based on analyses performed along the Vostok and the Dome C ice cores (Petit et al., 1999; Siegenthaler et al., 2005; Spahni et al., 2005). At Vostok, an ice core reached a depth of 3,623 m in 1998. The stratigraphy is undisturbed down to a depth of 3,310 m, and the ice at this depth is about 420,000 years old. More recently, an ice core was drilled at EPICA Dome C down to a depth of 3,270 m. The stratigraphy is probably undisturbed down to a depth of 3,200 m where the ice has an estimated age of about 800,000 years. Gas analyses have hitherto been published for ages up to 650,000 years. A very important result is that the atmospheric CO₂ and CH₄ concentrations never reached the present levels (about 370 ppm for CO₂ and 1,700 ppb for CH₄ in 2002) during this entire period.

The delta-deuterium (δD) record is a measure of regional temperature (see *Deuterium, deuterium excess*, this volume). A rather close correlation between variations of the two greenhouse gas concentrations and Antarctic temperature is obvious. CH₄ variations are more or less caused by climatic variations but there is also an important interplay between climatic and CO₂ variations, as will be discussed later.

Temperature during interglacial epochs before 430,000 yrBP was lower than in the subsequent interglacials but the duration of warm phases was longer. CO₂ concentrations were also lower in the interglacial epochs before 430,000 yrBP. At the end of glacial epochs, temperature started to increase between 600 and 2,800 years before the beginning of the increase in

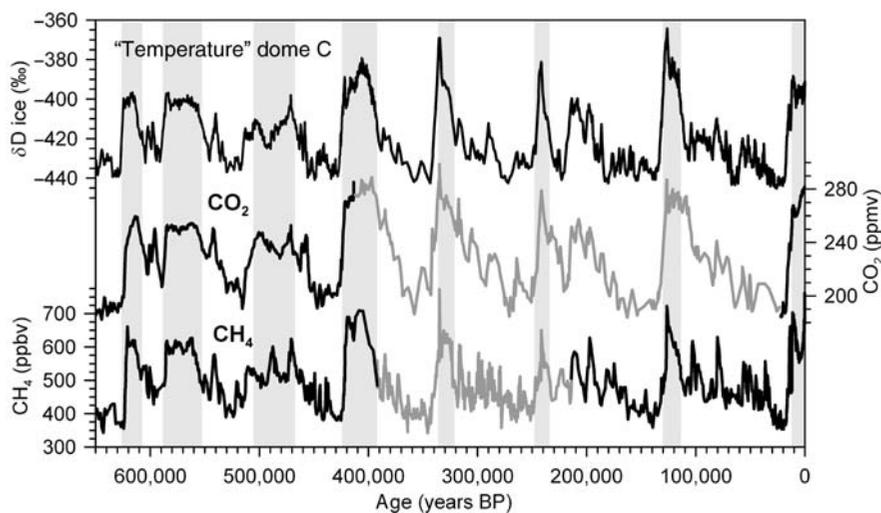

Figure C5 CO₂ and CH₄ records from Dome C and Vostok compared with the δD record from Dome C, which are characteristic for the local temperature (Petit et al., 1999; EPICA members, 2004; Siegenthaler et al., 2005; Spahni et al., 2005). Black lines are from Dome C, gray lines from Vostok. The shaded areas characterize interstadials.

the CO₂ concentration. This time lag does not call into question the interplay between temperature and CO₂ increase at the end of glacial epochs, which take place over several millennia.

The last glacial epoch

The last glacial epoch was characterized by large and fast temperature variations in Greenland, so called Dansgaard-Oeschger events, as documented by the $\delta^{18}\text{O}$ profile shown in Figure C6 (Dansgaard et al., 1993). The CH₄ concentration measured along the GRIP (Greenland Ice core Project) ice core shows variations parallel to the temperature variations, with higher concentrations during mild interstadials and lower concentrations in cold phases (Chappellaz et al., 1993). The variations are mainly caused by changes in CH₄ sources due to the productivity and the extension of wetlands in low and mid latitudes. The CH₄ variations are, therefore, a very convincing indication that Dansgaard-Oeschger events were not limited to Greenland but were climatic events of global significance.

The deuterium record from Antarctica and the $\delta^{18}\text{O}$ record from Greenland are scaled so that equal amplitudes correspond approximately to equal regional temperature variations. While these two records are quite different, the CH₄ records from Greenland and Antarctica are practically identical and show the same characteristics. Fast variations can, therefore, be used to synchronize age scales between Antarctic and Greenland ice core records (Blunier and Brook, 2001). This synchronization, however, shows an asynchrony in temperature variations between Greenland and Antarctica. As soon as a fast temperature increase in Greenland occurred, the temperature in Antarctica decreased.

The CO₂ concentrations measured along the Taylor Dome ice core (Indermühle et al., 2000) also show significant fluctuations but these are smoother and smaller than for CH₄. The variations are parallel to Antarctic temperature. Temperature variations in Antarctica were smaller than in Greenland, but

were accompanied by large variations in non-sea salt calcium deposition (nssCa) in Antarctica, indicating significant variations of terrestrial dust. A possible cause of the CO₂ variations with an amplitude of about 20 ppmv could, therefore, have been a variation of iron fertilization by eolian dust in the Southern Ocean (Röthlisberger et al., 2004).

The transition from the last glacial epoch to the Holocene

The transition from the last glacial epoch to the Holocene was the last large global temperature increase and was accompanied by a substantial increase in atmospheric CO₂ and CH₄. It is therefore a key period for investigating the interactions between global temperature and greenhouse gas concentrations. Figure C7 shows a section of Figure C6 with greater resolution (Monnin et al., 2001). The CO₂ concentration increased by 76 ppmv from 189 to 265 ppmv between about 17,000 and 11,100 yrBP in Antarctica. The increase occurred in four clearly distinguishable intervals. After a first, relatively fast (20 ppmv per thousand years) linear increase (I), a reduced linear increase followed in interval II, with a very fast increase of about 8 ppmv at its end. In interval III, characterized by a temperature decrease in Antarctica (Antarctic Cold Reversal), the CO₂ concentration also decreased slightly. In interval IV the CO₂ concentration increased at about the same rate as in interval I. This interval was concluded by another fast increase of about 6 ppmv, rising to 265 ppmv at the beginning of the Holocene.

The increase of the CO₂ concentration parallels the temperature increase in Antarctica, confirming that the Southern Ocean played a key role in causing the CO₂ increase. The rapid concentration increases at the end of interval II and IV occurred during rapid temperature increases in the Northern Hemisphere, indicating that it also had a significant global influence. Several

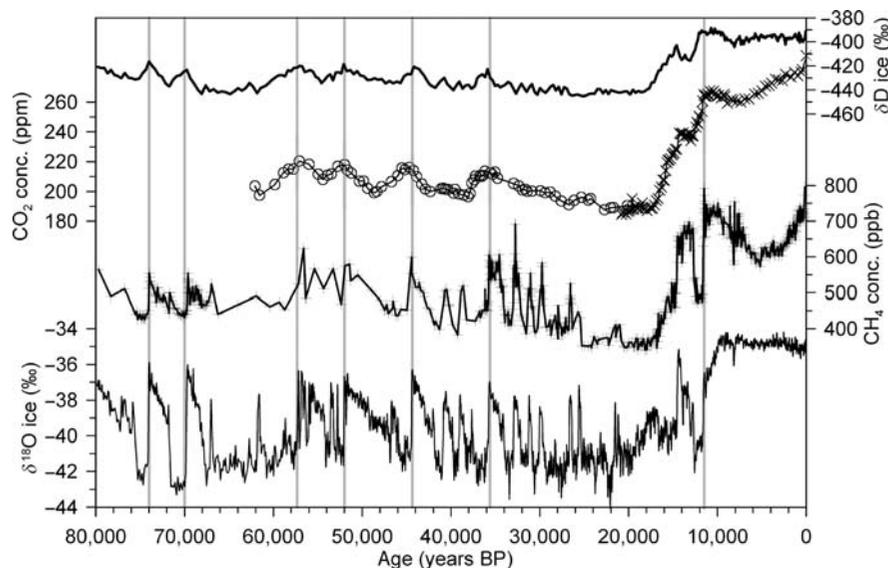

Figure C6 CO₂ and CH₄ records representing variations of the past 80,000 years compared with stable isotope records from Antarctica and Greenland, characterizing the corresponding local temperature (Chappellaz et al., 1993; Dansgaard et al., 1993; Indermühle et al., 2000; Blunier and Brook, 2001). Open circles of the CO₂ record are from Taylor Dome and diagonal crosses from Dome C ice cores (Antarctica). The δD record is also from Antarctica. The CH₄ record is from the Greenland GRIP ice core. Vertical lines highlight some important, fast temperature increases in Greenland ($\delta^{18}\text{O}$ curve).

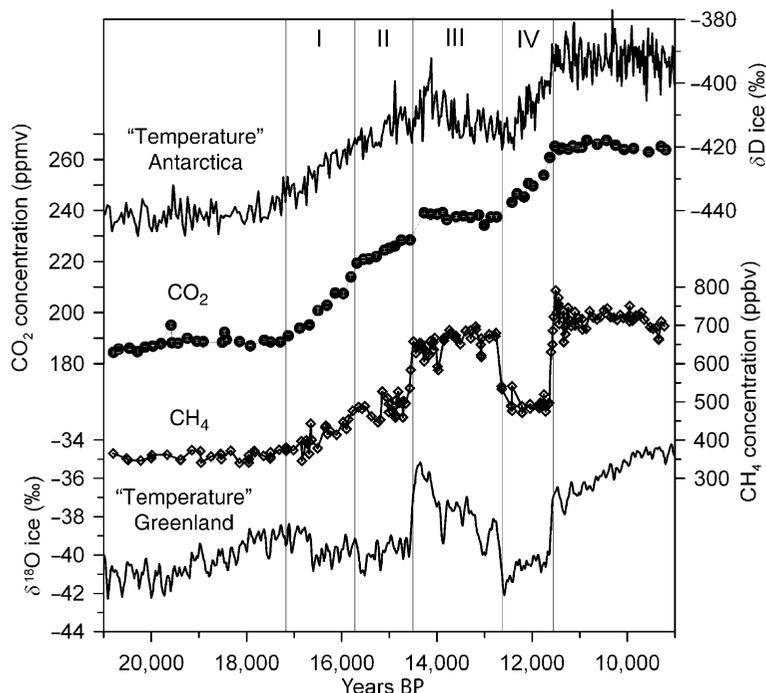

Figure C7 Evolution of the CO₂ and CH₄ concentration increases during the transition from the last glacial epoch to the Holocene, compared with records characterizing the temperature increases in Antarctica and Greenland (Monnin et al., 2001). Roman numerals mark the four time intervals mentioned in the text.

mechanisms have been suggested as causes for the atmospheric CO₂ increase: Reduced solubility of CO₂ in the Southern Ocean because of temperature increase, enhanced air-sea exchange due to reduced sea-ice extent, decreasing bioactivity due to reduced iron fertilization by eolian dust and changes in deepwater formation parallel to the fast temperature increases in the North Atlantic region.

The evolution of the atmospheric CH₄ concentration during the transitional periods is, as during Dansgaard-Oeschger events in the glacial epoch, approximately parallel to that of the Greenland δ¹⁸O record. However, the beginning of the CO₂ increase lags the beginning of the temperature increase by 800 ± 600 years (Monnin et al., 2001). This time lag is small compared with the duration of 6,000 years for the entire increase. It does not call into question the important amplification effect of the CO₂ increase with regards to the global temperature increase during the transition from the glacial epoch to the Holocene. The increase of atmospheric CO₂ concentration from 189 to 265 ppmv corresponds to a direct radiative forcing of about 2 W m^{-2} . The radiative forcing caused by CH₄ increase is about 10 times smaller (Joos, 2005). CH₄ increases parallel to fast temperature increases in Greenland are typically delayed by a few decades giving rise to the conclusion that CH₄ variations are mainly a response to abrupt northern climatic changes rather than a driver.

The Holocene

Ice cores from Taylor Dome and Dome C allow reconstruction of detailed records of the CO₂ and CH₄ concentration during the Holocene (Blunier et al., 1995; Flückiger et al., 2002; Indermühle et al., 1999; Monnin et al., 2004). Both records are shown in Figure C8. The CO₂ record clearly shows that the

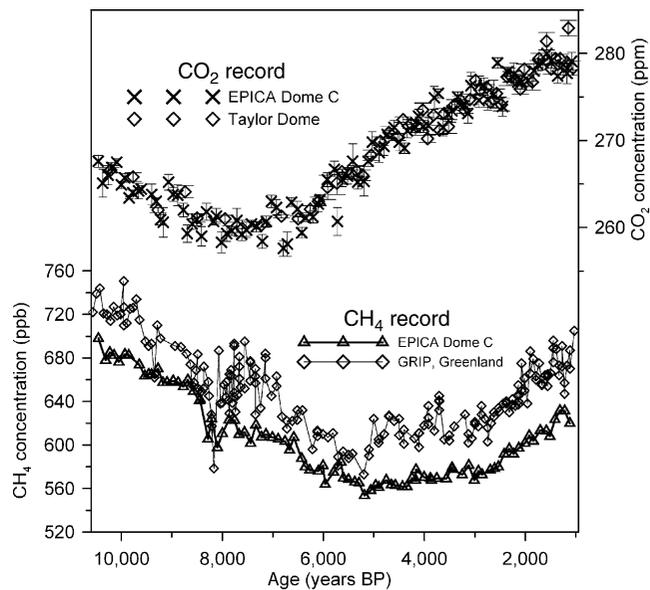

Figure C8 CO₂ and CH₄ records representing the pre-industrial Holocene (Blunier et al., 1995; Indermühle et al., 1998; Flückiger et al., 2002; Monnin et al., 2004). CH₄ concentrations in Greenland are on average about 40 ppbv higher than in Antarctica.

carbon cycle was not in a steady state during the Holocene. The CO₂ concentration decreased from 268 ppmv at 10,500 yBP to 260 ppmv at about 8,200 yBP and increased steadily in the following 7,000 years to about 280 ppmv at the beginning of

the last millennium. These variations are caused by the ocean and the terrestrial biosphere. An uptake of CO₂ by the terrestrial biosphere could be responsible for the decrease until 8,200 yrBP, with a release of CO₂ from the slightly relapsing biosphere and the ocean (due to an increase of the surface temperature) accounting for the increase afterwards. Because carbon in the terrestrial biosphere is significantly depleted in the carbon isotope ¹³C, it is quite clear that δ¹³C measured on CO₂ extracted from ice cores can help in estimating the relative contributions by the ocean and terrestrial biosphere. Based on presently available δ¹³C results, the CO₂ release by the ocean was responsible for about one third of the increase after 8,200 yrBP, and the release by the terrestrial biosphere responsible for about two thirds.

The atmospheric CH₄ concentration decreased in Antarctica from 720 ppbv at 10,500 yrBP to about 575 ppbv at about 5,000 yrBP. The results from the Greenland GRIP ice core show a larger scatter and are about 45 ppbv higher on average. The higher average in Greenland reflects the heterogeneous latitudinal distribution of CH₄ sources and the fact that the atmospheric residence time of CH₄ is only an order of magnitude longer than the inter-hemispheric exchange time. These differences between measured CH₄ concentrations in Greenland and Antarctica can be used to estimate a rough latitudinal distribution of CH₄ sources as will be outlined in a later section. The result of the estimate is that the CH₄ sources in the tropics were increasing from the Last Glacial Maximum until about 8,000 yrBP, then decreasing until about 5,000 yrBP and subsequently increasing again. Sources north of 30° N increased dramatically between the glacial maximum until about 10,000 yrBP, but surprisingly started to decrease again until 8,000 yrBP and increased again afterwards.

Remarkable is a significant CH₄ minimum that occurred for a short duration. It is synchronous with a temperature drop of about 7°C in Greenland and had a duration of 100–150 years. The CH₄ minimum is more pronounced in the Greenland record due to the higher accumulation rate. At Dome C in Antarctica, where the accumulation rate is more than six times lower, a signal of only about 100 year duration is attenuated by about 50% (Spahni et al., 2003).

The last millennium

The CO₂ and CH₄ concentrations were rather constant during the first eight centuries but increased dramatically during the last two centuries to values never experienced during the last 650,000 years, as shown in Figure C9. The CO₂ concentrations of different Antarctic ice cores are in good agreement, and also agree with the short overlapping interval and continuous direct atmospheric measurements, which started in 1958 (Blunier et al., 1995; Etheridge et al., 1996; MacFarling Meure et al., 2006). For the first eight centuries, they show a mean concentration of about 280 ppmv. Measurements from Greenland ice cores show significantly higher values, caused most probably by artifacts due to higher temperature and higher impurity concentrations. Greenland results are, therefore, not shown in Figure C9. The most detailed Antarctic record for the last millennium is available from the Law Dome ice core. The reproducibility of the measurements is 1.2 ppmv and individual results represent short time intervals due to a very high accumulation rate at the coastal Law Dome. The Law Dome record suggests an increase from about 279 ppmv at the beginning of the millennium to 282 ppmv at AD 1100, then a relatively

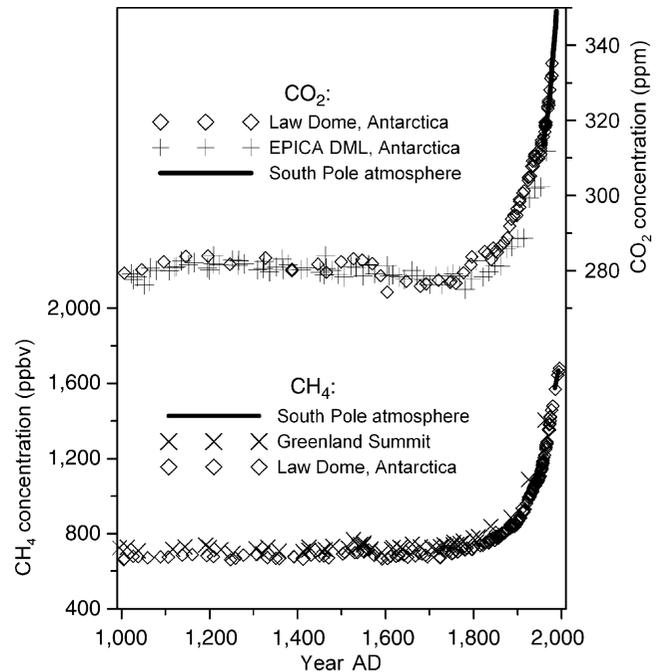

Figure C9 CO₂ records from Antarctica and CH₄ records from Greenland and Antarctica for the last millennium (Blunier et al., 1995; Etheridge et al., 1996; MacFarling Meure et al., 2006).

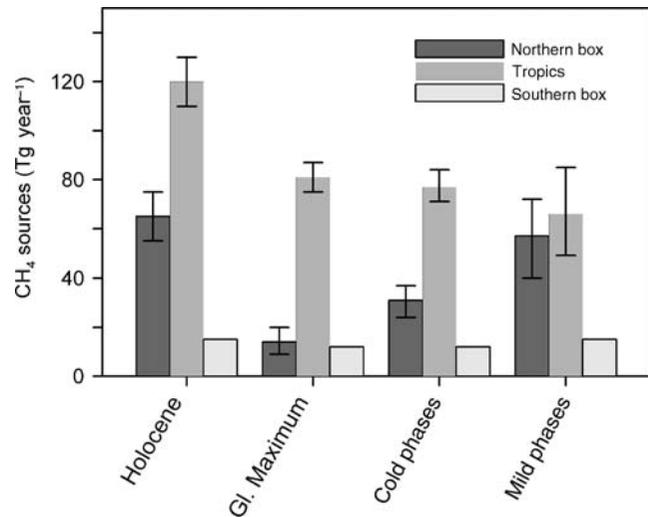

Figure C10 Estimated CH₄ sources for different climatic epochs from 90–30° N, 30° N–30° S and 30–90° S based on concentration differences between Greenland and Antarctica (Chappellaz et al., 1997; Dällenbach et al., 2000).

constant concentration until AD 1600, followed by a decrease to 277 ppmv, lasting until about AD 1750.

The CH₄ record shows relatively constant values of about 700 ppbv until AD 1750. Greenland values are slightly higher, but in this case it is assumed that this is not an artifact but is caused by the inter-hemispheric difference of the atmospheric concentration. Records from Law Dome again provide results that are more detailed. The concentration is about 640 ppbv at

the beginning of the millennium and shows smaller variations but also an increasing trend to a value of 700 ppbv at AD 1750. The increase could already be attributed to pre-industrial anthropogenic influences, such as expansion of rice cultivation and cattle.

Latitudinal distribution of pre-industrial CH₄ sources

Not only does the CH₄ concentration change with climatic variations but so does the inter-hemispheric concentration difference. This combination of results can be used to make a rough estimate of the latitudinal source distribution. In a simple model, sources in the three boxes 90–30° N (northern box), 30° N–30° S (tropical box) and 30–90° S (southern box) are taken into account (Chappellaz et al., 1997). It is assumed that the source in the southern box contributed 12 Tg yr⁻¹ during the cold periods of the last glacial period and 15 Tg yr⁻¹ during the mild periods of the last glacial epoch and the pre-industrial Holocene. The model results are shown in Figure C10 (Dällenbach et al., 2000). A remarkable, but still tentative, conclusion based on these estimates is that the CH₄ variations during the last glacial epoch were not mainly due to source changes in the tropics but in the northern box.

CARBON DIOXIDE, DISSOLVED (OCEAN)

The ocean contains about 60 times more carbon in the form of dissolved inorganic carbon than in the pre-anthropogenic atmosphere (~600 Pg C). On time scales <10⁵ yr, the ocean is the largest inorganic carbon reservoir (~38,000 Pg C) in exchange with atmospheric carbon dioxide (CO₂) and as a result, the ocean exerts a dominant control on atmospheric CO₂ levels. The average concentration of inorganic carbon in the ocean is ~2.3 mmol kg⁻¹ and its residence time is ~200 ka.

Dissolved carbon dioxide in the ocean occurs mainly in three inorganic forms: free aqueous carbon dioxide (CO₂(aq)), bicarbonate (HCO₃⁻), and carbonate ion (CO₃²⁻). A minor form

is true carbonic acid (H_2CO_3) whose concentration is less than 0.3% of $[\text{CO}_2(\text{aq})]$. The sum of $[\text{CO}_2(\text{aq})]$ and $[\text{H}_2\text{CO}_3]$ is denoted as $[\text{CO}_2]$. The majority of dissolved inorganic carbon in the modern ocean is in the form of HCO_3^- (>85%), as described below.

Carbonate chemistry

In thermodynamic equilibrium, gaseous carbon dioxide ($\text{CO}_2(\text{g})$), and $[\text{CO}_2]$ are related by Henry's law:

$$\text{CO}_2(\text{g}) \stackrel{K_0}{\rightleftharpoons} [\text{CO}_2] \quad (1)$$

where K_0 is the temperature and salinity dependent solubility coefficient of CO_2 in seawater (Weiss, 1974). The concentration of dissolved CO_2 and the fugacity of gaseous CO_2 , $f\text{CO}_2$, then obey the equation $[\text{CO}_2] = K_0 \times f\text{CO}_2$, where the fugacity is virtually equal to the partial pressure, $p\text{CO}_2$ (within ~1%). The dissolved carbonate species react with water, hydrogen and hydroxyl ions and are related by the equilibria:

The pK^* values ($= -\log(K^*)$) of the stoichiometric dissociation constants of carbonic acid in seawater are $pK_1^* = 5.94$ and $pK_2^* = 9.13$ at temperature $T = 15^\circ\text{C}$, salinity $S = 35$, and surface pressure $P = 1$ atm (Prieto and Millero, 2001). At typical surface seawater pH of 8.2, the speciation between $[\text{CO}_2]$, $[\text{HCO}_3^-]$, and $[\text{CO}_3^{2-}]$ is 0.5%, 89%, and 10.5%, respectively, showing that most of the dissolved CO_2 is in the form of HCO_3^- and not in the form of CO_2 (Figure C11). The sum of the dissolved carbonate species is denoted as total dissolved inorganic carbon (ΣCO_2):

$$\Sigma\text{CO}_2 = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad (3)$$

This quantity is also represented as DIC, TIC, TCO_2 , and C_T . Another essential parameter to describe the carbonate system

is the total alkalinity (TA), a measure of the charge balance in seawater.

$$\text{TA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] - [\text{H}^+] + \text{minor compounds} \quad (4)$$

ΣCO_2 and TA are conservative quantities, i.e., their concentrations measured in gravimetric units (mol kg^{-1}) are unaffected by changes in pressure or temperature, for instance, and they obey the linear mixing law. Therefore, they are the preferred tracer variables in numerical models of the ocean's carbon cycle. Of all the carbon species and carbonate system parameters described above, only $p\text{CO}_2$, pH, ΣCO_2 , and TA can be determined analytically. However, if any two parameters and total dissolved boron are known, all parameters ($p\text{CO}_2$, $[\text{CO}_2]$, $[\text{HCO}_3^-]$, $[\text{CO}_3^{2-}]$, pH, ΣCO_2 , and TA) can be calculated for a given T , S , and P (cf. Zeebe and Wolf-Gladrow, 2001).

Buffering

The dissolved carbonate species in seawater provide an efficient chemical buffer to various processes that change the properties of seawater. For instance, the addition of a strong acid such as hydrochloric acid (naturally added to the ocean by volcanism), is strongly buffered by the seawater carbonate system. In distilled water, the addition of HCl leads to an increase of $[\text{H}^+]$ and $[\text{Cl}^-]$ in solution in a ratio 1:1. This is not the case in seawater. For example, the addition of $1 \mu\text{mol kg}^{-1}$ HCl to distilled water at pH 7 reduces the pH to very close to 6. The same addition to seawater at pH 7 and $\Sigma\text{CO}_2 = 2,000 \mu\text{mol kg}^{-1}$ at $T = 15^\circ\text{C}$ and $S = 35$ only reduces the pH to 6.997. The seawater pH buffer is mainly a result of the capacity of CO_3^{2-} and HCO_3^- ions to accept protons.

One specific buffer factor, the so-called Revelle factor, is important in the context of the oceanic uptake of anthropogenic CO_2 . The Revelle factor, R , is given by the ratio of the relative

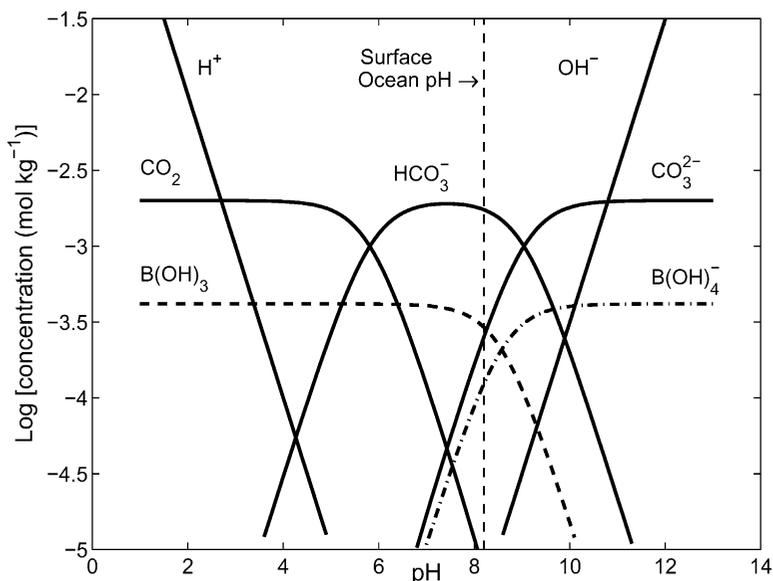

Figure C11 Concentrations of the dissolved forms of the carbonate system in seawater (so-called Bjerrum plot). $\Sigma\text{CO}_2 = 2,000 \mu\text{mol kg}^{-1}$, temperature $T = 15^\circ\text{C}$, salinity $S = 35$, and pressure $P = 1$ atm (after Zeebe and Wolf-Gladrow, 2001).

change of atmospheric $p\text{CO}_2$ (in equilibrium with dissolved CO_2) to the relative change of ΣCO_2 in seawater:

$$R = (d[p\text{CO}_2]/[p\text{CO}_2])_a / (d\Sigma\text{CO}_2/\Sigma\text{CO}_2)_{\text{sw}} \quad (5)$$

and varies roughly between 8 and 15, depending on temperature and $p\text{CO}_2$. As a consequence, the current increase of ΣCO_2 in surface seawater occurs not in a 1:1 ratio to the increase of atmospheric CO_2 (the latter being mainly caused by fossil fuel burning). Rather, a doubling of $p\text{CO}_2$ will only lead to an increase of ΣCO_2 of the order of 10%.

ΣCO_2 and TA of a water parcel

Important processes that can change the carbonate chemistry of a water parcel in the ocean can be described by considering changes in ΣCO_2 and TA (Figure C12). Invasion of CO_2 from (or release to) the atmosphere increases (or decreases) ΣCO_2 , respectively, while TA stays constant. This leads to a rise and drop of $[\text{CO}_2]$, respectively, with opposite change in pH (as CO_2 is a weak acid). Respiration and photosynthesis lead to the same trends, except that TA changes slightly due to nutrient release and uptake. CaCO_3 precipitation decreases ΣCO_2 and TA in a ratio 1:2, and, counterintuitively, increases $[\text{CO}_2]$ although inorganic carbon has been reduced. For a qualitative understanding, consider the chemical reaction

which indicates that during CaCO_3 precipitation CO_2 is liberated. Quantitatively, however, the conclusion that $[\text{CO}_2]$ in solution

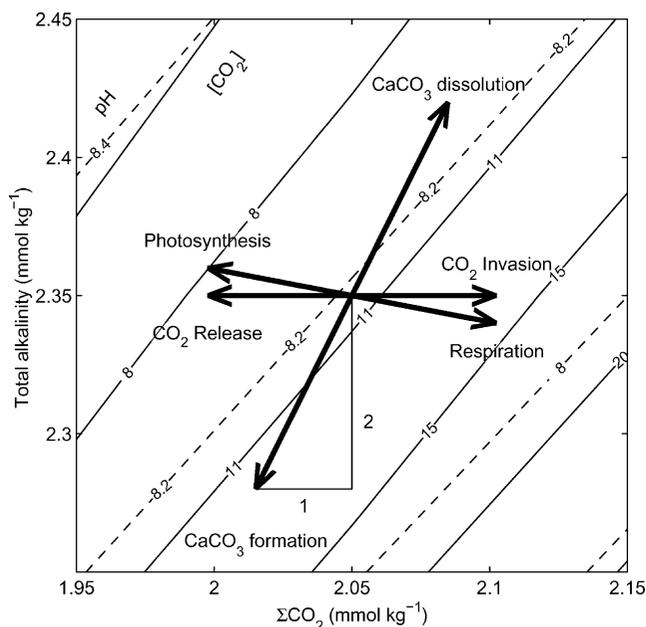

Figure C12 Important processes changing the carbonate chemistry of a water parcel in the ocean (values shown refer to $T = 15^\circ\text{C}$, $S = 35$, and $P = 1$ atm). Solid and dashed lines indicate contours of constant dissolved CO_2 and pH, respectively. Many processes are most easily described by considering changes in ΣCO_2 and TA. For example, the invasion of CO_2 increases ΣCO_2 while TA stays constant, which leads to an increase of dissolved CO_2 and a decrease of pH (as CO_2 is a weak acid).

is increasing by one mole per mole CaCO_3 precipitated is incorrect because of buffering. The correct analysis takes into account the decrease of ΣCO_2 and TA in a ratio 1:2 and the buffer capacity of seawater. That is, the medium gets more acidic because the decrease in alkalinity outweighs that of total carbon and hence $[\text{CO}_2]$ increases. For instance, at surface water conditions ($\Sigma\text{CO}_2 = 2,000 \mu\text{mol kg}^{-1}$, $\text{pH} = 8.2$, $T = 15^\circ\text{C}$, $S = 35$), $[\text{CO}_2]$ increases by only $\sim 0.03 \mu\text{mol}$ per $\mu\text{mol CaCO}_3$ precipitated.

Measurements and data

As stated above, the following parameters of the carbonate system can be determined experimentally: $p\text{CO}_2$, pH, ΣCO_2 , and TA. The $p\text{CO}_2$ of a seawater sample refers to the $p\text{CO}_2$ of a gas phase in equilibrium with that seawater sample. It is usually measured by equilibrating a small volume of gas with a large volume of seawater at given temperature. Then the mixing ratio of $\text{CO}_2(\text{g})$ in the gas phase is determined either using a gas chromatograph or an infrared analyzer. Finally, the $p\text{CO}_2$ is calculated from the mixing ratio. pH is routinely measured using a glass/reference electrode cell or spectrophotometrically using an indicator dye. ΣCO_2 is usually measured by an extraction/coulometric method or a closed cell titration. A potentiometric titration is used to determine TA. For summary, see DOE (1994) and Grasshoff et al. (1999).

A great volume of data on the carbonate chemistry of the oceans has been obtained over the last few decades through programs such as GEOSECS (Geochemical Ocean Sections Study), TTO (see Transient Tracers in the Oceans), and WOCE (World Ocean Circulation Experiment). Much of these data are available through CDIAC (Carbon Dioxide Information Analysis Center) at <http://cdiac.ornl.gov>.

Distribution of ΣCO_2 and TA

The vertical distribution of ΣCO_2 in the ocean is a result of the so-called biological and physical carbon pumps. Uptake of carbon into organic matter and production of CaCO_3 in the surface ocean, the transport to deeper layers, and the remineralization at depth (biological pump) reduces ΣCO_2 in surface waters while ΣCO_2 in deep water increases (Figure C13a). The increased solubility of CO_2 in high-latitudes at low temperatures where the ocean's deep water forms and descends to the abyss leads to the same vertical trend in ΣCO_2 (physical pump). Vertical profiles of TA in the ocean (Figure C13b) are mostly governed by production and dissolution of CaCO_3 . Generally, uptake of Ca^{2+} and CO_3^{2-} in the surface and release in the deep ocean reduces and increases TA, respectively. This is similar to the cycling of organic carbon and ΣCO_2 but the maximum in TA occurs at greater depth because CaCO_3 is mainly redissolved in deep water. The vertical distribution of ΣCO_2 and TA constitutes one major control on atmospheric CO_2 concentrations. For example, without the biological pump, the pre-anthropogenic atmospheric CO_2 concentration would have been >500 ppmv (parts per million by volume) rather than 280 ppmv (Maier-Reimer et al., 1996).

The horizontal distribution of CO_2 and ΣCO_2 in the surface ocean is mainly governed by the temperature-dependent solubility of CO_2 on interannual timescales. Warm low-latitude surface water generally holds less CO_2 ($\sim 10 \mu\text{mol kg}^{-1}$) and ΣCO_2 ($\sim 2,000 \mu\text{mol kg}^{-1}$) than cold high-latitude surface water ($\text{CO}_2 \sim 15 \mu\text{mol kg}^{-1}$ and $\Sigma\text{CO}_2 \sim 2,100 \mu\text{mol kg}^{-1}$), because of the enhanced solubility at low temperature. Locally,

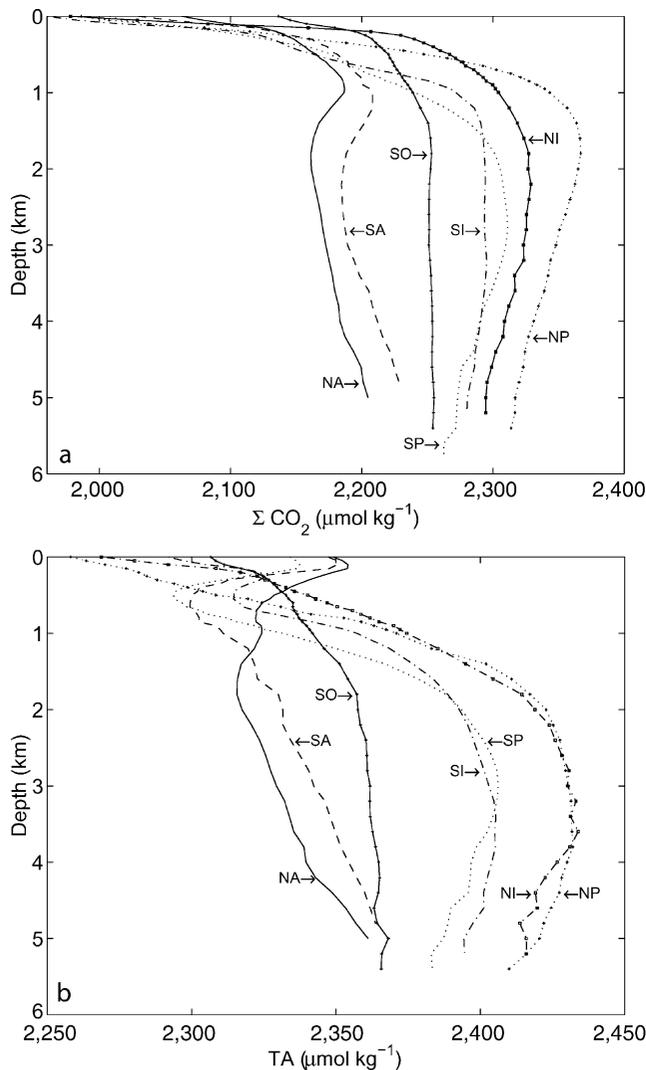

Figure C13 Average vertical distribution of ΣCO_2 (a) and TA (b) in the oceans. NA/SA: North/South Atlantic, SO: Southern Ocean, NI/SI: North/South Indian, NP/SP: North/South Pacific. The data (www.ewoce.org) were compiled using Ocean Data View (Schlitzer, R., www.awi-bremerhaven.de/GEO/ODV).

and on seasonal time scales, however, significant deviations from these general patterns may occur due to changes in salinity and processes such as biological activity, upwelling, temperature variations, river runoff, and other processes that affect ΣCO_2 and TA.

Deep ocean circulation, whose mass transport is predominantly from the North Atlantic through the Southern Ocean into the Indian and Pacific Ocean, produces horizontal deep-water gradients in ΣCO_2 and TA. While the details of deep ocean circulation are much more complex in general, the “youngest” water, which was most recently in contact with the atmosphere, resides in the Atlantic, whereas the “oldest” water resides in the Pacific. As a corollary, the water in the deep North Pacific has collected the most respired CO_2 on its way and thus has the highest ΣCO_2 (Figure C13a).

Inventories of ΣCO_2 and TA over time

Under most natural conditions, the global inventories of ΣCO_2 and TA constitute one major control on atmospheric CO_2 concentrations. Understanding changes of these inventories over time is therefore crucial to understanding climate. Thus, the characterization of the dominant carbon and alkalinity fluxes on different time scales is of fundamental importance. [Note that due to our limited knowledge on this subject, the following analysis is to be considered a simplification (Sundquist, 1986)].

Millennial ($<10^3$ yr) timescale

On timescales shorter than $\sim 10^3$ yr, the natural reservoirs that exchange carbon with the ocean are the atmosphere (pre-anthropogenic inventory ~ 600 Pg C), the biosphere (~ 550 Pg C), and soils ($\sim 1,500$ Pg C) and thus the oceanic inventory of ΣCO_2 ($\sim 38,000$ Pg C) can be considered essentially constant. Exceptions to this are potential rapid carbon inputs from otherwise long-term storage reservoirs. Examples are the current combustion of fossil fuel carbon by humans (which will eventually be mostly absorbed by the ocean), and catastrophic events such as possible impact events over carbonate platforms, or abrupt methane releases from gas hydrates (as postulated for the Paleocene-Eocene Thermal Maximum).

Glacial-interglacial (10^3 – 10^5 yr) timescale

On timescales of 10^3 – 10^5 yr, fluxes between reactive carbonate sediments ($\sim 5,000$ Pg C) and the ocean’s inventories of ΣCO_2 and TA have to be considered as well. Oceanic inventories may vary, for instance, during glacial cycles (see so-called calcite compensation below). The magnitude of these changes is, however, limited and so are associated changes in atmospheric CO_2 .

Tectonic ($>10^5$ yr) timescale

A large amount of carbon is locked up in the Earth’s crust as carbonate carbon ($\sim 70 \times 10^6$ Pg C) and as elemental carbon in shales and coals ($\sim 20 \times 10^6$ Pg C). On time scales $>10^5$ yr, this reservoir is active and imbalances in the fluxes to and from this pool can lead to drastic changes in ΣCO_2 and TA and atmospheric CO_2 . The balance between CO_2 consumption by subduction of marine sediments, weathering, subsequent carbonate burial, and volcanic degassing of CO_2 are the dominant processes controlling carbon fluxes on this time scale (Berner et al., 1983). This so-called rock cycle is driven by tectonic processes that lead to changes in seafloor spreading rates and continental uplift.

$[\text{CO}_3^{2-}]$ and CaCO_3 saturation

The accumulation and dissolution of reactive CaCO_3 sediments in the deep sea provide a powerful feedback to regulating the carbonate ion content ($[\text{CO}_3^{2-}]$) and thus the concentration of dissolved CO_2 in the ocean. The inventory of carbonate ion in the ocean cannot be viewed independently of carbonate sediments because of the control of CO_3^{2-} on the solubility of CaCO_3 . In today’s ocean, there is a close correspondence between $[\text{CO}_3^{2-}]$ of deep water and the observed distribution of CaCO_3 in deep sea sediments. Depending on the geographic location, there is a certain depth above which the ocean floor is mainly covered with calcite, while it is largely calcite-free

below this depth. The depth at which the sediments are virtually free of calcium carbonate is called the calcium carbonate compensation depth (CCD). The transition from calcite-rich to calcite-depleted sediments is not abrupt but gradual and the depth of rapid increase in the rate of dissolution as observed in sediments is called the calcite lysocline. Aragonite is more soluble than calcite and the aragonite lysocline occurs at shallower depth than the calcite lysocline. In the Pacific, the aragonite lysocline can be as shallow as 500 m and ~3 km in the Atlantic. The calcite lysocline lies at ~3–4 km in the Pacific and between 4 and 5 km in the Atlantic.

The reason for the disappearance of CaCO_3 at depth is the increase of solubility with pressure and thus with depth. The CaCO_3 saturation state of seawater is expressed by Ω :

$$\Omega = \frac{[\text{Ca}^{2+}]_{\text{sw}} \times [\text{CO}_3^{2-}]_{\text{sw}}}{K_{\text{sp}}^*} \quad (7)$$

where $[\text{Ca}^{2+}]_{\text{sw}}$ and $[\text{CO}_3^{2-}]_{\text{sw}}$ are the concentrations of Ca^{2+} and CO_3^{2-} in seawater and K_{sp}^* is the solubility product of calcite or aragonite at the in situ conditions of temperature, salinity, and pressure. Values of $\Omega > 1$ signify supersaturation and $\Omega < 1$ signify undersaturation. Because K_{sp}^* increases with pressure (the temperature effect is small) there is a transition of the saturation state from $\Omega > 1$ (calcite-rich) to $\Omega < 1$ (calcite-depleted) sediments at depth.

In the modern ocean, $[\text{Ca}^{2+}]_{\text{sw}}$ is large (compared to $[\text{CO}_3^{2-}]_{\text{sw}}$) and virtually constant (except for variations in salinity) and thus variations of the saturation state are controlled by variations in $[\text{CO}_3^{2-}]_{\text{sw}}$. The crossover of $[\text{CO}_3^{2-}]_{\text{sw}}$ and the carbonate ion concentration at calcite saturation is called calcite saturation horizon. The feedback that controls the average carbonate ion content of seawater and the distribution of CaCO_3 on a multi-millennial time scale via variations of the saturation horizon is called calcite compensation. This in turn exerts a major control on dissolved CO_2 and alkalinity in the ocean.

Calcite compensation

Calcite compensation maintains the balance between CaCO_3 weathering fluxes into the ocean and CaCO_3 burial fluxes in marine sediments on time scales of 10^3 – 10^5 yr (Broecker and Peng, 1987). In steady state, the riverine flux of Ca^{2+} and CO_3^{2-} ions from weathering must be balanced by burial of CaCO_3 in the sea, otherwise $[\text{Ca}^{2+}]$ and $[\text{CO}_3^{2-}]$ would rise or fall. The feedback that maintains this balance works as follows. Assume that there is an excess weathering influx of Ca^{2+} and CO_3^{2-} over burial of CaCO_3 . Then, the concentrations of Ca^{2+} and CO_3^{2-} in seawater increase, which leads to an increase of the CaCO_3 saturation state. This in turn leads to a deepening of the saturation horizon and to an increased burial of CaCO_3 just until the burial again balances the influx. The new balance is restored at higher $[\text{CO}_3^{2-}]$ than before.

ΣCO_2 and $\delta^{13}\text{C}$

In the ocean, there is an inverse relationship between the vertical distribution of ΣCO_2 and the stable carbon isotope ratio $^{13}\text{C}/^{12}\text{C}$ of ΣCO_2 ($\delta^{13}\text{C}_{\Sigma\text{CO}_2}$). In the surface ocean, phytoplankton takes up inorganic carbon to produce organic carbon via photosynthesis. This process discriminates against the heavy isotope ^{13}C such that the organic carbon is depleted in ^{13}C and, as a result, surface ΣCO_2 becomes enriched in ^{13}C . At

depth, the process is reversed. The organic carbon settling down to intermediate and deep waters is remineralized and the “isotopically light” carbon is set free, which causes deep ΣCO_2 to become enriched in ^{12}C (i.e., it has relatively less ^{13}C). In today’s ocean, the mean difference in $\delta^{13}\text{C}$ of ΣCO_2 between surface and deep ocean is $\Delta\delta^{13}\text{C} \cong 2\text{‰}$. In a very simple two-box view of the ocean, one can show that $\Delta\delta^{13}\text{C}$ depends on the strength of the carbon export to deep water (biological pump), the photosynthetic fractionation factor (Δ^{photo}), and mean ΣCO_2 of the ocean (Broecker, 1982):

$$\Delta\delta^{13}\text{C} = \Delta^{\text{photo}} \times \Delta\Sigma\text{CO}_2 / \Sigma\text{CO}_2 \quad (8)$$

where $\Delta\Sigma\text{CO}_2$ is the surface-to-deep difference in ΣCO_2 due to the biological pump. Given information on past $\Delta\delta^{13}\text{C}$ from differences in $\delta^{13}\text{C}$ of planktonic and benthic foraminifera, and assumptions regarding the strength of the biological pump, and Δ^{photo} , estimates of ΣCO_2 of past oceans have been derived (e.g., Shackleton, 1985).

CARBON ISOTOPE VARIATIONS OVER GEOLOGIC TIME

In order to understand quantitatively the evolution of the Earth we have to deal with two types of records, direct and indirect (proxies). The isotopic composition of past seawater may be about the best proxy reflecting the evolution of our planet. This is because, due to its mixing rate of $\sim 1,000$ years, seawater is well mixed on million-year timescales and registers a globally averaged signal. The latter, however, is true only for chemical species with seawater residence times in excess of the mixing rate of the oceans. This contribution discusses the basic structures of the isotopic seawater curves for carbon on billion to million years of geologic history, a time scale well beyond the residence time of inorganic carbon in seawater that is about 2–4 thousand years (Ka).

The recording media

Apart from inclusions of possible modified seawater in Phanerozoic salts, no samples of ancient seawater are available for direct isotope studies. We have to rely therefore on biominerals and sediments precipitated from seawater, such as carbonate rocks and shells. Note that the evolution of seawater is a temporal continuum. In contrast, the recording media are generated by episodic events (sedimentation, biomineralization), that is they represent a point in time. It is estimated that for shallow marine sequences the sediments represent only $\sim 1/30$ of the elapsed time. The situation is somewhat better for deep-sea sediments, but in each case the erosional and non-depositional episodes represent more time than the actual sedimentary record. This imposes constraints on correlation of higher order patterns in the isotopic records of paleoseawater.

Carbonate components formed in seawater are orthorhombic aragonite (A) and rhombohedral calcite, the latter further subdivided into low-Mg calcite (LMC) with less than 4 mole% MgCO_3 and high-Mg calcite (HMC) with 4–28 mole-% MgCO_3 . The molar Mg/Ca ratio for present-day seawater is 5:1 and inorganically precipitated phases should be either A or HMC with about 7 mole-% MgCO_3 . LMC in marine environments is known mostly from the shells of some organisms, such as pelagic foraminifera, belemnites or brachiopods. Other organisms have shells composed of various combinations of A, HMC, and LMC. On average, shallow marine carbonate sediments, containing inorganically precipitated phases and skeletal debris, are composed of variable mixtures of HMC and A. Deep-sea oozes, on the other hand, consist almost exclusively of pelagic skeletal material and are predominantly LMC. The primary minerals that compose the sediment become exposed to the influence of meteoric waters and/or are subjected to higher pressures and temperatures during burial, rendering the original mineralogical assemblage unstable and converting them into a monomineralic limestone or dolostone.

Incorporation of carbon into carbonates

The incorporation of C isotopes into carbonate minerals (Hoefs, 1980) is governed by the so-called fractionation factor α :

$$R_S = \alpha_S - W R_W \quad (1)$$

where R is the ratio of relative abundances of isotopes, in this instance, $^{13}\text{C}/^{12}\text{C}$, the subscript S represents the solid carbonate

phase, and W stands for water (and its solutes, such as carbon species). Since α -values are close to unity and their variations are mostly in the third decimal place, the difference in α_{S-W} is better expressed in whole units as per mil ‰. Thus,

$$\Delta_{S-W} = \left[\left(\frac{R_S}{R_W} \right) - 1 \right] \times 10^3 = (\alpha_{S-W} - 1) \times 10^3 \quad (2)$$

For reasons connected with the design of mass spectrometers, it is easier to compare the measured isotope ratio (R_S) of an unknown sample to a standard with known R , and to express the measured difference as

$$\delta_S = \left[\left(\frac{R_S}{R_{\text{Standard}}} \right) - 1 \right] \times 10^3 \quad (3)$$

For carbon isotope studies in carbonate rocks, the standard usually utilized is the PDB (*Belemnitella americana* from the Cretaceous Peedee Formation of South Carolina).

The equilibrium isotopic fractionation factor α is inversely proportional to temperature and the relationship takes the form:

$$\ln \alpha = AT^{-2} + BT^{-1} + C \quad (4)$$

where A, B and C are constants determined experimentally and T is absolute temperature in degrees Kelvin. However, the temperature dependence of α for C isotopes is relatively small. Gaseous CO_2 that diffuses into seawater then dissociates and can finally precipitate as a CaCO_3 mineral, with fractionation involved at each step. The temperature dependencies of fractionation factors between $\text{CO}_2(\text{gas})$ and the $\text{CO}_2(\text{aq})$ (α_1), HCO_3^- (α_2), CO_3^{2-} (α_3) and calcite (α_4), respectively, are as follows:

$$1,000 \ln \alpha_1 = 0.0063 (10^6 T^{-2}) - 0.91 \quad (5)$$

$$1,000 \ln \alpha_2 = 1.099 (10^6 T^{-2}) - 4.54 \quad (6)$$

$$1,000 \ln \alpha_3 = 0.87 (10^6 T^{-2}) - 3.4 \quad (7)$$

$$1,000 \ln \alpha_4 = 1.194 (10^6 T^{-2}) - 3.63 \quad (8)$$

The overall variations in $\delta^{13}\text{C}$ of natural calcites induced by temperature are usually less than the scatter caused by other factors (about 0.04‰ per 1°C) and marine calcites have $\delta^{13}\text{C}$ mostly close to 0‰ PDB. Theoretically, the CaCO_3 should be enriched by about 1–3‰ in ^{13}C relative to the total dissolved C, because bicarbonate is the dominant C species in natural waters. In addition, aragonite should be somewhat enriched in ^{13}C relative to calcite. At 25°C , the theoretical calculations yield about a 0.9‰ enhancement, whereas the observed experimental enrichment has been about 1.8‰.

Disequilibrium phenomena

In nature, observed isotopic ratios deviate from the theoretical equilibrium values because of *kinetic factors*. Of these, perhaps the rate of precipitation of solid phases is the most important variable. Usually, the faster the rate, the closer α is to unity. The situation is still more complex if biomineralization is involved. Secretion of carbonate skeletons may proceed under equilibrium conditions or result in non-equilibrium fractionation of isotopes, known as *biogenic fractionations* or *vital effects* (Figure C14a). Such effects may be a consequence of biochemical processes that influence the kinetics of shell formation, result from incorporation of metabolic ^{13}C -depleted

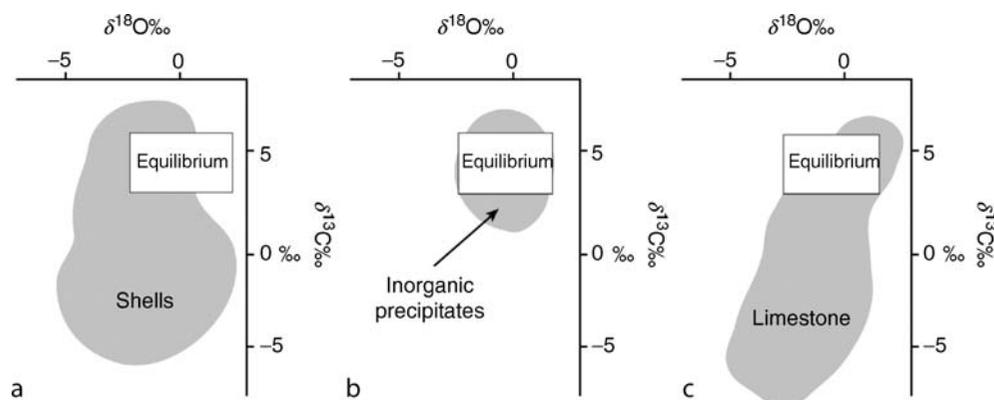

Figure C14 Oxygen and carbon isotopic composition of modern carbonate components. (a) The range observed in modern shells, (b) in “inorganic” precipitates, and (c) in diagenetically stabilized limestones. Box delineates the range of values in equilibrium with present day seawater. Modified from Veizer (1992).

CO₂ into CaCO₃ (McConnaughey, 1990a,b), or be due to a pH gradient between ambient water and intercellular fluid, the latter controlling the calcification process (Adkins et al., 2003). When this deviation is systematic, as for some foraminifera species, it can be corrected. In other cases, the degree, but not necessarily the sign of disequilibrium, is random. It is also possible, and by no means exceptional, to see different parts of the same skeleton having different isotopic compositions.

Recent marine carbonates

The components of recent marine carbonates include skeletal parts, chemical and/or biochemical precipitates, and early marine cements. Low-latitude shallow water assemblages are dominated by aragonitic corals and green algae, frequently accompanied by marine precipitates (whittings, ooids, peloids) and having ubiquitous early marine HMC and A cements. In contrast, carbonates of temperate zones, and of deeper slope settings in tropical regions, contain mostly skeletal remains with Mg-calcitic mineralogy. The dominant contributors are molluscs, foraminifera, and bryozoans. Early marine cements of Mg-calcitic composition in this assemblage are rare. Finally, the off-shore assemblage of pelagic organisms, such as calcitic foraminifera and coccoliths as well as aragonitic pteropods accumulate above their respective carbonate dissolution depths to produce *deep sea oozes* on the ocean floor.

The wide spread in O and C isotopic compositions (Figure C14) of recent marine carbonates reflects this complexity and the relative proportions of constituent components. Note that, for ecological reasons, even specific groups of organisms, such as shallow marine brachiopods that are of paleoclimatic interest, have a spread of oxygen and carbon isotopic values today of about 4‰, and this would also be expected to have been the case for their ancient counterparts. The inorganic (?) precipitates, such as ooids and early marine cements, tend to fall much closer to expected equilibrium values (Figure C14b). In detail, however, they may be characterized by slight ¹³C and/or ¹⁸O enrichment and, if so, biochemically-mediated processes may be involved in their precipitation.

Post-depositional diagenetic overprint

Diagenetic modification of freshly deposited sediments begins on the seafloor with mechanical and biological breakdown of the carbonate components and their binding by cements. This

process of rock generation from a loose sediment continues via two major pathways, designated here as meteoric (fresh water) and burial diagenesis (James and Choquette, 1990a, b; Choquette and James, 1990). These two pathways converge with time and some overlaps are possible even in the early stages of diagenesis.

Carbonate sediments deposited originally in *shallow marine environments* are exposed to the influence of continental, or meteoric, waters. Such waters are frequently charged with CO₂ and thus highly corrosive. The original marine mineralogical assemblage (A, HMC) transforms into a monomineralic (LMC) limestone via sequential dissolution-reprecipitation. This dissolution-reprecipitation process proceeds in a flow regime that is comprised of two components, regional flow and diffusion. The latter is relatively slow, on the order of a hundred meters in a million years, whereas the former can vary considerably. At high flow rates, the system is water-dominated. At slow flow-rates, local dissolution-reprecipitation gradients, maintained by diffusion and local physical parameters, are not entirely dissipated. This is a rock-dominated system, where the precursor phases play a considerable role in controlling the chemistry and isotopic composition of waters in the microenvironments and thus of the locally precipitated successor calcite. In most natural cases, there is a partially rock-dominated system, characterized by intermediate *water/rock ratios*. Nevertheless, C in the waters of these microenvironments originates mostly from the precursor carbonate phases (e.g., water/rock ratio ~10) and the δ¹³C therefore retains its near-original values.

The situation is complicated somewhat by the fact that oxidation of organic matter is an important diagenetic process. With burial, the sediment passes successively (Hesse, 1990) through the zones of (a) oxidation by dissolved O₂, (b) nitrate reduction, (c) sulfate reduction, (d) carbonate reduction, (e) fermentation, and (f) thermocatalytic decarbonation. The processes in the first five zones are mediated by assemblages of specific bacteria to temperatures of about 75°C. The mostly abiogenic zone (f) extends to about 150°C and at higher temperatures equilibria between graphite, CO₂, and CH₄ dominate. Processes (a) and (c) produce CO₂ and bicarbonate that are released to the pore space. The C in these species is thus derived from the oxidation of organic carbon, C_{org}, that is depleted in ¹³C, with δ¹³C usually around -25‰. The passage

of sediment into zone (d), particularly at the trailing edge of sulfate depletion, leads to production of methane. This CH_4 is isotopically very light ($-80 \pm 20\text{‰}$) and the residual C_{org} , which is subsequently oxidized to CO_2 , thus becomes exceptionally heavy ($\delta^{13}\text{C}$ in excess of $+10\text{‰}$). A return to ^{13}C -depleted values again characterizes zone (f).

In continually subsiding shallow water basins and in deep-sea environments, diagenetic stabilization is due to progressive *burial*. The entrapped pore waters are of marine origin and in equilibrium with the assemblage of carbonate minerals. The conversion of sediment into limestone in this case is achieved not by a chemical gradient but through loading of younger sediments. This results in a pressure and temperature rise that, in turn, increases the solubility of the solid phases. Their dissolution-reprecipitation proceeds sequentially in a manner similar to that described for the meteoric pathway, but at a slower rate. The recrystallization front, as it migrates upwards with continuous loading causes “smoothing” of the original isotope signals, but the overall shifts are similar to meteoric pathways, albeit of lesser magnitude.

The carbonate sediment, regardless whether following the meteoric or the burial pathway, eventually reaches the *deep burial* environment. The boundaries can be set at cessation of most bacterial processes at about 75°C (or ~ 2 km depth). The major process occurring at these depths is pressure-solution that results in dissolution of a portion of the already stabilized limestone and reprecipitation of this material as late, mostly iron-rich, blocky calcite cements that occlude the residual porosity. The deep meteoric waters that are involved in this process are mostly saline, but in terms of C isotopes, the system is mostly rock buffered. However, introduction of light $\delta^{13}\text{C}$ from thermocatalytic decarboxylation may be important locally.

It is essential to understand the fundamentals of these post-depositional processes if we are to interpret the origin of an isotopic signal preserved in the rock record (Figure C14c).

Sample selection

From the above discussion, it is clear that if we are to obtain a record of past seawater isotopic composition, it is essential that the samples be well preserved or at the minimum “least altered.” One alternative is to concentrate on phases that are relatively stable and resistant to diagenesis. Such a phase is the LMC of some fossil shells, such as foraminifera, belemnites, and brachiopods. Even with these samples, it is mandatory that they be screened by optical (microscope, cathodoluminescence, SEM) and chemical (trace element composition) techniques in order to ensure their good preservation. The details of these techniques are given, for example, in Veizer (1983), McArthur (1994), and Grossman et al. (1996). For whole rocks, or components composed originally of A and HMC, that were as a rule subjected to diagenetic stabilization, the effort has to concentrate on domains that were recrystallized at the lowest possible water/rock ratio, such as fine-grained limestones (micrites) or some types of cements. Note nevertheless that any given rock can contain, side by side, massively recrystallized and well-preserved domains.

Isotopic evolution of seawater

Based on the background understanding of isotope systematics in (bio)chemical sedimentary rocks, minerals, and fossils, we can now tackle the evolutionary history of this planet as

recorded by the isotopic composition of past seawater. In this outline, only the billion to million year time resolution will be considered. Discussion of the Quaternary record is beyond the scope of this contribution.

The two dominant exogenic reservoirs of carbon are carbonate rocks and organic matter in sediments. They are linked in the carbon cycle via atmospheric CO_2 and the C species dissolved in the hydrosphere. The $\delta^{13}\text{C}$ for the total dissolved carbon (TDC) in seawater is about $+1 \pm 0.5\text{‰}$, with surficial waters generally heavier and deep waters lighter than this average (Kroopnick, 1980). Atmospheric CO_2 in equilibrium with TDC of marine surface water has a $\delta^{13}\text{C}$ of about -7‰ . The CO_2 is utilized by photosynthetic plants for production of organic C causing depletion in ^{13}C .

Most land plants utilize the so-called C_3 , or Calvin, pathway that results in tissue with a $\delta^{13}\text{C}_{\text{org}}$ of about -25 to -30‰ . The situation for aquatic plants is somewhat different because they utilize dissolved and not gaseous CO_2 . Tropical grasses, on the other hand, utilize the C_4 (Hatch-Slack or Kranz) pathway and have a $\delta^{13}\text{C}$ of some -10 to -15‰ . A third group that combines these two pathways, the CAM plants (algae and lichens), has intermediate $\delta^{13}\text{C}$ values. In detail, the nature of the discussed variations is far more complex (Sackett, 1989) and depends on the types of organic compounds involved. For our purposes, however, it is only essential to realize that C_{org} is strongly depleted in ^{13}C . This organic matter, which is very labile, is easily oxidized into CO_2 that inherits the ^{13}C -depleted signal.

The $\delta^{13}\text{C}$ of mantle carbon is about -5‰ (Hayes et al., 1992) and in the absence of life and its photosynthetic capabilities, this would also be the isotopic composition of seawater (Figure C15). Yet, as far back as 3.5 billion years (Ga) ago, and possibly as far as ~ 4 Ga ago (Schidlowski et al., 1983),

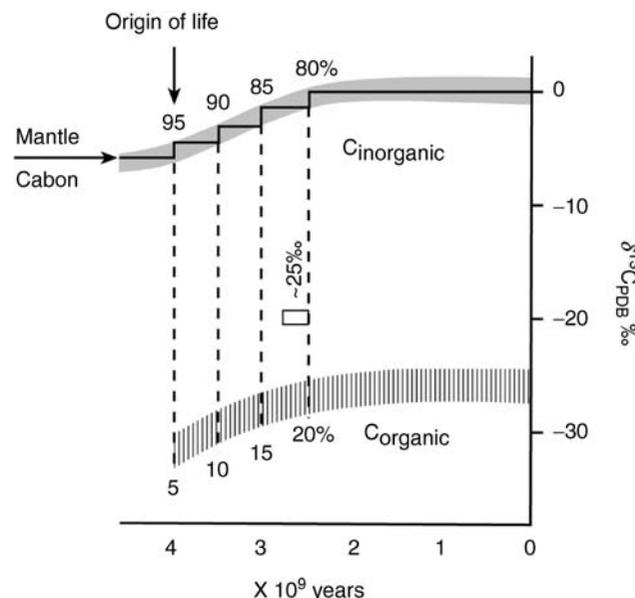

Figure C15 Theoretical evolution of $\delta^{13}\text{C}$ for inorganic (seawater) and organic matter, assuming that life originated ~ 4 Ga ago and the pool of organic carbon increased to its present day value (20% of all carbon) by ~ 2.5 Ga ago. Reproduced from Veizer (1988).

the carbonate rocks (\sim seawater) had $\delta^{13}\text{C}$ values of around 0‰ PDB (Figure C16). This suggests that a reservoir of reduced organic carbon that accounted for $\sim 1/5$ of the entire exogenic carbon existed already some 4 billion years ago, “pushing up” the residual 4/5 of carbon, present in the oxidized form in the ocean/atmosphere system, from -5 to 0‰. This is an oxidized/reduced partitioning similar to that of today. Stated in a simplified manner, life with its photosynthetic capabilities, and possibly of present day magnitude, can be traced almost as far back as we have a rock record. This photosynthesis may or may not have been generating oxygen as its by-product, but was essential in order to “lift” the seawater $\delta^{13}\text{C}$ to values similar to present day levels. In order to sustain seawater $\delta^{13}\text{C}$ at this level during the entire geologic history, it is necessary that inputs and outputs to the carbon cycle have the same $\delta^{13}\text{C}$. Since the input from the mantle, via volcanism and hydrothermal systems, has a $\delta^{13}\text{C}$ of -5 ‰ and the subducted carbonates are 0‰, the subduction process must also involve a complementary ^{13}C -depleted component of organic matter. This is possible to contemplate as long as oceanic waters were not fully oxygenated, such as may have been the case in the Archean (>2.5 Ga ago). This is either because oxygen generating photosynthesis was “invented” as late as the late Archean or early Proterozoic (Cloud, 1976), or because tectonic evolution led to a progressive oxygenation of the ocean/atmosphere system due to a switchover from a “mantle”-to a “river”-buffered ocean system (Goddéris and Veizer, 2000). For the latter alternative, it is possible to argue that the oxygen-generating photosynthesis (photosystem 2) may have been extant as far back as we have a geological record, without necessarily inducing oxygenation of the early ocean/atmosphere system (but see Lasaga and Ohmoto, 2002). Whatever the cause, the oxygenation of the system in the early Proterozoic (~ 2.5 – 1.8 Ga ago) would have resulted in oxidation of organic matter that was settling down through the water column. Today only $\sim 1\%$ of organic productivity reaches the ocean floor and $\sim 0.1\%$ survives into sedimentary rocks. As a result, the addition of mantle carbon, coupled with the subduction loss of the ^{13}C -enriched limestone carbon, would slowly force the $\delta^{13}\text{C}$ of seawater back to mantle values. In order to sustain the near 0‰ PDB of seawater during all of geologic history, it may be necessary to lower the input of mantle carbon into the ocean/atmosphere system by

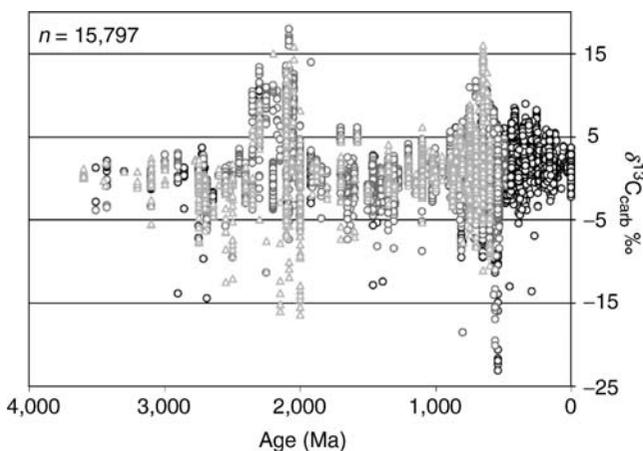

Figure C16 The record of $\delta^{13}\text{C}$ in limestones (circles) and dolostones (triangles) during geologic history. Reproduced from Shields and Veizer (2002), with permission from G³.

progressively diminishing the impact of hydrothermal and volcanic activity over geologic time.

Superimposed on this invariant Precambrian $\delta^{13}\text{C}$ seawater trend are two intervals with very heavy (and very light) values, at ~ 2.2 Ga ago and in the Neoproterozoic (Figure C16). The former has been interpreted as a result of the development of oxygen-generating photosynthesis that resulted in sequestration of huge quantities of organic matter (Karhu and Holland, 1996) into coeval sediments and the Neoproterozoic interval was the time of the proposed “snowball Earth” (Hoffman et al., 1998). At this stage, the reasons for the high frequency of the anomalous $\delta^{13}\text{C}$ values during these two intervals are not well known (see Rothman et al., 2003), but it is interesting that both were associated with large glaciations, as was the later discussed ^{13}C -enriched Permo/Carboniferous interval.

The sampling density and time resolution in the *Phanerozoic* enabled the delineation of a much better constrained secular trend (Figure C17), with a maximum in the late Permian, but even in this case we are dealing with a band of data. This reflects the fact that the $\delta^{13}\text{C}$ of total dissolved inorganic carbon ($\delta^{13}\text{C}_{\text{DIC}}$) of seawater is not uniform in time and space, that organisms can incorporate metabolic carbon into their shells (vital effect), and that some samples may also contain a diagenetic overprint. Superimposed on the overall trend are higher oscillations, on timescales of tens of millions of years and less, but their meaning is not yet understood.

It was proposed (Frakes et al., 1992) that the $\delta^{13}\text{C}_{\text{carbonate}}$ (seawater) becomes particularly heavy at times of glaciations, and that such times are also characterized by low CO_2 levels. The coincidences of the $\delta^{13}\text{C}$ peaks with the Late Ordovician and Permo-Carboniferous glacial episodes (Figure C17) appear to support this proposition, but the Mesozoic/Cenozoic record does not. Nevertheless, accepting the validity of the present $\delta^{13}\text{C}$ trend, it is possible to estimate the $\Delta^{13}\text{C}$ ($=\delta^{13}\text{C}_{\text{carb}}-\delta^{13}\text{C}_{\text{org}}$) that is proportional to $p\text{CO}_2$. Making a set of additional assumptions, one can then model $p\text{CO}_2$ levels of the ancient atmospheres. Three such *Phanerozoic* $p\text{CO}_2$ reconstructions do exist (Figure C18). However, they are internally inconsistent and not one of them shows any correlation

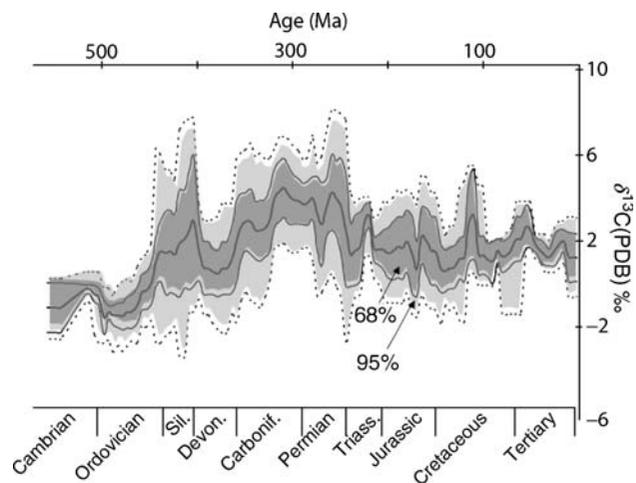

Figure C17 The *Phanerozoic* $\delta^{13}\text{C}$ trend for LMC shells. The running mean is based on a 20 Ma window and 5 Ma forward step. The shaded areas around the running mean include the 95% ($\pm 2\sigma$) of all data. Reproduced from Veizer et al. (1999), with permission from Elsevier Science.

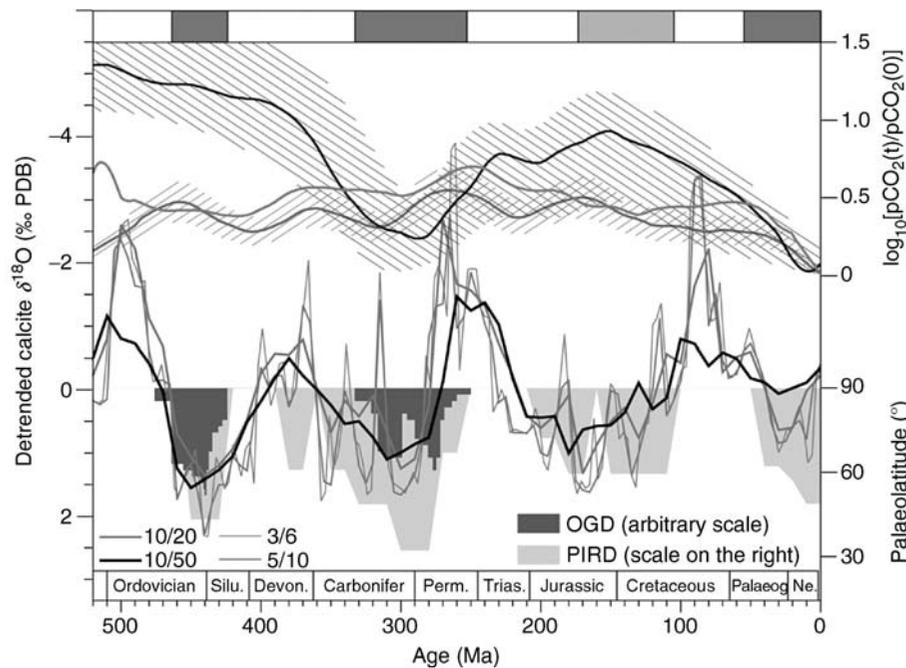

Figure C18 Phanerozoic climatic indicators and reconstructed $p\text{CO}_2$ levels. The bottom set of curves are the detrended running means of $\delta^{18}\text{O}$ values of calcitic shells over the Phanerozoic (3/6 means step 3 Myr, window 6 Myr). Histograms are paleolatitudes of ice-rafted debris (PIRD) and other glacial deposits (OGD) – such as tillites and glacial marine strata. The dark bars at the top represent cool climate modes (icehouses) and the white bars are the warm modes (greenhouses). The upper set of curves are reconstructed histories of the past $p\text{CO}_2$ variations. Modified from Shaviv and Veizer (2003).

with the paleoclimate deduced from sedimentological criteria. This led Veizer et al. (2000) to conclude that either the estimates of paleo- CO_2 were unreliable or there was no direct relationship between $p\text{CO}_2$ levels and climate for most of the Phanerozoic. In contrast, the “paleotemperature” trend for tropical Phanerozoic oceans, as deciphered from oxygen isotope record, correlates exceptionally well with the record of past variations in the flux of cosmic rays, suggesting that celestial phenomena were the primary driver of planetary climate (Shaviv and Veizer, 2003), at least on geological timescales.

Higher order peaks, at million-year resolution, have been observed in the geologic record, particularly in deep-sea borehole sections. An example of such an episode is the Cenomanian/Turonian boundary, some 91 million years ago, explained variously as due to a high organic carbon burial rate and draw-down of atmospheric CO_2 , increased thermohaline circulation, increased preservation of organic matter, or to diminished riverine input. However, the modeling of this excursion (Kump and Arthur, 1999) did not yield any unique solution.

CARBON ISOTOPES, STABLE

General

Carbon has two stable (non-radioactive) isotopes. In nature, the ^{12}C isotope comprises 98.89% of all carbon and ^{13}C makes up the remaining 1.11%. A variety of physico-chemical processes whose rates are mass-dependent, such as kinetic reactions involving diffusion, and temperature-controlled equilibrium reactions serve to “fractionate” the isotopes into proportions slightly different from the bulk averages. These isotopes are therefore most useful when used in tandem as isotope ratios ($^{13}\text{C}/^{12}\text{C}$) in order to explore paleoclimates and paleoenvironments. Carbon isotopes are preserved and expressed in the bulk composition of a wide variety of materials such as shells, speleothems, bones, leaves, peat, soils, sediments, wood, and food, and more recently in the composition of specific compounds or

biomarkers contained therein. In some cases, the climate influence may be quite direct, but in many others the isotopic variations are less direct, linked to climate effects on the global carbon cycle and photosynthetic pathways of plants.

Notation

The $^{13}\text{C}/^{12}\text{C}$ in materials is measured with a stable-isotope ratio mass spectrometer (IRMS), taking advantage of the mass differences in ionized $^{13}\text{CO}_2$ molecules (or ^{13}CO molecules) relative to $^{12}\text{CO}_2$ (or ^{12}CO) that cause them to follow different trajectories in a magnetic field on the path to detectors. The isotopic ratio of an unknown sample is ultimately expressed in permil (‰) with the delta (δ) notation:

$$\delta^{13}\text{C} \text{ (in ‰)} = \left[\left(\frac{^{13}\text{C}}{^{12}\text{C}_{\text{sample}}} / \frac{^{13}\text{C}}{^{12}\text{C}_{\text{PDB}}} \right) - 1 \right] \times 1000 \quad (1)$$

where the conventional standard is PDB calcite from belemnite fossils of the Cretaceous PeeDee Formation of South Carolina. Although no original PDB standard remains from its initial adoption about five decades ago, there exist secondary standards such as NBS-21 graphite National Bureau of Standards-21) and V-PDB (Vienna PDB), whose isotopic composition is known with respect to PDB (Coplen, 1996). The $^{13}\text{C}/^{12}\text{C}$ ratio in PDB is 0.0112372, so positive $\delta^{13}\text{C}$ values have more ^{13}C (i.e., are “enriched”), and negative $\delta^{13}\text{C}$ values have less ^{13}C (i.e., are “depleted”). More generally when comparing $\delta^{13}\text{C}$ between samples, those with less negative (or more positive) $\delta^{13}\text{C}$ values are more enriched in ^{13}C relative to samples with more negative (less positive) $\delta^{13}\text{C}$. The range of $\delta^{13}\text{C}$ in many types of materials may be several permil but some, like ocean water dissolved inorganic carbon, are very homogeneous (Figure C19).

When examining carbon isotopic behavior of plants, discrimination (Δ) is often a useful parameter that eliminates the effect of any variability in atmospheric $\delta^{13}\text{C}$ ($\delta^{13}\text{C}_{\text{air}}$) in plant isotopic variation

$$\Delta = \frac{\delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{plant}}}{1 + \delta^{13}\text{C}_{\text{plant}}} \approx \delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{plant}} \quad (2)$$

Terrestrial environments

Most paleoclimate inferences from $\delta^{13}\text{C}$ in terrestrial settings are based on plant matter that acquires an isotopic composition related to the environment in which the plants grew. This signal may be subsequently passed on to other elements of the Earth system, to humans/animals from food consumption or to soils during plant respiration and decomposition of plant matter, for example. Temperature-dependent equilibrium reactions usually play a minor role, if any, in the source of the primary environmental signals in these materials.

Terrestrial vegetation is dominated by plants with the C_3 (Calvin-Benson) photosynthetic pathway for which carbon isotope composition is modeled by the equation of Farquhar et al. (1982):

$$\delta^{13}\text{C}_{\text{plant}} = \delta^{13}\text{C}_{\text{air}} - a - (b - a) \times \frac{C_i}{C_a} \quad (3)$$

where $\delta^{13}\text{C}_{\text{air}} = \delta^{13}\text{C}$ of the atmospheric CO_2 ; C_i/C_a = ratio of leaf intercellular CO_2 concentration to the atmospheric concentration; a = fractionation during CO_2 diffusion through stomata ($\sim 4.4\text{‰}$); and b = enzymatic fractionation by ribulose

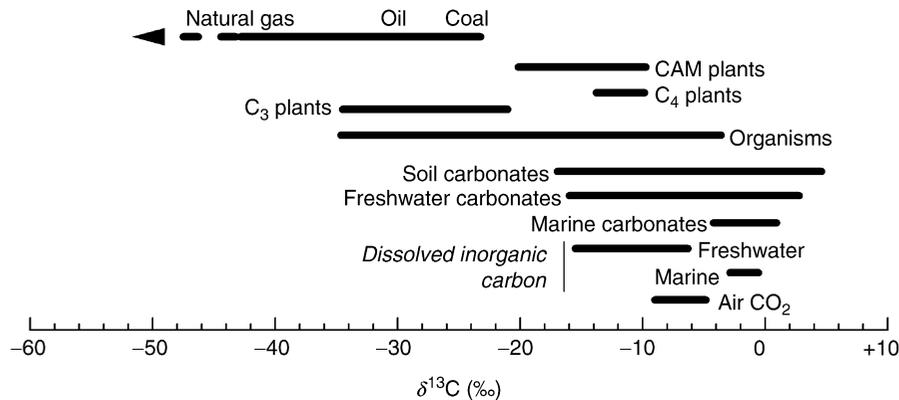

Figure C19 Typical stable-carbon isotope composition of natural materials.

bisphosphate carboxylase (Rubisco) ($\sim 27\%$). With regard to paleoclimate, C_i/C_a , and hence $\delta^{13}\text{C}_{\text{plant}}$, may be influenced by any and all environmental factors that affect rates of stomatal conductance and carbon fixation, such as light, temperature, relative humidity, and soil moisture (Farquhar et al., 1982). The $\delta^{13}\text{C}$ of C_3 plants generally falls into the range of -20 to -32% , with a mean of about -26 or -27% (Figure C19).

Equation 1 is a guide to interpreting possible climatic and environmental effects (relative humidity, temperature, soil moisture, etc.) on tree-ring $\delta^{13}\text{C}$ series in which the cellulose component is frequently isolated for higher fidelity of climate signal (Leavitt and Long, 1989; Robertson et al., 1997). There are also eco-physiological parameters such as water-use efficiency that may be reconstructed from the $\delta^{13}\text{C}$ of tree rings (Bert et al., 1997) and from plant macrofossils (Van de Water et al., 1994).

A second major group of plants uses the C_4 (Hatch-Slack) photosynthetic pathway, producing much more enriched $\delta^{13}\text{C}$ values (Figure C19), generally between -10 and -14% (mean -12%), largely because of reduced discrimination against ^{13}C by another enzyme, PEP-carboxylase, involved in the initial fixation of CO_2 (Farquhar, 1983). Trees, most shrubs and “cool-season” grasses tend to be C_3 plants (including crops such as wheat, alfalfa, and oats), whereas “warm-season” grasses (high summer precipitation in conjunction with high minimum temperatures, including crops such as maize, sorghum, and sugar cane) and some woody dicots adapted to arid conditions tend to be C_4 plants. It is suggested that the C_4 pathway may have evolved in response to periods of low atmospheric CO_2 concentrations whereby PEP-carboxylase serves to effectively pre-concentrate CO_2 at low atmospheric levels before the final carbon fixation by RuBP in bundle sheath cells (Ehleringer et al., 1997). C_3 plants are thought to be at a disadvantage at low CO_2 concentrations because oxygen will more readily react with Rubisco (a process called photorespiration). Theoretically, however, there are effects besides $p\text{CO}_2$, such as temperature, that can determine the success of C_3 versus C_4 (Figure C20), and there is direct evidence that climate may indeed be more important than CO_2 in determining C_4 plant distribution and expansion under some circumstances (Huang et al., 2001).

Because of the different climatic conditions favoring C_3 and C_4 plants, variations in their spatial and temporal proportions can be used as a paleoenvironmental indicator. The $\delta^{13}\text{C}$ of some materials can be used to estimate the proportion of

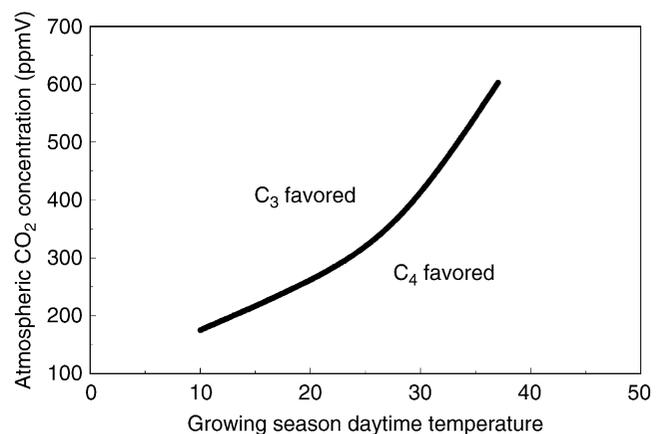

Figure C20 Approximate $p\text{CO}_2$ and temperature conditions that determine prevalence of C_3 versus C_4 plants based on their physiology. (After Ehleringer et al., 1997.)

C_3 and C_4 biomass present by means of a mixing model with -12% and -27% as approximate end members for pure (100%) C_3 and C_4 communities, respectively. For example, $\delta^{13}\text{C}$ of dated soil carbonates and soil organic carbon (and even teeth) has been used to estimate the global expansion of C_4 communities in the last 10 million years (Quade and Cerling, 1995; Cerling et al., 1998), and to infer regional vegetation shifts in the southern United States during the Quaternary (Monger et al., 1998). Even a shift in $\delta^{13}\text{C}$ of human bones in the U.S. Southwest (Figure C21) has been found to indicate a change in diet related to possible climate shifts (Coltrain and Leavitt, 2002).

Likewise, stalagmites and similar carbonate deposits deriving a substantial portion of their carbonate from respired soil CO_2 could record the $\delta^{13}\text{C}$ imprint of such C_3/C_4 changes. Even if C_3/C_4 has been constant, such as in the high-elevation C_3 landscape contributing carbonate to the hydrologic system producing vein calcite at Devil’s Hole, Nevada, the $\delta^{13}\text{C}$ variations have been used to infer density of past vegetation over tens of thousands of years (Coplen et al., 1994). Similarly, a strong correlation with El Niño/Southern Oscillation (ENSO) of a speleothem $\delta^{13}\text{C}$ record from Belize, Central America, might be related to teleconnected ENSO climate contributing to higher or lower ecosystem respiration (Frappier et al., 2002).

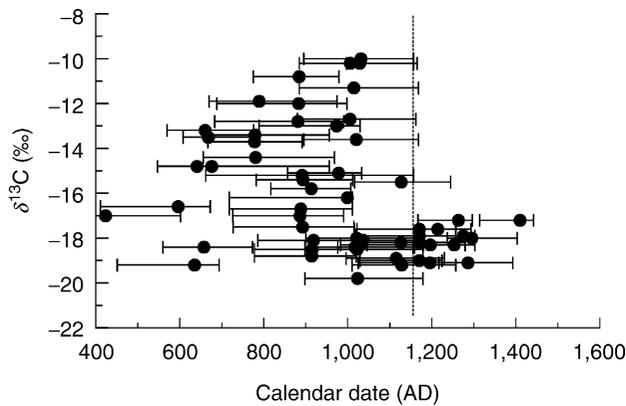

Figure C21 Shift in isotopic composition of bone collagen in the Fremont paleoculture of Utah from enriched values consistent with maize in the diet before AD 1100 and a C_3 -dominated diet afterward (after Coltrain and Leavitt, 2002). The period in which maize could be cultivated is attributed to farther northward penetration of the southwestern summer monsoon.

Marine environments

Initial isotopic analysis of foraminifera in Cenozoic marine sediment cores (Emiliani, 1972) was focused on the oxygen isotope composition as related to temperature or sea level (ice volume). Interpretation of $\delta^{13}C$ measurements on the same cores was delayed somewhat because of even more complicated environmental influences (Hoefs, 1987), but Shackleton and Kennett (1975) did find benthic forams consistently depleted relative to planktonic forams by about 1‰. In part, this is a consequence of planktonic forams incorporating dissolved carbonate species enriched by preferential removal of the isotopically light dissolved carbon during photosynthesis. There is now a 65 million-year record of $\delta^{13}C$ variation of carbonates in deep-sea sediment cores (Zachos et al., 2001) that shows overall variation of almost 4‰, with the lowest values occurring in the last 6 million years, and evidence of precipitous but brief $\delta^{13}C$ excursions (2–3‰), one of the largest occurring 55 million years ago.

The influences on this variability have been studied. Shackleton et al. (1983) used the $\delta^{13}C$ record of forams to infer greatly reduced CO_2 atmospheric concentrations (pCO_2) during the last full-glacial period, now known to be true in light of subsequent paleoatmosphere measurements in ice cores. Pagani et al. (1999) have since used compound-specific $\delta^{13}C$ analysis of alkenones derived from algae organic matter compared with $\delta^{13}C$ of planktonic forams to more precisely estimate pCO_2 (Figure C22). This is based on foram $\delta^{13}C$ representing the isotopic composition of aqueous CO_2 used in photosynthesis, and the fractionation between organic $\delta^{13}C$ and carbonate $\delta^{13}C$ being a function of aqueous CO_2 concentration (itself a function of pCO_2). The trend in calculated pCO_2 thus derived suggests CO_2 concentrations were very low 5–10 million years before a major continental C_4 plant expansion occurred around 8–4 million years ago, according to evidence from the $\delta^{13}C$ of teeth, soil carbonates, and terrestrial organic matter (Cerling et al., 1998). This implies that factors other than pCO_2 must have driven that C_4 boom.

Corals have provided a wealth of paleoenvironmental information from their chemical and isotopic composition. Coral

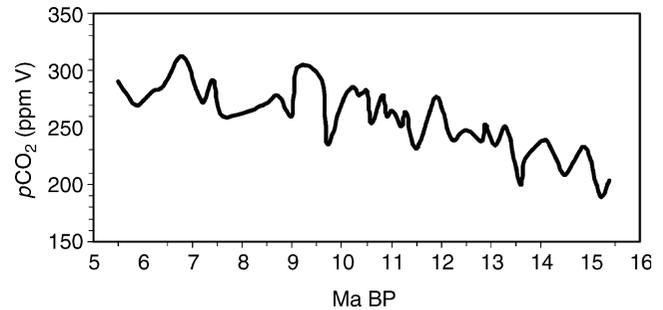

Figure C22 Atmospheric CO_2 concentrations between 16 and 5 million years ago, reconstructed from the difference between $\delta^{13}C$ of alkenones of organic matter and foram carbonates. (After Pagani et al., 1999.)

$\delta^{13}C$ variations have been attributed to a number of effects, such as variations in food source or dissolved carbonate isotopic composition (related to ecosystem productivity), but there is a growing body of evidence that at least in some cases light may be a dominating (and reconstructable) influence, whereby high levels promote more photosynthesis and less discrimination against ^{13}C (Swart et al., 1996).

Quay et al. (1992) demonstrated the merit in repeated measurement of $\delta^{13}C$ of dissolved inorganic carbon over two decades to help estimate ocean uptake of atmospheric CO_2 over time and space. Recent $\delta^{13}C$ investigations of calcareous sponges (Böhm et al., 2002), which deposit annual and subannual banding like corals, have further revealed their potential to reliably reconstruct $\delta^{13}C_{air}$ over hundreds of years or more.

A current area of great scientific interest is the possibility that methane (CH_4) in the form of hydrates or clathrates has periodically been released catastrophically from deep shelf sediments as a result of decreasing sea level, increasing temperature of the ocean water, or even submarine slope failure. Because methane is a powerful greenhouse gas, there is concern that any such future events might exacerbate global warming. Isotopic analysis of benthic foraminifera over the past 60,000 years from the Santa Barbara Basin reveals periodic large releases of methane (Kennett et al., 2000). Interstadials (warm intervals) are characterized by foram $\delta^{13}C$ values depleted by several permil. Detailed compound-specific $\delta^{13}C$ analysis of diplopterol, a product of methanotrophic bacteria, in sediments of the Santa Barbara Basin further confirms that the most negative values (interpreted as highest marine methane) occur during interstadials (Hinrichs et al., 2003).

Past and future

Stable carbon isotopes have been a highly valuable tool for the past 50 years in helping to build our current understanding of terrestrial and aquatic paleoenvironments, variously including past moisture conditions, temperature, light, plant productivity, the carbon cycle, and more. In some cases, $\delta^{13}C$ has provided a direct proxy of absolute conditions in past systems, and in others it has helped to constrain the range of likely paleoenvironmental conditions or provided independent support for conditions inferred from other evidence. With exciting improvements in mass-spectrometry, $\delta^{13}C$ measurements will unquestionably reveal even more about past changes in the Earth system. Advances such as compound-specific analysis are beginning to provide isotopic measurements of biomarkers exclusive to

land or aquatic organisms, to species or genera, and even to particular plant organs. Improvements in both the speed of analysis and ability to analyze extremely small quantities of compounds extracted from bulk samples enable even inherently microscopic materials such as pollen to be analyzed.

CARBONATE COMPENSATION DEPTH

Principles

The carbonate compensation depth (CCD) is the particular depth level in the oceans where the rate of supply of calcium carbonate to the sea floor is balanced by the rate of dissolution. In practice, the CCD is mapped as the level at which percent carbonate values in marine sediments drop towards zero, i.e., the depth transition from carbonate ooze to red clay or siliceous ooze. Because the supply and dissolution rates of carbonate differ from place to place, the depth of the CCD is variable. In the Indian Ocean and the Pacific, the CCD is typically found at depths between 3,500 and 4,500 m. In the North Atlantic and the eastern South Atlantic, the CCD occurs deeper than 5,000 m. Close to continental margins, the CCD tends to shoal due to higher biological productivity and hence respiration of organic matter in sediments, which releases metabolic CO_2 , in turn causing the dissolution of CaCO_3 . Beneath the equatorial upwelling zones, higher primary production of planktonic carbonate shells depresses the CCD by up to 500 m compared with the oligotrophic realms towards the north and south.

The depth of the CCD is determined by the kinetics of carbonate dissolution from sediments. If dissolution kinetics were infinitely fast, the CCD would coincide exactly with the saturation horizon of carbonate (the so-called chemical lysocline), which in turn is a function of pressure, temperature, salinity, and carbonate ion concentration of the overlying seawater (Figure C23), with generally increasing solubility in deeper waters. However, in real oceans the CCD is found at some degree of undersaturation, i.e., a few hundred meters below the lysocline (Archer, 1996). Because shells or skeletons made of aragonite (mainly corals and pteropods) dissolve more readily than those of calcite (coccoliths and foraminifers), the compensation depth for aragonite (ACD) is positioned some 1,000–2,000 m above the CCD. However, organic coatings of grains

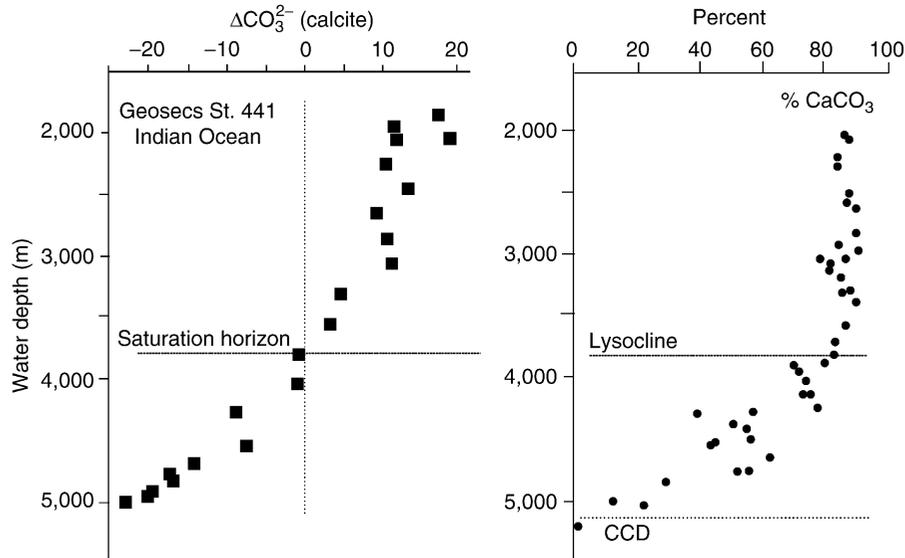

Figure C23 Calcite saturation data of GEOSECS station 441 ($5^{\circ}2'S$, $91^{\circ}47'E$) compared with carbonate contents (weight%) from surface sediment samples of the eastern equatorial Indian Ocean. (After Peterson and Prell, 1985.)

may inhibit the dissolution of sedimenting carbonate particles, thereby depressing the positions of lysocline and CCD below the predicted levels from carbonate chemistry. On the other hand, oxidation of organic matter in the sediments releases metabolic CO_2 and promotes CaCO_3 dissolution even above the chemical lysocline (Milliman et al., 1999).

Over longer timescales, the depth of CCD in the oceans is the expression of the mass balance of dissolved Ca^{2+} and HCO_3^- flowing into the oceans from weathering, and the removal of CaCO_3 from the ocean by burial. After an equilibration time of the order of 10,000 years, CaCO_3 compensation will have a profound impact on the buffering of the pH of the ocean. An imbalance between sources and sinks of CaCO_3 will drive the pH of the ocean toward restoring balance. For example, excess input of dissolved CaCO_3 will tend to drive the pH of the ocean toward higher, more basic values, deepening the CCD and increasing CaCO_3 accumulation on the seafloor until the rates return to balance.

Modern ocean distribution and Quaternary changes

The asymmetry of the modern ocean CCD pattern is largely a product of the thermohaline circulation. The greatest depth occurs in the eastern North Atlantic, where the production of supersaturated deep water increases the CCD to $>5,500$ m. The shallowest levels are in the northern North Pacific, where deep waters are old and enriched in CO_2 . This pronounced modern pattern has been termed basin-to-basin fractionation and is illustrated by the fact that roughly 65% of the present Atlantic seafloor is covered by carbonate ooze, while only 54% of the Indian Ocean sea floor and 36% of the Pacific sea floor share that distinction (Archer, 1996).

Regarding Quaternary times, observations from deep-sea sediment cores show that the CCD topography varied significantly over the glacial to interglacial cycles characteristic of the last 2.6 Myr of Earth history. The CCD fluctuations of the Pacific (first described by G. Arrhenius) are commonly described as dissolution cycles, with high dissolution

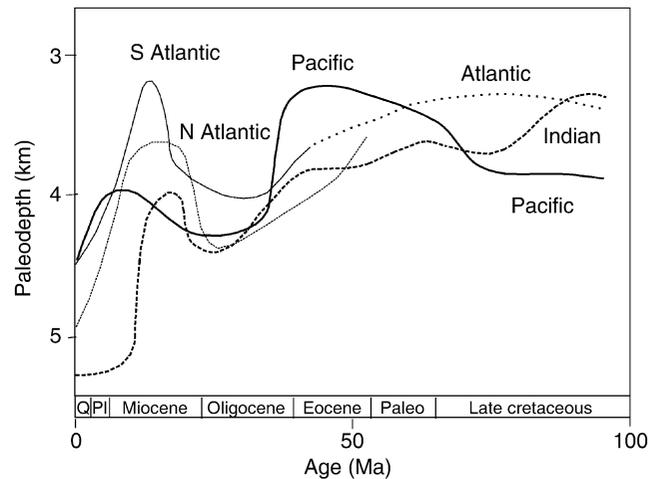

Figure C24 Carbonate compensation depth variation in different ocean basins through the late Cenozoic. (Redrawn from Van Andel, 1975.)

in interglacials and *vice versa*. Carbonate productivity plays a secondary role. On much of the Atlantic sea floor, the CCD fluctuations tend to change to counter those of the Pacific, with higher dissolution occurring during glacials. These changes in carbonate preservation are ascribed to changes in the formation of North Atlantic Deep Water, but also to changes in terrestrial carbon storage and in the fractionation between shallow and deep ocean carbonate deposition.

Pre-Quaternary history

Studies of longer cores from ocean floor drilling show that CCD fluctuations were similar in the various oceans and therefore driven by global mechanisms (Figure C24). The mean ocean CCD was about 1,000 m shallower than present during the Cretaceous and early Paleogene, followed by deepening levels going into

the Oligocene. Another shallowing occurred during the mid Miocene, before the CCD dropped to its present mean depth near 4,300 m. The drastic drop at the end of the Eocene is global in scale and reflects changes in the global carbon cycle, possibly linked to an increase in alkalinity due to higher silicate weathering caused by the Himalayan uplift (Francois and Walker, 1992). It might also be linked to the lowering of sea level at that time, reducing the area of shallow epicontinental seas available for the accumulation of coral reef carbonate. The late Neogene CCD drop is more pronounced in the North Atlantic as compared with that of all other ocean basins. It reflects mostly the increase in the production of North Atlantic Deep Water related to the opening and closing of ocean gateways at that time (Heinze and Crowley, 1997). However, there is still controversy about the cause of the CCD fluctuations in Earth history.

CARBONATES, COOL WATER

Introduction

The deposition of marine carbonate sediments in cool water environments has been long recognized (James, 1997). Despite this, the focus of study on carbonate sediments and their diagenesis has been carried out in warm, tropical waters in places such as the Caribbean, the Persian Gulf, the Great Barrier Reef, and Shark Bay. Not only do these places provide clear analogs for many ancient deposits, they are also often located in environments that are both pleasant to work in and easily accessible. Cool-water carbonates are, by way of contrast, deposited beneath some of the coldest and roughest waters of the world such as the Southern Ocean and North Atlantic. Furthermore, many of the best-exposed examples occur in Australia

([Figures C25 and C26](#)) and New Zealand, remote from European and North American centers of carbonate research.

Such disadvantages aside, understanding cool-water carbonates and their diagenesis is a vital component of carbonate sedimentology. They are currently being deposited across large areas of continental shelf, form extensive successions in Cenozoic basins, and are also known from many ancient high latitude environments. In addition, by virtue of their calcite-dominated mineralogy, cool-water carbonates provide excellent analogs for many Paleozoic limestones that were likewise dominated by calcite, in contrast to modern tropical carbonates, which are rich in aragonite.

History of investigations

Among the early studies, those of Chave (1967), Lees and Buller (1972) and Lees (1975) stand out as having established the conceptual framework for cool-water carbonate deposition. Meanwhile, Connolly and von der Borch (1967) and Wass et al. (1970) had discovered that cool-water carbonates were being deposited across the entire length and width of the southern Australian continental shelf. More recent compilations include the 1988 special issue of *Sedimentary Geology* (vol. 60), James and Clarke (1997), and Pedley and Carannante (2006). The last compilation paid particular attention to the cool-water carbonates of the Mediterranean Basin. Furthermore, ODP Leg 182 recovered a number of cores from the southern Australian margin in the Great Australian Bight (Feary et al., 2000).

Distinctive characteristics

James (1997) lists six characteristics for recognition of ancient cool-water carbonates. In decreasing order of reliability, these are:

1. Carbonates interbedded with glaciogene sediments
2. Carbonates situated in appropriate paleolatitudes
3. Glendonite-type minerals in carbonates
4. Carbonates composed wholly of the Heterozoan Association
5. Heterozoan Association outboard of mid to inner shelf/ramp Photozoan Association
6. Trace element and isotope geochemistry of skeletons

Of these, 1–3 are self explanatory but not always present, while 6 can be equivocal because of diagenesis. The following section therefore focuses on 4 and 5 as the characteristics that are most common and most readily determined by geological analysis.

Modern warm-water carbonates are dominated by photozoans, organisms that are either photosynthetic or are zooanthellate, with symbiotic photosynthetic organisms. These form the Photozoan Assemblage. In contrast, cool-water carbonates are predominantly dominated by Heterozoans, organisms that are non-photosynthetic and lack photosynthetic symbionts (James, 1997), and thus they are mostly dominated by bryozoans, with varying proportions of mollusks, foraminifers, echinoderms, brachiopods, barnacles, sponges, and coralline algae. As a result of this dichotomy, warm-water benthic carbonates are formed primarily in shallow water, especially in the first 30 meters where light is most intense. The biota that form cool-water carbonates are not limited to the photic zones, apart from coralline algae. Therefore, benthic carbonate production is not depth-limited but continues across the entire continental shelf and onto the upper continental slope. In addition to

Figure C25 The “Twelve Apostles,” sea stacks formed by erosion of the Oligo-Miocene Gambier Limestone, a cool-water carbonate on the south coast of Victoria, Australia (photo H. Apps).

Figure C26 Point Culver, Western Australia. Late Eocene cyclic cool-water chalky limestones rich in siliceous sponges, (photo by author).

the biota of the sediment surface, many of the organisms that contribute carbonate to these sediments grow prolifically on hard substrates, including rock reefs and sea floor hardgrounds. These rocky areas are in some ways analogous to the coral reefs of warm-water carbonates in that they provide a localized factory for carbonate production (Nelson et al., 1988a). Similarly, in shallow water, sea grass leaves provide a good substrate for epibionts, and the sheltered environment of sea grass banks (Figure C27) both encourages carbonate production and traps sediment (Gostin et al., 1984). In deeper water, bryozoan and sponge mounds are not uncommon (James et al., 2000), appearing in the geologic record both as discrete bioherms and biostromes.

In addition to their taxonomic distinctiveness, the Heterozan and Photozoan Assemblages differ in the dominant mineralogy produced. The Photozoan biotas produce skeletons that are predominantly aragonite and high magnesium calcite. Heterozan biotas are predominantly calcite, ranging from low to high magnesium contents. Aragonite is a comparatively minor component. This has major implications for the diagenesis of cool-water carbonates (see below).

Warm-water carbonates commonly contain ooids (formed in agitated shallow marine environments), abundant micrite (carbonate mud) formed either by disintegration of calcareous green algae or direct precipitation from seawater super-saturated with respect to carbonate, and intraclasts, formed by rapid sea floor

Figure C27 Seagrass beds and carbonate-rich sand, Esperance, Western Australia (photo by N. James).

cementation, again from super-saturated water. Ooids are absent in cool-water environments where saturation states are lower. True micrite is absent, and fine-grained carbonates are either carbonate silt formed by the erosion of other carbonates or coccoliths. Intraclasts are rare in cool-water successions, largely because the lower saturation state of carbonates in cooler marine waters reduces the rate of sea floor cementation.

Distribution

Modern marine carbonates occur wherever rates of biogenic carbonate production exceed terrigenous sediment supply. However, because biologic carbonate production is lower in cool as opposed to warm water, cool-water carbonates are generally found in areas of reduced terrigenous sedimentation (Chave, 1967). Gradations between warm and cool-water carbonates are known, such as on the west and southwest coasts of Australia (Cann and Clarke, 1993; Collins et al., 1997). However, a mean annual temperature of 22 °C or less serves as a useful dividing line between the warm and cool (or cold) water depositional realms (James, 1997). Cooler waters typically have a lower carbonate saturation than warmer waters, and this influences both the production of grains and the diagenesis of cool-water carbonates (see below).

Major settings for cool-water carbonate deposition include shelves and ramps, offshore banks, and large embayments. One of the largest and best-studied areas of cool-water carbonate shelf deposition is the continental shelf of southern Australia (James et al., 2001, and references therein). Rockhall (Scoffin et al., 1980) and Porcupine (Scoffin and Bowes, 1988) Banks in the North Atlantic are examples of modern offshore banks characterized by cool-water carbonate sediments. Large embayments floored by cool-water carbonates include Gulf St. Vincent (Shepherd and Sprigg, 1976) and Spencer Gulf of South Australia (Gostin et al., 1984).

In addition to temperature, several other processes can give rise to a cool-water aspect in otherwise warm water carbonate environments. One is turbidity, where high levels of suspended sediment reduce the competitive advantage of the photozoan biota so that, even in shallow water, the carbonate component

may be dominated by mollusks, bryozoan, and other heterozoan biota. The sediments in Bonaparte Gulf in northern Australia provide one such example (Clarke et al., 2001). Another is high nutrient loadings, which, in shallow water, will favor algal growth over that of zooanthellate organisms (James, 1997). In warmer waters, the algae will include calcareous green forms, but in areas where water temperatures are marginal for calcareous green algae, red algae and other components of the heterozoan biota will dominate. A third factor is water depth. Below the photic zone, biota is typically heterozoan in aspect. Deeper waters are cooler than shallow waters, especially where there is a well-developed thermocline. Deep shelf or upper slope carbonates of heterozoan aspect may therefore occur seaward either shallow cool-water shelf heterozoan carbonates or shallow warm-water shelf photozoan carbonates (James, 1997). Finally, cool or cold currents moving towards the equator along continental margins can result in conditions suitable for the Heterozoan Assemblage in low latitudes.

Diagenesis

Tropical carbonates often experience rapid seafloor cementation (Tucker and Wright, 1990). In contrast, cool-water carbonates for the most part experience limited seafloor cementation because of generally lower levels of carbonate saturation and the slower reaction times at lower temperatures. Rao (1981a) showed the presence of minor calcite seafloor cements in sediments on the Tasmania continental shelf. Ancient cool-water carbonates similarly show only limited seafloor cementation for the most part (e.g., Nicolaides, 1994 and Shubber et al., 1997). During exposure to meteoritic waters, limestones containing abundant aragonite have undergone extensive carbonate dissolution, which is reprecipitated as calcite. Dissolution and reprecipitation stabilizes the limestones and causes extensive lithification even in young carbonates that have undergone little burial, such as those of exposed Pleistocene reefs. Because aragonite is much less abundant in most cool-water carbonates, they do not undergo anywhere near as extensive dissolution and reprecipitation. In consequence, many cool-water carbonates that have undergone limited burial, such as

Figure C28 Oligo-Miocene Gambier Limestone exposed in cliffs near the Twelve Apostles, showing characteristic cyclic bedding (photo H. Apps).

the Oligocene carbonates of southern Australia, are only weakly lithified, despite their age (James and Bone, 1989). Most cementation in cool-water carbonates appears to be related to burial. This contrasts with aragonite-rich carbonates, where burial cements are more commonly associated with infill of remnant porosity after extensive seafloor and meteoric cementation. The Oligocene Te Kuiti Limestone of New Zealand has been buried to a depth of up to 1,100 m (Nelson et al., 1988b) and is, as a result, fully lithified and strongly stylolitized. It is likely that much of the carbonate needed to fully cement calcitic, cool-water limestones comes from pressure dissolution (Nicolaidis and Wallace, 1997). Pressure-dissolution appears to require at least ~200 m of burial to begin the process.

Examples of cool-water carbonates through geologic time

Cenozoic cool-water carbonates are best known from southern Australia, New Zealand, and southern Europe. The Australian examples range in age from Eocene to Pliocene and are very extensive, but have experienced little burial (rarely more than a few tens of meters), although some (Nicolaidis and Wallace, 1997) have had several hundred meters of burial (Figure C28). Most formed on Cenozoic shelves and slopes (e.g., Nicolaidis, 1994; Bernecker et al., 1997); however, some (Clarke et al., 1996; Shubber et al., 1997) formed in sheltered embayments similar to the modern gulfs of southern Australia. Because of their very limited burial diagenesis, they provide a useful link between the carbonates of modern cool-water environments and those that have experienced deep burial and subsequent uplift. Cool-water carbonates have also been documented from the margins of the Mediterranean, including examples from Spain (Franseen et al., 1997; Martin et al., 1996), Austria (Nebelsick, 1992), Italy (Bassi et al., 2006), and Greece (Spjeldnaes and Moissette, 1997). Cool-water carbonates of New Zealand, such as those of the Oligocene Te Kuiti Group

(Nelson et al., 1988b), have experienced deep burial and are fully lithified, unlike their Australian and Mediterranean counterparts. New Zealand carbonates were deposited on both shelf and platform environments (Nelson, 1978).

The well-known Cretaceous and Danian chalks of Europe (Scholle et al., 1983) are now regarded as cool-water carbonates. These were deposited in a range of environments directly analogous to those of modern southern Australia, from high-energy skeletal grainstones along the shores to offshore bryozoan mounds and deep shelf coccolith lime mudstones (Surlyk, 1997). Other documented examples of Mesozoic carbonates with cool-water affinities are the open shelf carbonates of Sardinia and the southern Appenines (Carannante et al., 1997).

The first Paleozoic carbonates recognized as being of cool-water origin were the Permian limestones of Tasmania. These were shown by Rao (1981b) to have formed on a polar shelf marginal to the Gondwana glaciation on the basis of their dropstones and close association with glaciomarine facies. In addition, they were deposited at a high paleolatitude and had a primary calcite-dominant mineralogy. Other cold-water carbonates of Tasmania include the Darlington Limestone (Brill, 1982), deposited in a near-shore facies. Equivalent sediments of the Northern Hemisphere are found in the Permian of the Sverdrup Basin (Beauchamp and Desrochers, 1997; Stemmerik, 1997).

Other known Paleozoic cool-water carbonates have been described from the Early Carboniferous of western Canada (Brandley and Krause, 1997; Martindale and Boren, 1997), to the Middle Ordovician of Canada by Brookfield (1988) and Kentucky by Pope and Read (1997). Lavoie (1995) provided a Late Ordovician example from Quebec. These three examples all occur at relatively low paleolatitudes. They are attributed to a combination of factors including upwelling, thermally stratified oceans, and cool or cold currents flowing towards the paleoequator.

CARBONATES, WARM WATER

Sediments composed of calcium carbonate form a large, but not major, part of the world's continental shelf seas and deep ocean basins (Figure C29). The best-known examples of these sediments are coral reefs and white beaches made up of calcareous (CaCO_3) sand grains, typically seen in tropical environments.

What are warm-water carbonate sediments?

Most carbonate sediments are formed from the accumulation of skeletons and shells constructed by marine organisms through the precipitation of calcium carbonate (e.g., corals, mollusks and foraminifera). These are called skeletal, or bioclastic, carbonate sediments. Skeletal carbonates occur in both the warm and the cold waters of the shelf areas in the world (Figure C29). They are most common on continental shelves that are not diluted by large amounts of eroded and transported siliciclastic sediments, as is the case near major river mouths and adjacent to mountainous coastal regions. The composition of skeletal carbonates differs in warm and cool water areas because of the different skeletal organisms that live in these areas. Today's warm or tropical waters are characterized by sea-floor, or benthic, communities of the rapidly calcifying corals and calcareous green algae, together with mollusks, foraminifera, echinoids, bryozoans, etc. Coral reefs today are restricted to waters warmer than 18°C (Kleypas et al., 1999). Other carbonate sediments are formed by the chemical precipitation of crystals of calcium carbonate from seawater, with some authors arguing for a microbial mediation to this process (Riding and Awramik, 2000). Precipitation is favored in the warm, saline waters of some tropical seas and results in spherical, sand-sized grains known as ooids, aggregate grains, peloids and precipitated lime mud (for details, see below). These are labeled as non-skeletal carbonate sediments and are only found in warm-water areas. Lees and Buller (1972) found that modern ooids and grain aggregates form in waters with maximum annual temperatures $>20^\circ\text{C}$ and in waters with salinities greater than 37‰ (parts per thousand). This temperature together with the temperature

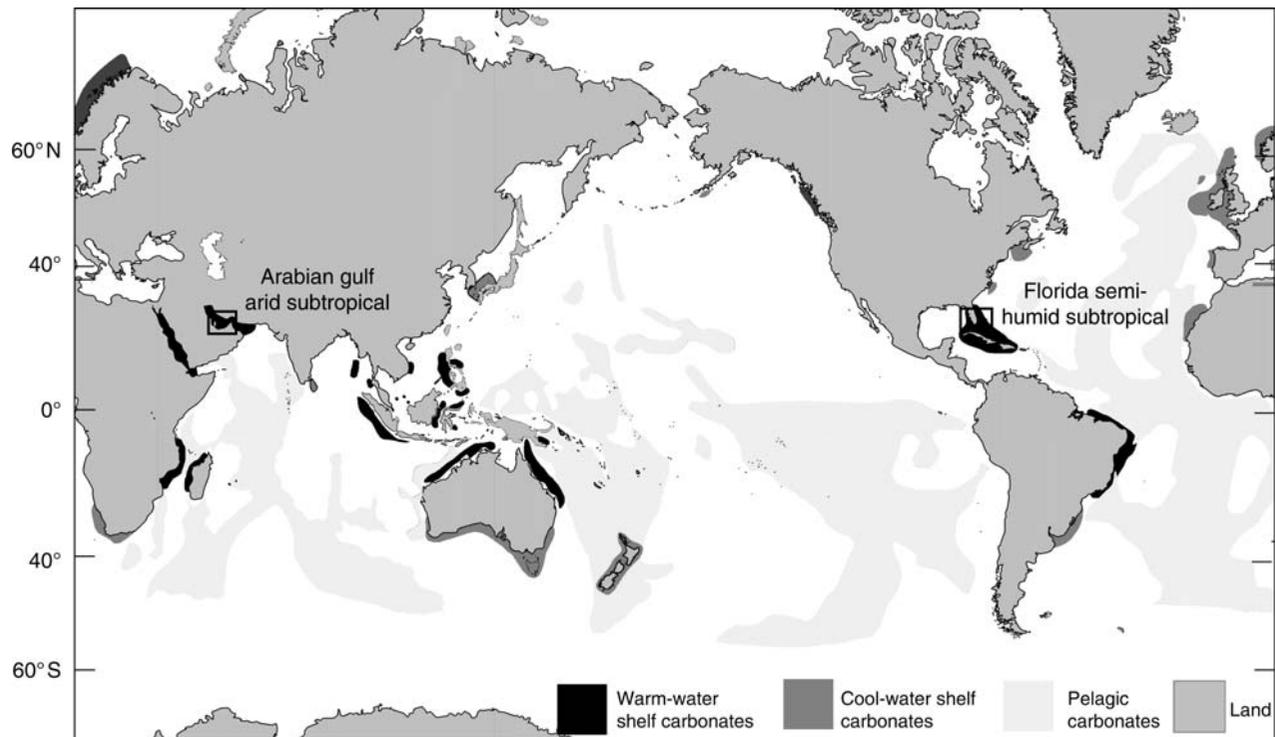

Figure C29 Global distribution of modern carbonate sediments. The two case studies discussed in the text are also located (after Bosence and Wilson, 2003).

restriction for coral reefs (i.e., 18–20°C) may therefore be taken as the boundary between what are regarded as warm (or tropical) and cool (or temperate) water carbonate sediments.

Warm-water carbonates through geological time

The abundance of carbonate rocks formed in marine shelf environments has varied considerably over geological time (Figure C30). Not surprisingly, they were most abundant when global sea levels were high and large areas of continents were flooded by shallow, warm-water, shelf seas. These conditions occurred several times in Earth history, during “greenhouse periods” when there were prolonged periods with no major ice caps covering the polar regions (Figure C30). The types of warm-water organisms that produced skeletal carbonates changed as life evolved, so that late Precambrian, early and late Paleozoic, Mesozoic and Cenozoic bioclastic limestones are quite different in their composition (Figure C30). An independent measure of paleotemperature may be made by analyzing the oxygen isotope ratios of original skeletal calcium carbonate of fossils within bioclastic limestones. Similarly, the mineralogy of ooids also changed through time in tune with greenhouse (low magnesium calcite ooids) and icehouse periods (aragonitic and high magnesium calcite ooids, Figure C30). The abundance of ooids has also changed with time, and possibly with sea-level changes, as peaks are found at times of major

long term sea-level change (Figure C30). Although the mineralogy of ooids has changed through time, and there is still debate as to what controls this (see discussion in Tucker and Wright, 1990), all indications are that ooids still represent ancient environments of increased temperature and increased salinity. The use of non-skeletal marine carbonate grains (such as ooids and grain aggregates) has proven to be more reliable than fossils as a warm-water indicator. This is because the formation of non-skeletal grains is predominantly controlled by the chemical conditions at or near the seafloor and, apart from the changes illustrated in Figure C30, these do not appear to have changed significantly through time. Studies on the nature of warm-water carbonate rocks over the last 650 Ma indicate that the present is not always the key to the past. A 400 Ma warm-water limestone will differ in its preserved biota and ooid mineralogy from its present day equivalent and care has to be taken in undertaking any paleoenvironmental analysis based on carbonate grain types.

Case studies of warm-water carbonate depositional environments; humid versus arid settings

Two case studies of present-day environments accumulating warm-water carbonate sediments are given below. These examples are used extensively in the interpretation of ancient environments as they illustrate the range of different sediment

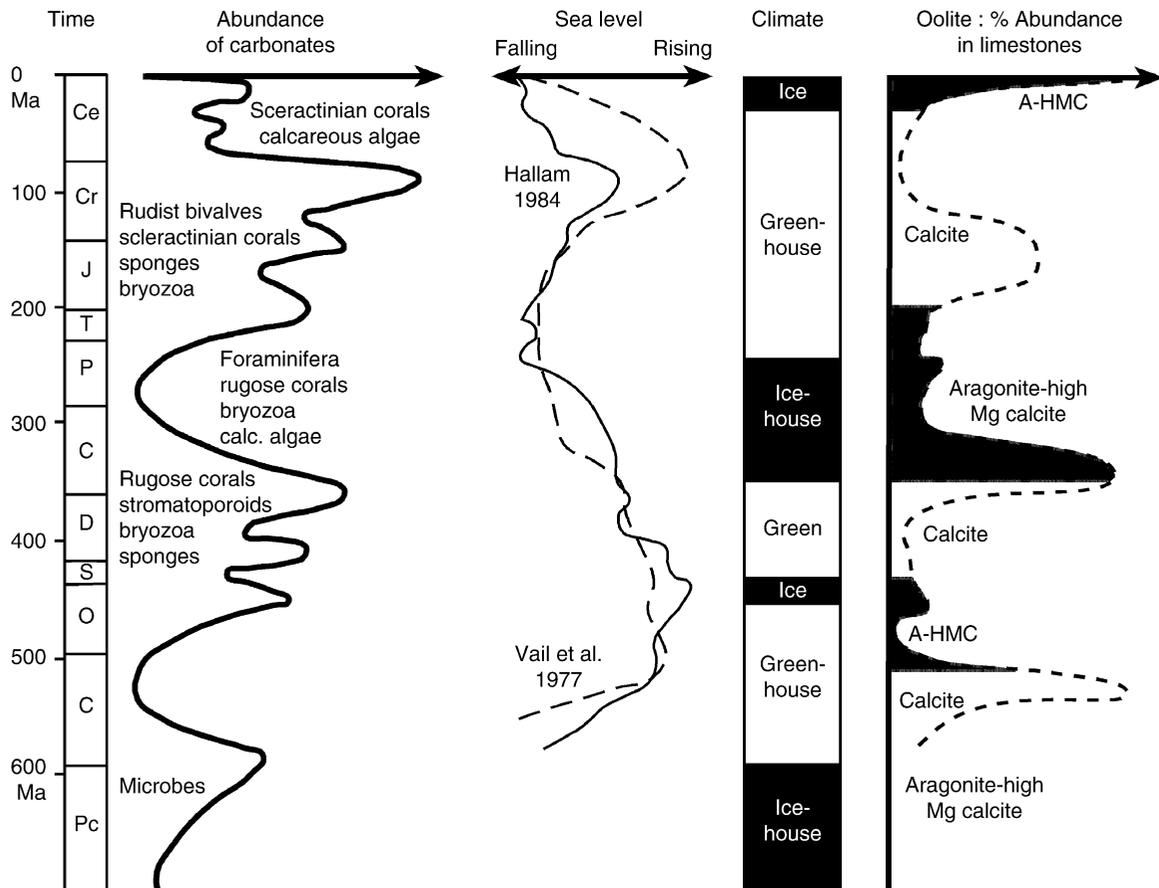

Figure C30 Secular changes in warm-water carbonate grains with respect to sea-level changes and icehouse–greenhouse periods. For details, see text (modified from many studies, for details see Tucker and Wright, 1990; Bosence and Wilson, 2003; Hallam, 1984; Vail et al., 1977).

grains and facies found in warm-water settings. They are both examples of carbonate shelves that are attached to continental areas, as opposed to isolated shelves, banks and atolls that form in offshore settings (for details see Tucker and Wright, 1990). They differ, however, in that South Florida is in a semi-humid subtropical setting and the Arabian Gulf is in an arid climate setting (Figure C29). The climatic setting is seen to have an overriding control on the nature of the sediments, particularly those accumulating in the shallow, nearshore areas.

South Florida

South Florida is a shelf with a large, low-lying hinterland (including the Everglades Swamps) set in a semi-humid, subtropical climate fringed by coastlines stabilized by mangroves (Figure C31a). Warm-water carbonate sediments accumulate throughout this shelf area and deep boreholes in the region show that this has been the case since Jurassic times. The platform comprises four main elements; a semi-enclosed lagoon (known as Florida Bay) that is partially isolated from open-marine waters by a chain of islands (the Florida Keys), a back reef area of normal marine waters that are protected from high

wave-energy by the rimmed margin, the reef and sand shoal margin to the platform, and the forereef slope that descends into the deep waters of the Strait of Florida (Figure C31f).

The semi-humid climate is seasonal, with a wet season from July to December (100–150 cm annual precipitation) when there is runoff of freshwater, reducing salinities in inner parts of Florida Bay to 6‰ (normal marine waters have on average 34–38‰). By contrast, in the warmer conditions of spring and summer, temperatures increase and salinities up to 60‰ are found in the restricted waters of Florida Bay. The reef areas experience normal marine salinities of 35–38‰ and water temperatures varying from 18–30 °C. The region has a very low tidal range, reaching 0.8 m in open-water settings and reducing to zero in the semi-enclosed lagoons of Florida Bay.

Organisms that are fully marine cannot survive in the semi-isolated shallow coastal waters of Florida Bay because of the variable salinities, dissolved oxygen levels and fine carbonate sediment suspended within the bay waters. Seagrass (e.g., *Thalassia*) beds (Figure C31b,e) and the calcareous organisms that encrust the grass blades (foraminifera, serpulid worms and bryozoa) are common, as are other skeletal organisms such

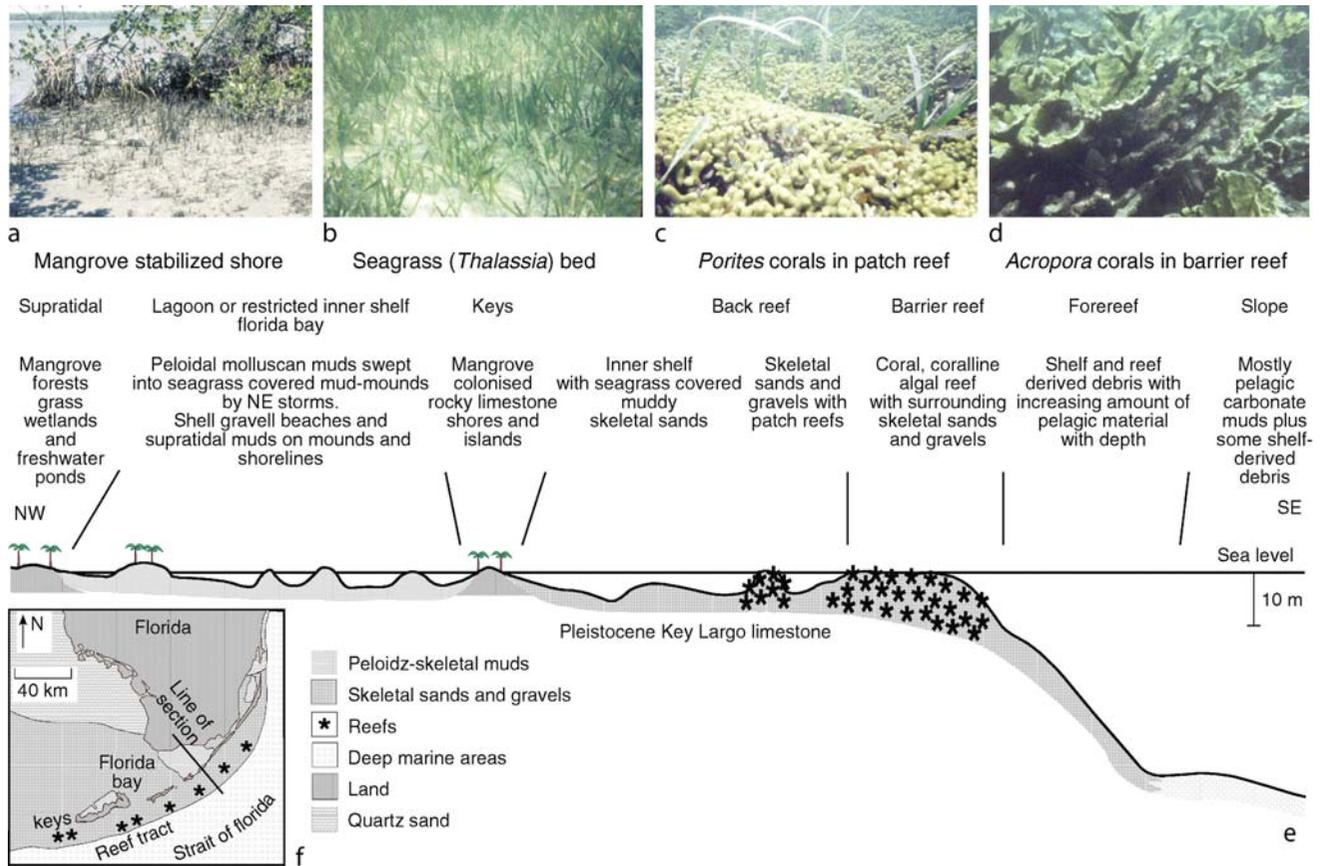

Figure C31 Nature and distribution of sediments in humid subtropical region of South Florida. Photographs (a)–(d) illustrate the control that organisms have on carbonate sediment production and accumulation. (a) Mangrove roots stabilizing the shoreline of Florida Bay (foreground 4 m across). (b) *Thalassia* seagrass bed. The grass leaves (20–30 cm high) act as a substrate for carbonate-secreting organisms whose skeletal debris is trapped and stabilized within the grass beds. (c) *Porites* coral (branches 1 cm across) are common reef builders in the back reef zone. Note also encrusted seagrass blades. (d) The shallow zone of the shelf margin barrier reef is mainly constructed by the elk horn coral, *Acropora palmata* (branches 15–20 cm across). Map and cross section ((e)–(f)) illustrate nature and distribution of sediments discussed in text (after Bosence and Wilson, 2003).

as mollusks, foraminifera and calcareous green algae (*Penicillus* and *Udotea*). When these organisms die, their skeletal debris accumulates as shelly muds that form bioclastic mudstones and wackestones in the geological record (for more details on these sediments, together with carbonate rock terminology, see Tucker and Wright (1990) and Flugel (2004)). Shells are concentrated on beaches and storm ridges as bioclastic gravels and sands. The carbonate mud has the same mineralogical (calcite and aragonite) and geochemical (Ca, Mg and Fe, etc.) composition as the skeletal organisms, which implies that most of the mud is produced from the breakdown of skeletons of algae and benthic invertebrates. Once formed, the mud is reworked by burrowing organisms (mainly shrimps and worms) that digest what they can from the mud and defecate the remainder as sedimentary faecal pellets or peloids.

Back reef areas are of normal marine salinity and more exposed to waves that generate well-oxygenated waters. These conditions favor a more diverse community of carbonate-secreting organisms such as corals, encrusting coralline algae, calcified plate-like green algae (*Halimeda*), mollusks, echinoderms and foraminifera. Corals are not abundant in this environment but they locally form small patch reefs constructed by corals and coralline algae overgrowing each other to form a rigid reef framework (Figure C31c,e). This framework forms an attractive habitat for many other organisms, including those that eat or bore into the coral such as sponges, worms, parrotfish, echinoids and mollusks. The coral debris they generate forms much of the skeletal carbonate sand and gravel that accumulates around the patch reefs. These, if lithified, will form skeletal or bioclastic packstones or grainstones in the geological record.

The rimmed margin of this platform comprises a barrier reef (because the reefs are detached from the shoreline and act as a barrier to the back reef and lagoonal areas inshore of them) with intervening high-energy, shallow-water shoals of coarse skeletal sand and gravel. These breaks in the arc of reefs are probably due to the fact that Florida is near the northernmost limit of both reef growth and warm-water carbonates (Figure C29). The shallowest zone of the reefs is formed by the branching coral *Acropora palmata* (Figure C31d,e), and by some round shaped (or head) corals and encrusting coralline algae. Deeper down the ocean-facing front of the reef, more massive and rounded coral growth forms are found that give way to deeper-water, flattened or plate-shaped corals. Lower areas of this fore reef slope are characterized by coarse-grained reef talus deposits formed of broken and bioeroded debris from the reef. Similar reef morphologies and coral zones are preserved in ancient reef limestones where they are called coral boundstones and are composed mainly of fossil corals. Reef corals are one of the most unequivocal biogenic indicators of warm, shallow-water conditions in the Cenozoic and Mesozoic.

Arabian Gulf

The southern coast of the Arabian (or Persian) Gulf offshore from the Gulf Coast States (Abu Dhabi, Dubai and Qatar) slopes gradually from the low relief desert of the coastal plain, through the coastal waters and down to a maximum depth of about 100 m over a distance of a couple of hundred kilometers (Figure C32). This gently sloping shelf morphology is the distinctive feature of what is known as a carbonate ramp. The shelf has no major reef systems or rimmed shelf margins as

are found in South Florida. The prevailing winds blow onshore from the northwest, which make this a storm-wave dominated coastline (Figure C32f). Due to the restricted opening to the Indian Ocean through the Strait of Hormuz and the arid climate setting, salinities in the Gulf are elevated to 40–45‰ and temperatures range annually from 20 to 34 °C. Details of the region and its sediments are given in Purser (1973).

Wave-base, the water depth at which wave-generated currents affect the sea floor, has an important control on sediment texture in gently sloping ramps and is used to subdivide ramps into zones (Figure C32e). In the Gulf, the outer ramp areas (below storm wave base) accumulate muds with a mixed composition (called marl); these are partly carbonate, of pelagic origin, and partly siliciclastic mud brought into the Gulf by rivers. These marls pass up-slope to the south into muddy and then clean skeletal and oolitic sands at the fair-weather wave base at around 10–20 m (Figure C32e, f). Moderate energy waters characterize this windward facing shore and hence areas of clean skeletal sand are found in inner ramp environments. These sands are commonly cemented at or just below the sea-floor to produce extensive hardgrounds, another feature of warm-water carbonates. Small patch reefs (Figure C32d) occur but with a low diversity coral fauna because of the elevated salinities and sometimes low winter temperatures.

The inner ramp in the Abu Dhabi area, prior to the extensive coastal developments of today, used to be dominated by ooid barrier beaches (with minor skeletal grains and peloids) (Figure C32c). Aragonitic ooids are precipitated in the relatively high salinity marine waters that have a moderate tidal and wave energy regime. Ooid barrier islands are situated up to 20 km away from the shoreline and broad, shallow lagoons have developed behind the barriers (Figure C32c). The lagoons have elevated salinities of 40–50‰ and so have a reduced diversity of marine faunas, comprising gastropods and ostracods that occur in lime muds and peloidal muddy sands. The lime muds are aragonitic and both the absence of calcified green algae (like those present in South Florida) and geochemical evidence from the lagoon waters and the deposited muds indicate that these muds were precipitated chemically within the lagoon (Kinsman and Holland, 1969) rather than having a skeletal origin such as those of Florida Bay.

The sabkhas are broad, saline, intertidal areas and coastal plains (Figures C32a, b, e, f) that may be flooded by lagoon waters during storms and high tides. The sabkhas have extensive microbial populations that alternate with sediment-rich layers to form stromatolites (Figure C32a, b). High aridity in the area leads to a net evaporation of floodwaters, and saline groundwaters in the sabkha, which results in the precipitation of evaporite minerals such as dolomite, gypsum and anhydrite.

Summary

From this review it can be seen that warm-water (>18–20 °C) continental shelf seas today have extensive areas of carbonate sediment accumulation. This, together with their relatively rapid accumulation rates, explains why limestones that deposited in warm-water shelf environments form the commonest types of limestone in the geological record. Warm-water carbonates have distinctive assemblages of component grains, both skeletal and non-skeletal in origin. However, these vary back through geological time so that the present is not always the key to the past and care must be taken with paleoclimatic and paleoenvironmental interpretations based on grain occurrences.

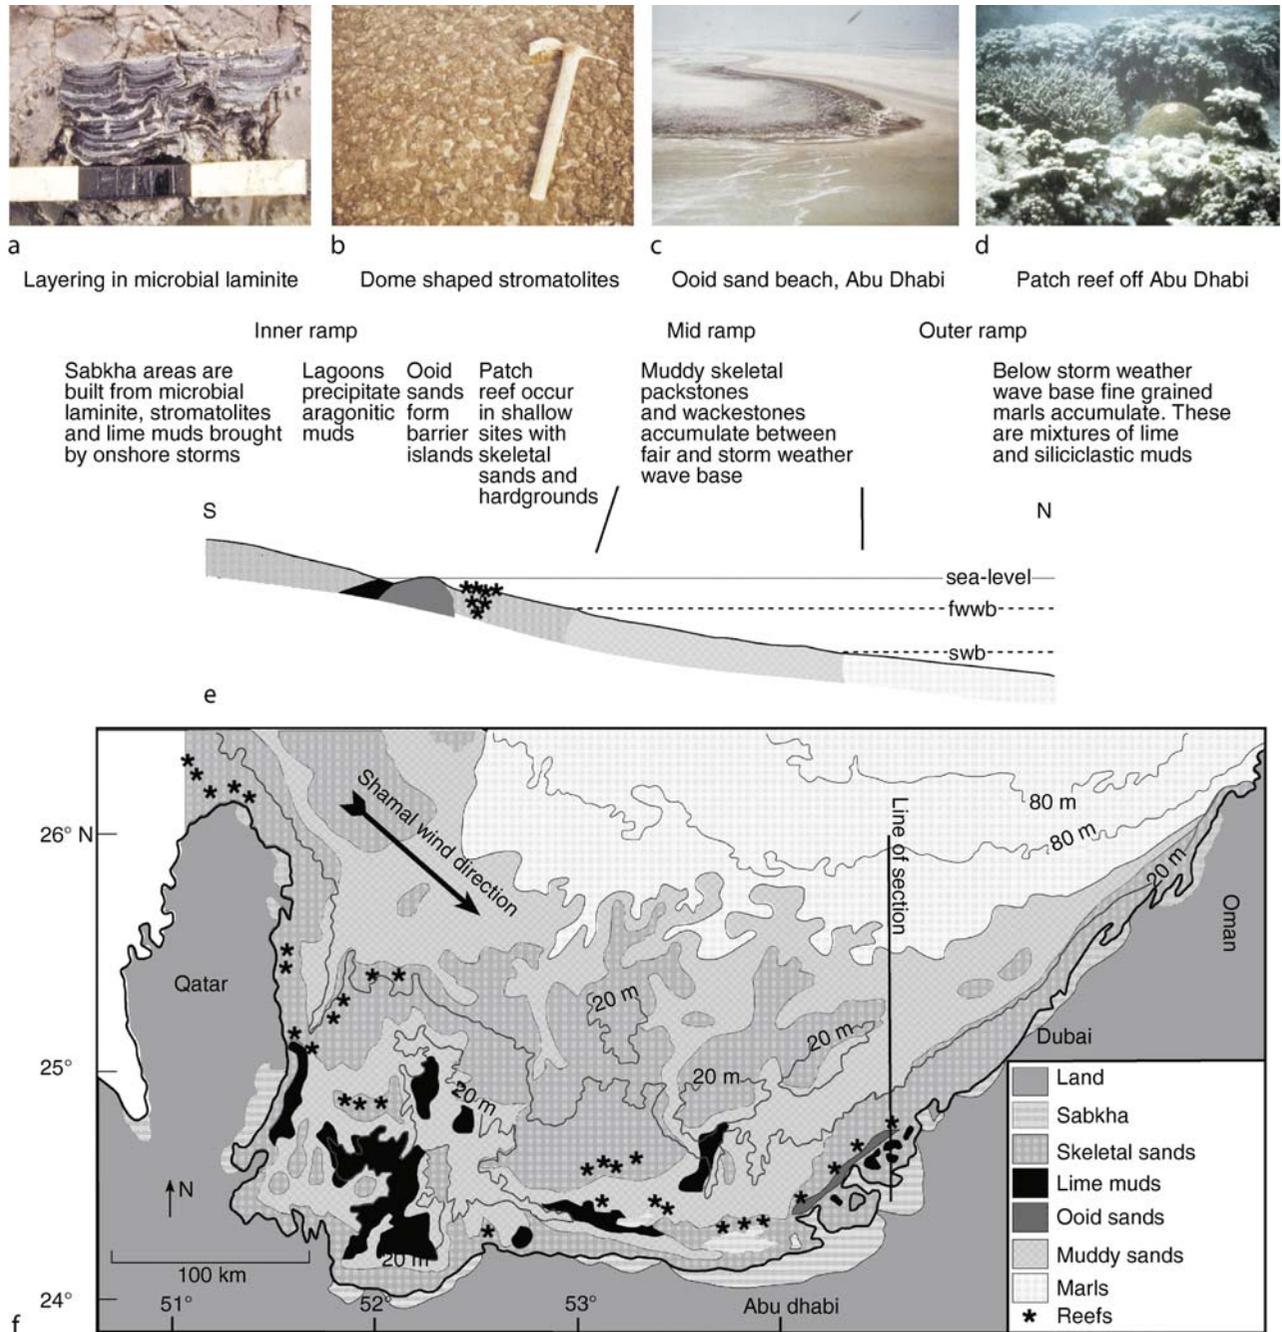

Figure C32 Nature and distribution of sediments in arid subtropical region of the Arabian Gulf. (a) Intertidal flats showing alternating microbial (dark) and sediment (light) layers: white patches within layering are precipitates of the calcium sulfate salt, anhydrite (scale in inches). (b) Dome-shaped stromatolites in intertidal sabkha. These result from upward growth of microbial mats and sediment with lighter colored sediment accumulating between domes. (c) Ooid sand beaches occur on barrier islands on the Abu Dhabi coast. Dark area by waters edge is microbial mat. (d) Patch reefs offshore from the barrier islands have a low diversity compared with reefs of the nearby Indian Ocean because of the high salinity of the Gulf waters. Map and cross-section ((e), (f)) of southeastern margin of the Arabian Gulf illustrate depth-related sediment types on carbonate ramp. Note change in sediment type with storm wave base (swb) and fairweather wave base (fwwb) (modified from Bosence and Wilson, 2003).

The two case studies of warm-water carbonate depositional systems illustrate the range of sedimentary grain types and sedimentary facies found in such environments today and explain how these are controlled by their climatic setting.

Studies such as these provide the raw data for interpretation of warm-water carbonates in the geological record.

CENOZOIC CLIMATE CHANGE

The Cenozoic Era, or the last 65 million years, is a contrast of two worlds. Climates during the first 15 million years of the Cenozoic were generally warm and the Earth could be characterized as a greenhouse world. Fossil remains of early Eocene age (ca. 50 Ma) alligators found on Ellesmere Island (75°–80° N) contrast sharply with the polar climates that exist there today. This is not an isolated discovery or quirk of nature. An ever-growing body of faunal, floral, and geochemical evidence shows that the beginning of the Cenozoic Era was much warmer than the present time. What maintained such a warm climate and could it be an analog for future global warming? How did we go from the warm, greenhouse conditions to the cold poles that characterize today's world? To address these and other questions, it is necessary to consider more than a qualitative estimate of planetary temperatures. Quantitative temperature estimates (both magnitudes and rates of change) are required to depict how the Earth's climate has changed through time. One of the most powerful tools used to reconstruct past climates during the Cenozoic Era is the analysis of oxygen isotopes in the fossil shells of marine organisms. The calcium carbonate shells of the protist foraminifera are the most often analyzed organisms because the different species are distributed throughout surface (planktonic) and deep (benthic) marine environments.

Oxygen isotopes as a paleothermometer

The stable isotopes of oxygen used in paleoceanographic reconstructions are ¹⁶O and ¹⁸O. During the 1940s, Harold Urey at the University of Chicago predicted that the ¹⁸O/¹⁶O ratio in calcite (CaCO₃) should vary as a function of the temperature at which the mineral precipitated. His prediction spurred on experiments by himself and others at the University of Chicago, where they measured ¹⁸O/¹⁶O ratios in CaCO₃ precipitated in a wide range of temperatures, leading to the development of a paleotemperature equation based on oxygen isotopes.

The temperature during the precipitation of calcite can be estimated by measuring the δ¹⁸O value in calcite-secreting organisms (foraminifera, corals, and mollusks) and the δ¹⁸O value of the water in which the organisms live. The various paleotemperature equations all follow the original proposed by Sam Epstein and his colleagues (University of Chicago):

$$T = 16.5 - 4.3 \times (\delta^{18}O_{\text{calcite}} - \delta^{18}O_{\text{water}}) + 0.14 \times (\delta^{18}O_{\text{calcite}} - \delta^{18}O_{\text{water}})^2 \quad (1)$$

where T and $\delta^{18}O_{\text{water}}$ are the temperature (°C) and oxygen isotope value of the water in which the organism lived, and $\delta^{18}O_{\text{calcite}}$ is the oxygen isotope value of calcite measured in the mass spectrometer.

Equation 1 shows that the changes in $\delta^{18}O_{\text{calcite}}$ are a function of the water temperature and $\delta^{18}O_{\text{water}}$ value. A one-to-one relationship between $\delta^{18}O_{\text{calcite}}$ and $\delta^{18}O_{\text{water}}$ values dictates that a change in the $\delta^{18}O_{\text{water}}$ term will cause the exact change in the measured $\delta^{18}O_{\text{calcite}}$ value. However, an inverse relationship between $\delta^{18}O_{\text{calcite}}$ and T changes dictates that for every 1 °C increase in temperature, there is a 0.23‰ decrease in the measured $\delta^{18}O_{\text{calcite}}$ value. These relationships enable us to interpret $\delta^{18}O_{\text{calcite}}$ changes generated from foraminifera, corals, and mollusks. Most researchers follow a convention that plots $\delta^{18}O_{\text{calcite}}$ values with the axis reversed (higher values to the left or bottom) so that $\delta^{18}O$ records mimic temperature changes (e.g., colder to the left or bottom).

Temporal variations

Variations in the amount of water stored on land through time, usually in the form of ice, can have a significant effect on the mean ocean $\delta^{18}O_{\text{water}}$ value, and hence, the marine $\delta^{18}O_{\text{calcite}}$ record. At present, high-latitude precipitation returns to the oceans through summer ice/snow melting. During glacial periods, snow and ice accumulate into large ice sheets. Because the difference in ice sheet and mean ocean values is large ($\delta^{18}O_{\text{ice}} = -35$ to -40 ‰ vs. $\delta^{18}O_{\text{water}}$ mean ocean = ~ 0 ‰), ice sheet fluctuations are reflected in mean oceanic $\delta^{18}O_{\text{water}}$ values. This relationship can be illustrated by examining how the mean ocean $\delta^{18}O_{\text{water}}$ value increased during the Last Glacial Maximum (LGM) relative to the present (Figure C33). During the LGM, water stored in continental ice lowered global sea level by 120 m, removing $\sim 3\%$ of the ocean's volume. Thus, the mean ocean $\delta^{18}O_{\text{water}}$ value increased by 1.2‰ during the LGM relative to the present (Figure C33; the marine $\delta^{18}O_{\text{calcite}}$ record is also affected by mean ocean temperature).

Cenozoic δ¹⁸O records

The first Cenozoic $\delta^{18}O$ syntheses based on foraminiferal $\delta^{18}O$ records were produced during the mid-1970s. Nicholas Shackleton and James Kennett produced a composite benthic

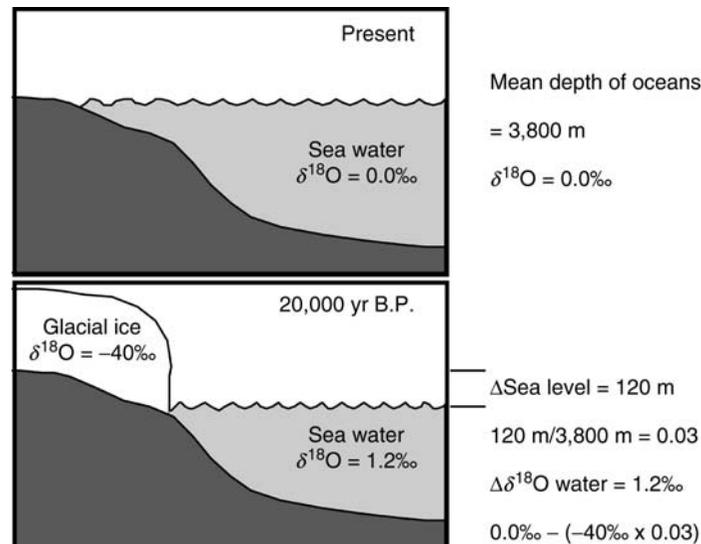

Figure C33 The growth and shrinkage of large ice sheets can have a significant effect on the $\delta^{18}\text{O}$ composition of the ocean. Removal of 3% of the ocean's water during the Last Glacial Maximum lowered sea level by 120 m. The $\delta^{18}\text{O}$ difference between the ocean and the ice is 40‰, causing a whole ocean $\delta^{18}\text{O}$ change of 1.2‰. The reverse process occurs during the melting of large ice sheets. If the Antarctic and Greenland ice were to melt, then sea level would rise ~ 70 m. The volume of water stored in these ice sheets is equivalent to $\sim 2\%$ of the water in the ocean. Therefore, the mean $\delta^{18}\text{O}$ value of the ocean would decrease by 0.7–0.8‰.

$\delta^{18}\text{O}$ record for the Cenozoic using cores from a region to the south of Australia. A second group led by Samuel Savin generated low-latitude planktonic and benthic foraminiferal $\delta^{18}\text{O}$ syntheses. Both records are important in understanding Cenozoic climate changes. Benthic foraminiferal records best reflect global temperature and ice volume changes. Additional advantages of the benthic foraminiferal composite include the following: (a) deep-ocean temperatures are more uniform than surface water with respect to horizontal and vertical gradients; (b) deep ocean $\delta^{18}\text{O}_{\text{water}}$ values are less variable than large surface water changes; (c) the deep ocean approximates high-latitude surface water conditions from which deep waters originated during the Cenozoic (i.e., Antarctica, northern North Atlantic); and (d) many benthic foraminiferal taxa are long-lived, therefore one species can be used to construct records spanning several millions of years, in contrast to planktonic taxa, which have shorter durations, such that records have to be spliced together from several species.

Low-latitude planktonic foraminiferal $\delta^{18}\text{O}$ records are good proxies for tropical sea-surface temperatures. Tropical temperatures are an important component of the climate system because they influence evaporation, and hence, total moisture in the atmosphere. A comparison of planktonic and benthic foraminiferal $\delta^{18}\text{O}$ values allows assessment of equator-to-pole as well as vertical temperature gradients during the Cenozoic, and thus, determination of planetary temperature changes. Much of the climatic change in the last 65 million years has been ascribed to poleward heat transport or greenhouse gas fluctuations. General circulation models indicate that each mechanism would produce different temperature patterns that can be validated using the planktonic and benthic $\delta^{18}\text{O}$ records.

The first benthic $\delta^{18}\text{O}$ syntheses generated, as well as more recent compilations, show the same long-term patterns. After the Cretaceous-Tertiary (K/T) boundary event, deep-water $\delta^{18}\text{O}$ values remained relatively constant for the first 7 million years of the Paleocene (Figure C34a). At 58 million years (Ma)

ago, benthic foraminiferal $\delta^{18}\text{O}$ values began a decrease over the next 6 Myr, which culminated during the early Eocene with the lowest recorded value (-0.5‰) of the Cenozoic. Following this minimum at 52 Ma, $\delta^{18}\text{O}$ values increased by 5.5‰, with maximum values ($\sim 5\text{‰}$) occurring during the glacial intervals of the Pleistocene. The first part of this long-term change was a gradual increase of 2‰ through the end of the Eocene (52–34 Ma). The remainder of the increase was accomplished through large steps at the Eocene/Oligocene boundary (~ 33.5 Ma), during the middle Miocene (ca. 15–13 Ma), and late Pliocene (ca. 3.2–2.6 Ma). After 2.6 Ma, the amplitude of the high-frequency signal increased to $>1\text{‰}$, reaching 1.8‰ over the past 800 thousand years.

Planktonic and benthic foraminiferal $\delta^{18}\text{O}$ values co-varied in general during the early Cenozoic (65–34 Ma). Planktonic values averaged about -1‰ between 65 and 58 Ma, before decreasing to -2.5‰ during the early Eocene, which were the lowest values of the Cenozoic (Figure C34a). From 52 to 33 Ma, planktonic foraminiferal values increased by 2‰. In spite of a break in the latest Eocene record, it appears that the tropical ocean differed from the deep ocean across the Eocene/Oligocene boundary. For much of the Oligocene (~ 33 –25 Ma), planktonic foraminiferal $\delta^{18}\text{O}$ values remained unusually high, averaging -0.5‰ . Beginning around the Oligocene/Miocene boundary (~ 25 Ma), planktonic foraminiferal $\delta^{18}\text{O}$ values began a long-term decrease, culminating in the Pleistocene, with average values of -1.5‰ . In contrast, the benthic $\delta^{18}\text{O}$ record permanently changed during the middle Miocene $\delta^{18}\text{O}$ shift and late Pliocene increase.

Apportioning the $\delta^{18}\text{O}$ changes recorded by the benthic and planktonic foraminifera between temperature and ice volume changes requires knowledge of or reasonable estimates for one of these parameters. One promising tool that may help discriminate between each effect is the Mg/Ca ratio measured in benthic foraminifera. Initial studies by a group at Cambridge University using Mg/Ca ratios confirmed the

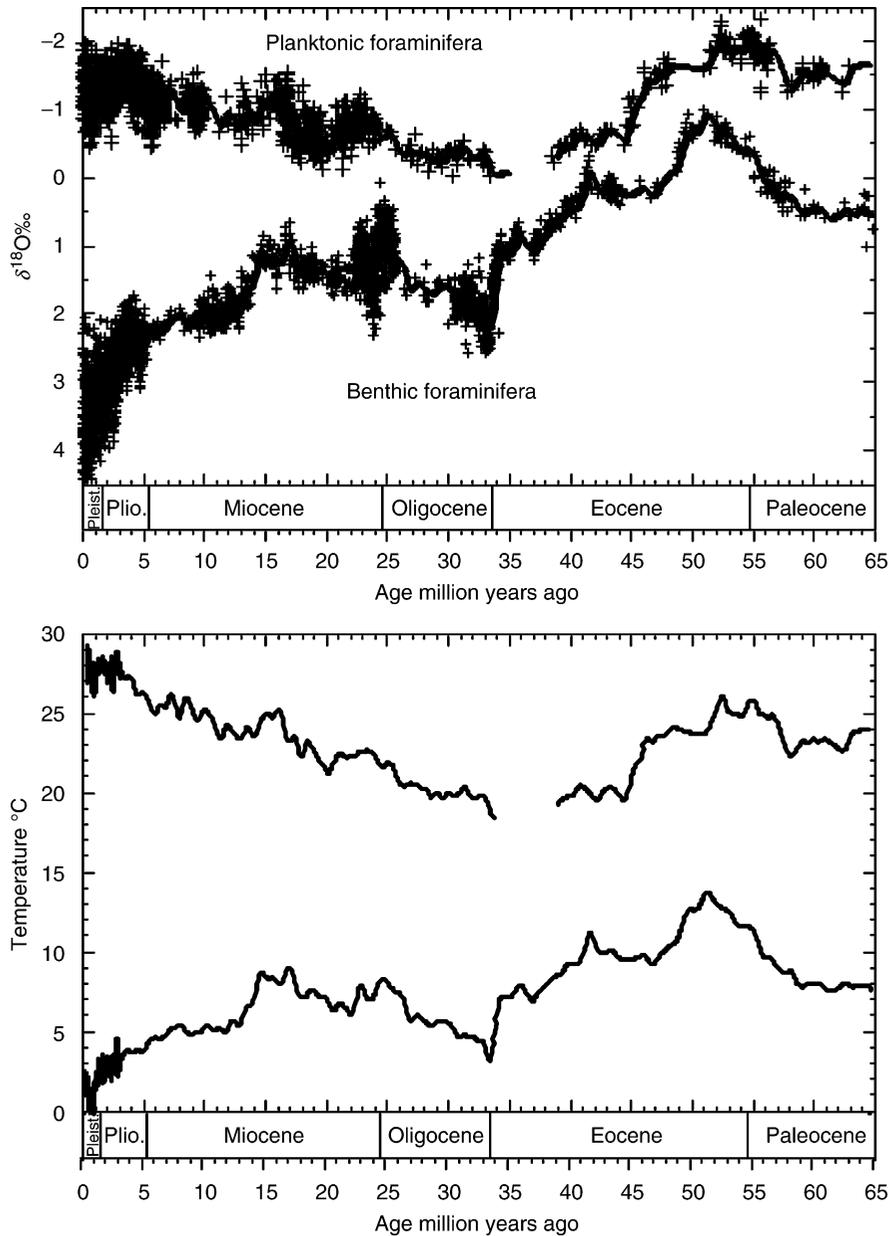

Figure C34 Planktonic and benthic foraminiferal $\delta^{18}\text{O}$ composite records, representing the tropical surface and deep ocean conditions. The *thick line* through both records was generated using a 1 million year Gaussian filter. Temperature estimates based on planktonic and benthic records and ice volume estimates discussed in the text are shown in (b).

long-term temperature changes during the Cenozoic that were calculated using the $\delta^{18}\text{O}$ record and other climate proxies. If verified, this record implies that small ice sheets grew during the middle and late Eocene and fluctuated in size throughout the Oligocene to Miocene. At present, the Mg/Ca record lacks the resolution for key intervals and still requires verification of interspecies offsets before it can be applied unequivocally to isolate the ice volume-induced $\delta^{18}\text{O}_{\text{water}}$ component in the foraminiferal $\delta^{18}\text{O}$ records. For the discussion that follows, glaciological evidence is used to estimate the ice volume/ $\delta^{18}\text{O}_{\text{water}}$ variations.

The greenhouse world

The oldest unequivocal evidence for ice sheets on Antarctica, ice-rafted detritus (IRD) deposited by icebergs in the ocean, places the first large ice sheet in the latest Eocene or earliest Oligocene. Thus, it is reasonable to assume that ice sheets were small to absent and that surface and deep-water temperature changes controlled much if not all of the $\delta^{18}\text{O}$ change prior to 34 Ma. The modern Antarctic and Greenland ice sheets lock up $\sim 2\%$ of the total water in the world's ocean. If melted, these ice sheets would raise global sea level by $\sim 70\text{--}75$ m and mean

ocean $\delta^{18}\text{O}_{\text{water}}$ value would decrease to -0.9‰ PDB. One can then apply Equation 1 to the benthic and planktonic foraminiferal $\delta^{18}\text{O}$ records to estimate deep- and surface-ocean temperatures for the first half of the Cenozoic (ca. 65–34 Ma).

During the early to middle Paleocene, deep-water temperatures remained close to 10°C (Figure C34b). The 1‰ decrease between 58 and 52 Ma translates into a deep-water warming of 4°C , reaching a high of 14°C . This is in sharp contrast to modern deep-water temperatures, which range between 0 and 3°C . Following the peak warmth at 52 Ma, the $\sim 2\text{‰}$ increase in benthic foraminiferal values indicates that the deep waters cooled by 7°C and were 7°C by the end of the Eocene. If small ice sheets existed during the Paleocene and Eocene, then temperature estimates would be on the order of 1°C warmer than those calculated for the ice-free assumption.¹

Tropical surface water temperatures warmed from 22 to 24°C , based on Equation 1, at the beginning of the Cenozoic to 28°C during the early Eocene (52 Ma; Figure C34b). The higher estimate is similar to temperatures in the equatorial regions of the modern oceans. Planktonic foraminiferal $\delta^{18}\text{O}$ values recorded a long-term increase of 2‰ (-2.5 to -0.5‰) through the remainder of the Eocene. Just prior to the Eocene/Oligocene boundary, tropical surface water temperatures were $\sim 21^\circ\text{C}$, ending the long-term tropical cooling of 7°C from 52 to 34 Ma.

The icehouse world of the last 33 million years

As mentioned above, southern ocean cores contain IRD at and above the Eocene/Oligocene boundary. Widely distributed IRD and glacial tills on parts of the Antarctic continental margin that represent the period from Oligocene to Recent mark the onset of large ice sheets. Whether these sediments represent persistent or periodic ice cover is uncertain. At least some ice was present on Antarctica during the Oligocene to early Miocene. Glaciological studies show that Antarctic ice sheet has been a fixture since the middle Miocene (~ 15 Ma). Our record of Northern Hemisphere ice sheets suggests that they were small or non-existent prior to the late Pliocene. For the purpose of estimating surface and deep temperatures, an ice volume estimate slightly lower than the modern ice volume will be applied for the interval that spans from the Oligocene into the middle Miocene (33–15 Ma). For the interval between 15 and 3 Ma, average ice volumes were probably similar to today's ice sheets. From 3 Ma, ice volumes varied between the modern and LGM. Using these broad estimates for ice volumes, mean ocean $\delta^{18}\text{O}_{\text{water}}$ values for those three intervals were -0.5 , -0.22 , and 0.4‰ PDB, respectively. The 0.4‰ estimate reflects the average between the maximum and minimum conditions during the Plio-Pleistocene. As discussed below, the largest portion of the high frequency signal is controlled by ice volume changes.

The benthic foraminiferal $\delta^{18}\text{O}$ increase at the Eocene/Oligocene boundary occurred rapidly (~ 100 kyr; Figure C35a). At the peak of the Eocene/Oligocene boundary event, benthic foraminifera recorded $\delta^{18}\text{O}$ values similar to modern values. Using the ice volume assumption from above, deep-water temperatures approached modern deep-ocean temperatures (3°C). This marks an important transition from the relatively warm

oceans of the Paleocene and Eocene to the cold deep waters of the Oligocene to present. This switch to a cold ocean where bottom waters formed at near-freezing temperatures heralded the development of the psychrosphere, where warm surface waters are found above the cold deep waters. Following the Eocene/Oligocene boundary, deepwater temperatures began a long-term warming over the next 18 million years (33–15 Ma). The coldest deep-water temperatures of 3°C were recorded at 33 Ma, while temperatures reached 9°C at ~ 25 and ~ 15 Ma (Figure C34b).

There is a gap in the planktonic foraminiferal $\delta^{18}\text{O}$ record for the latest Eocene that hampers our assessment of the tropical response during the Eocene/Oligocene climate event. However, it is clear from the data that do exist that the planktonic response across the Eocene/Oligocene boundary differed from the benthic response. The planktonic foraminiferal $\delta^{18}\text{O}$ values for the early Oligocene are similar to late Eocene values, whereas there was a 1.5‰ increase in benthic values. Planktonic foraminiferal records from other regions that span the Eocene/Oligocene boundary indicate that the surface water $\delta^{18}\text{O}$ increase was on the order of 0.5‰ . This change is approximately equal to the effect of the modern Antarctic ice sheet. Combined with the physical evidence, it seems probable that the planktonic foraminiferal $\delta^{18}\text{O}$ increase at the Eocene/Oligocene boundary recorded the ice volume influence with little temperature effect. Therefore, tropical surface temperatures remained around 22°C while the deep ocean cooled during this $\delta^{18}\text{O}$ shift. Following the boundary event, planktonic foraminifera $\delta^{18}\text{O}$ record during the Oligocene and early Miocene mirrored the benthic record in many respects. For much of the Oligocene and early Miocene, the absolute values were close to -0.5‰ , which translates into a temperature estimate of 21°C (Figure C34b). By 15 Ma, tropical surface waters had warmed to 26°C .

The middle Miocene $\delta^{18}\text{O}$ shift represents an increase of 1.5‰ in the benthic record between 15 and 13 Ma. This transition is composed of two sharp increases around 14 and 13 Ma (Figure C35b). These $\delta^{18}\text{O}$ steps occurred in less than 200 thousand years with each showing an increase of $\sim 1\text{‰}$ followed by a small decrease. During these two shifts, deepwaters cooled from 9 – 5°C . The planktonic foraminiferal $\delta^{18}\text{O}$ record from 15 to 13 Ma shows two increases as recorded in the benthic foraminiferal record (Figure C34). However, it does not show the large permanent shift recorded by the benthic foraminifera, indicating a small cooling from 26 to 24°C . From 13 to 3 Ma, the deep ocean cooled slightly from 5 to 3°C while the surface waters warmed from 24 to 26°C (Figure C34b).

The last of the large $\delta^{18}\text{O}$ steps in the Cenozoic was recorded during the late Pliocene from 3.2 to 2.6 Ma. This "step" is better characterized as a series of $\delta^{18}\text{O}$ cycles with increasing amplitudes and values over this interval (Figure C35c). The cycles have been subsequently determined to be 40 kyr obliquity cycles related to variations in the solar radiation received at high latitudes. This interval ushered in the growth of large-scale Northern Hemisphere ice sheets that have since dominated Earth's climate. At 2.6 Ma, the first ice-rafted detritus was deposited in the open North Atlantic and was coeval with the $\delta^{18}\text{O}$ maximum. Prior to 2.6 Ma, IRD was confined to the marginal basins to the north: Greenland and Iceland's continental margins. Subsequent $\delta^{18}\text{O}$ maxima were associated with ice-rafted detritus. Between 2.6 and 1 Ma, large Northern Hemisphere ice sheets waxed and waned on a 40 kyr beat.

¹Some data indicate that smaller ice sheets may have existed on the inland parts of Antarctica during the late Eocene. However, these were not large enough to deposit ice rafted detritus in the ocean. Therefore, their effect on the $\delta^{18}\text{O}$ values of the ocean was probably less than 0.3‰ .

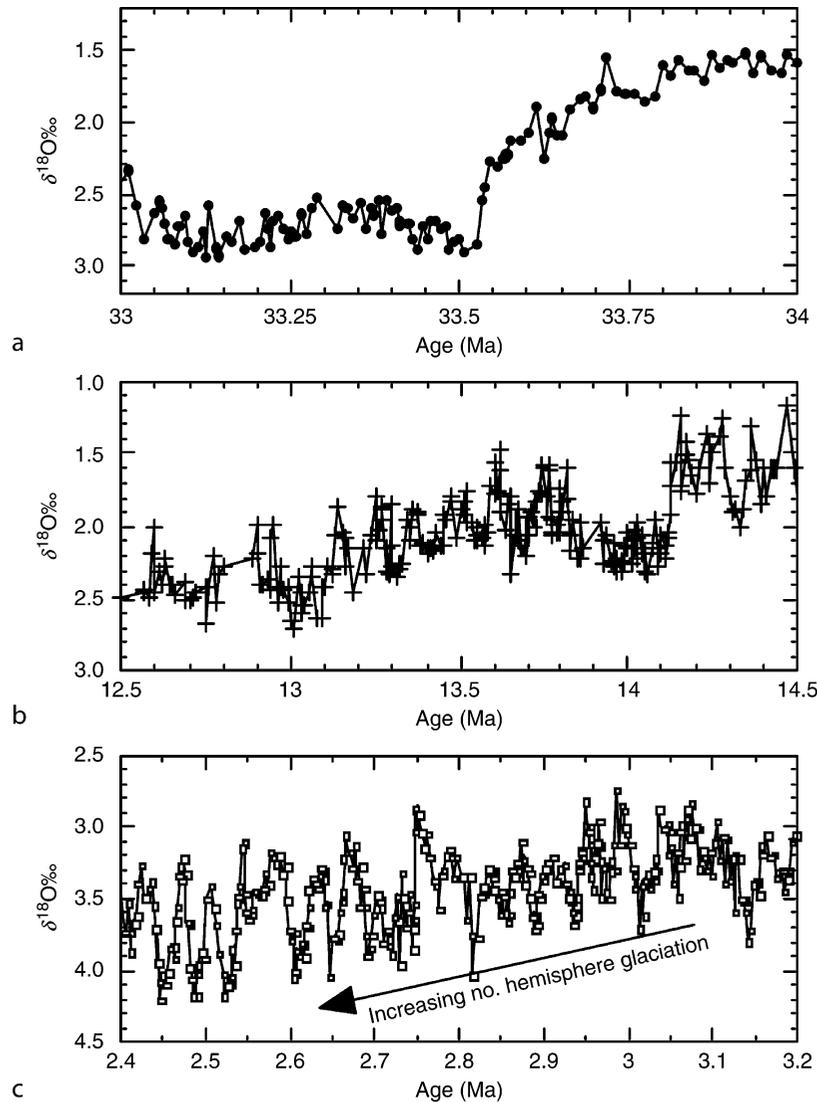

Figure C35 High-resolution $\delta^{18}\text{O}$ records representing the Eocene/Oligocene boundary (a), middle Miocene (b), and late Pliocene (c) $\delta^{18}\text{O}$ shifts.

Beginning around 1 Ma, the ice sheets increased in size and switched to a 100 kyr beat (Figure C36). During this interval, deep-water temperatures remained similar to those in the modern ocean (0–3 °C).

The planktonic foraminiferal $\delta^{18}\text{O}$ response during the late Pliocene event shows the cyclic behavior, but not the overall increase recorded by the benthic foraminifera. As with the middle Miocene $\delta^{18}\text{O}$ shift, the late Pliocene increase represents the cyclic build up of ice sheets accompanied by deep-water cooling. The tropical surface water temperatures, however, varied between 26 and 28 °C.

Pleistocene oxygen isotope variations

The first systematic downcore examination of the marine stable isotope record was made by Cesare Emiliani during the 1950s on $\delta^{18}\text{O}_{\text{calcite}}$ records generated from planktonic foraminifera in Caribbean deep-sea cores. Emiliani recognized the cyclic

pattern of low and high $\delta^{18}\text{O}_{\text{calcite}}$ values and concluded that these represented glacial-interglacial intervals. Emiliani identified the seven most recent climate cycles and estimated that they spanned the last 280,000 years.² To apply the paleotemperature equation to these records, Emiliani estimated that ice sheet induced ocean $\delta^{18}\text{O}_{\text{water}}$ variability was relatively small, 0.3‰.³ Therefore, most of the $\delta^{18}\text{O}_{\text{calcite}}$ variability between glacial and interglacial intervals represented temperature changes of 5–10 °C. Emiliani divided the $\delta^{18}\text{O}_{\text{calcite}}$ record into warm stages (designated with odd numbers counting down from the Holocene) and cold stages (even numbers). Hence, “Isotope Stage 1” refers to the present interglacial interval and “Isotope

²Current age estimates indicate that the duration of the cycles is approximately 525,000 years.

³As shown above, the maximum glacial – interglacial ice sheet signal was closer to 1.2‰.

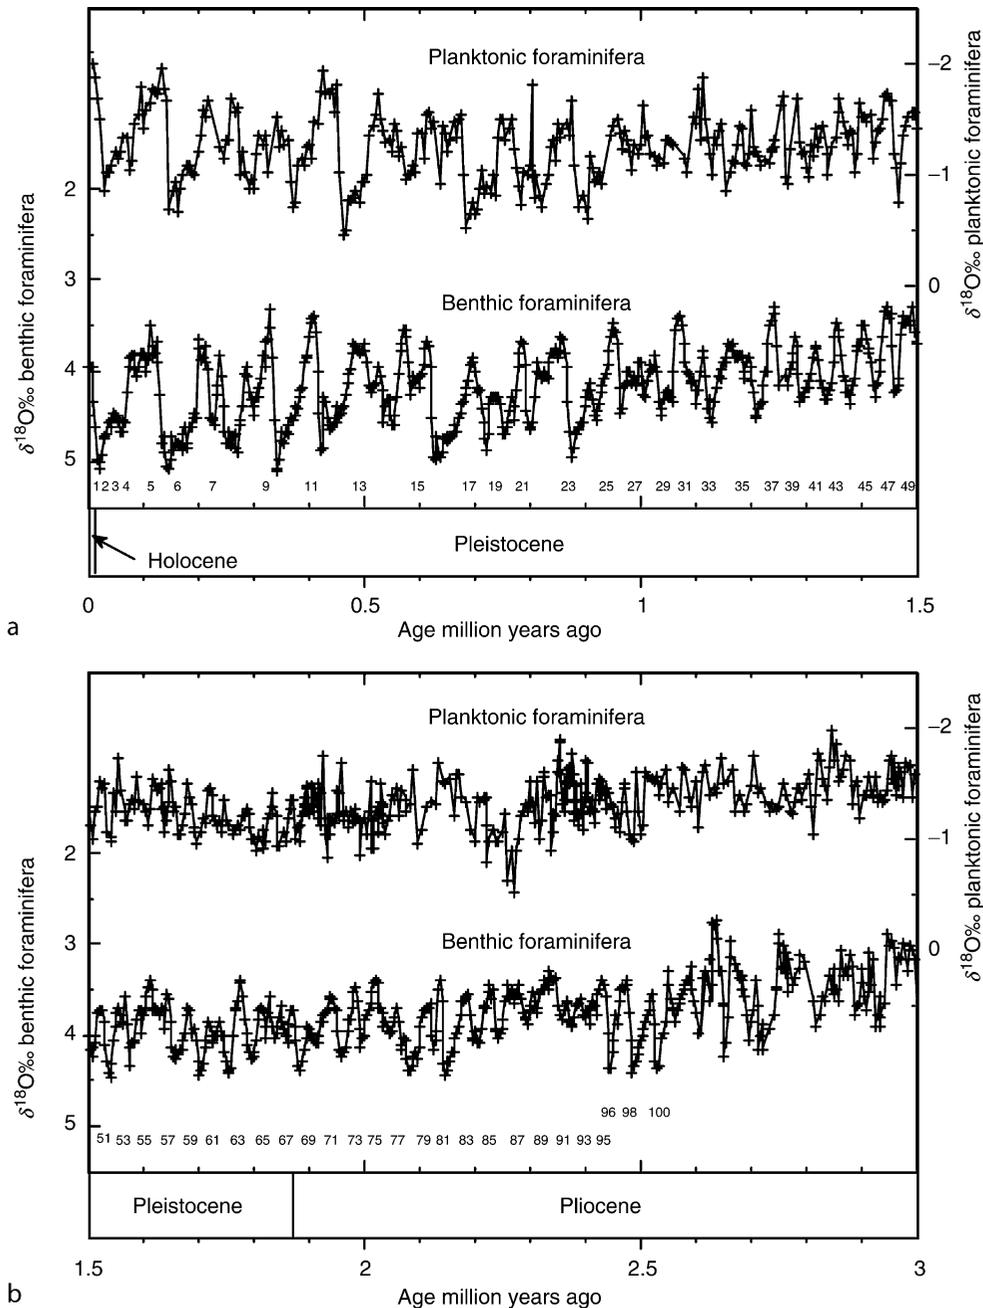

Figure C36 Planktonic and benthic foraminiferal $\delta^{18}\text{O}$ records for the last 3 million years. Note the high frequency signals in the records. For the interval between 3 and 1 Ma, a 40 kyr cycle dominates the records. After 1 Ma, the beat changes to a 100 kyr cycle and the amplitudes increase.

Stage 2" refers to the LGM (Figure C36). During the 1960s and 1970s, many argued that most of the glacial to interglacial difference in $\delta^{18}\text{O}_{\text{calcite}}$ values resulted from ice volume changes. Nicholas Shackleton of Cambridge University made the key observation that benthic foraminiferal $\delta^{18}\text{O}$ values show a glacial to interglacial difference of $\sim 1.8\text{‰}$ (which includes both ice volume and temperature effects). If the ice volume contribution were only 0.3‰ , as argued by Emiliani, then the deep

ocean temperatures would have been between 6 and 7°C colder than the present temperatures of 0 to 3°C . Seawater freezes at -1.8°C , precluding Emiliani's "low" ice volume estimate. By the early 1970s, numerous $\delta^{18}\text{O}$ records had been generated and showed a cyclic variation through the Pleistocene and into the late Pliocene. One hundred oxygen isotope stages, representing 50 glacial/interglacial cycles, have been identified for the interval since 2.6 Myr ago (Figure C36).

Mechanisms for climate change

Most climate change hypotheses for the Cenozoic focus on either oceanic heat transport and/or greenhouse gas concentrations. Each mechanism produces different responses in the equatorial-to-pole and surface-to-deep temperature gradients. An increase in the meridional heat transport generally cools the tropics and warms the poles. If poleward transport of heat decreases, then the tropics will warm and the poles will cool. Variations in greenhouse gas concentrations should produce similar changes in both the tropical and polar regions.

Tropical surface water and deep ocean records co-varied for the first part of the Cenozoic. The warming and subsequent cooling between 65 and 34 Ma are most often ascribed to changing greenhouse gas concentrations. The interval of warming that began around 58 Ma and peaked at 52 Ma coincided with the release of large amount of CO₂ into the atmosphere as a consequence of tectonic processes. The eruption of the Thulean basalts in the northeastern Atlantic Ocean began during the Paleocene and peaked around 54 Ma. It is also recognized that there was a large-scale reorganization of the mid-ocean ridge hydrothermal system beginning during the late Paleocene and extending into the Eocene. Both tectonic processes accelerate mantle degassing, which raises atmospheric levels of CO₂. Recently, evidence for another potentially large CO₂ reservoir was found along the eastern continental margin of North America. Methane hydrates frozen within the sediments appear to have been released catastrophically at least once and possibly multiple times during the latest Paleocene and early Eocene (~58–52 Ma). One or all of these sources could have contributed to the build-up of greenhouse gases in the atmosphere between 58 and 52 Ma.

Following the thermal maximum, the long-term cooling in both the surface and deep waters implies that greenhouse gas concentrations slowly decreased. Proxies for estimating pCO₂ concentrations ($\delta^{13}\text{C}$ fractionation within organic carbon and boron isotopes) are still being developed and refined. However, preliminary indications suggest that atmospheric pCO₂ levels were high (>1,000 ppm) during the early Eocene, dropped to ~400–500 ppm during the middle to late Eocene, and reached late Pleistocene concentrations (200–300 ppm) by the early Oligocene. It is generally thought that accelerated weathering of continents lowered atmospheric pCO₂ levels. The tectonic agent responsible was probably the uplift of the Himalayas and Tibetan Plateau.

The deepwater temperature cooling across the Eocene/Oligocene boundary (Figure C34b) was not accompanied by tropical cooling, and resulted from the first step in the thermal isolation of Antarctica. In the modern ocean, the Antarctic Circumpolar Current is a vigorous surface-to-bottom current that provides an effective barrier to southward-flowing warm surface waters. The development of this current during the Cenozoic hinged on the deepening of the Tasman Rise and the opening of the Drake Passage. Recent drilling indicates that marine connections developed across the Tasman Rise at or near the Eocene/Oligocene boundary (33.5 Ma). Tectonic constraints on the separation of the Drake Passage are less precise. Estimates range from 35 to 22 Ma for the opening of this gateway. The uncertainty lies in the tectonic complexity of the region, and the question of what constitutes an effective opening for water to flow through. The climatic consequence of creating a circum-polar flow was to thermally isolate Antarctica and promote the growth of the Antarctic ice sheet. As noted

above, the first large ice sheet developed beginning at the Eocene/Oligocene boundary.

The most notable divergence in the $\delta^{18}\text{O}$ records began during the middle Miocene (~15 Ma). For the first time during the Cenozoic, the tropical surface and deep waters recorded a clear divergence in $\delta^{18}\text{O}$ values, a trend that increased in magnitude and reached a maximum in the modern ocean. Any poleward transport of heat appears to have been effectively severed from Antarctica by 15 Ma, promoting further cooling. On the other hand, the tropics have been warming over the past 15 Ma. A combination of different factors fueled this warming. First, less heat was being transported out of the low- and mid-latitude regions to the high southern latitudes. Second, the opening of the Southern Hemisphere gateways that promoted the formation of the circumpolar circulation led to the destruction of the circum-equatorial circulation. The effects of the closure of the Tethys Ocean (predecessor to the Mediterranean) during the Miocene, shoaling of the Panamanian Isthmus (4.5–2.6 Ma), and constriction in the Indonesian Passage (~3 Ma to present) allowed the east-to-west flowing surface waters in the tropics to “pile” up and absorb more solar radiation. A consequence of the equatorial warming and high-latitude cooling was an increase in the equator-to-pole temperature gradient. As the gradient increased, winds increased, promoting the organization of the surface-ocean circulation patterns that persist today.

Some caveats

A concern in generating marine isotope records is that the isotopic analyses should be made on the same species. This is important because $\delta^{18}\text{O}_{\text{calcite}}$ values can vary between different species. Co-existing taxa of benthic foraminifera record $\delta^{18}\text{O}$ values that can differ by as much as 1‰. In planktonic foraminifera, variations between species can be as great as 1.5‰. For both the planktonic and benthic foraminifera, inter-specific differences are as large as the glacial-interglacial signal. These inter-specific $\delta^{18}\text{O}_{\text{calcite}}$ variations are often ascribed to a vital effect or kinetic fractionation of the oxygen isotopes within the organism. However, some of the difference in the planktonic taxa results from different seasonal or depth habitats and therefore provides important information about properties in the upper part of the water column. It is interesting to note that the first $\delta^{18}\text{O}$ syntheses were based on mixed species analyses and yet basic features captured in these curves still persist today. This attests to the robustness of these records and method for reconstructing climate changes in the ocean.

The high-frequency signal that dominates the late Pliocene to Pleistocene records is also present in the Miocene and Oligocene intervals. The cloud of points about the mean shown in Figure C34a reflects records that were sampled at a resolution sufficient to document the high frequency signal. For the interval between 35 and 1 Ma, the benthic foraminiferal $\delta^{18}\text{O}$ record has a 40 thousand year frequency superimposed on the long-term means that are represented by the smoothed line. The origin of the 40 thousand year cycles lies in variations in the tilt of the Earth’s axis (obliquity cycles) that influenced the amount of solar radiation received at high latitudes. This insolation signal was transmitted to the deep ocean because the high latitudes were the source regions for deep waters during much if not all of the Cenozoic. The record prior to 35 Ma is unclear with regard to the presence or absence of 40 thousand year cycles.

Finally, relatively high planktonic foraminiferal $\delta^{18}\text{O}$ values in the late Eocene to early Miocene indicate cooler than expected tropical temperatures. Recent work by Pearson and Palmer

(1999) indicates that post-burial diagenesis may have imprinted a cool signal on tropical planktonic foraminiferal calcite. Diagenesis occurs when calcium carbonate precipitates on the foraminiferal shells in the sediments in cold bottom water. Benthic foraminifera would not be adversely affected by this process since they grew in the cold bottom waters. If diagenesis did occur, one may conclude that the best estimate for tropical sea surface temperatures is that they have remained close to 28–30 °C for much of the Cenozoic. If verified, this would reconcile model results with observations. Climate models have a difficult time reconciling the cool tropics and warm poles paradox.

CIRQUES

Cirques are glacially eroded features characteristic of mountain glaciation, and are also known as corries or cwms. They have been widely studied, and useful summaries of previous research are provided by Benn and Evans (1998) and Bennett and Glasser (1996).

Cirques are mountainside hollows, open on the downslope side but characteristically bounded on the upslope side by a steep slope or cliff (the headwall) that is arcuate in plan around the more gently sloping or over-deepened floor of the hollow. Glacial cirques are created by the erosional action of localized snow and ice patches, and during glaciation they contain “cirque glaciers” which may feed ice downstream into valley glaciers. Cirques evolve through time under continuing glacial activity by a combination of deepening of the base and headward erosion of the back wall. Early in the glaciation, nivation beneath snow accumulating in a mountainside hollow may be the chief process leading to the development of the cirque. As more snow and ice accumulates in the hollow, glacial erosion of the base and of the lower part of the headwall, combined with subaerial weathering and erosion of the upper parts of the headwall exposed above the ice, lead to the characteristic steep-walled basin of a mature cirque. Cirques tend to become more enclosed, and deeper, with longer glacial occupation. Long-term evolution of cirques can occur over several glacial cycles, and cirques may be altered by ice-sheet processes if glaciation increases beyond local cirque and valley glaciation. Cirque morphology is therefore often complex, and several small cirques may grow together to form one large, complex feature. Typically cirques are of the order of 10^2 – 10^3 m in diameter.

Cirque elevation and orientation can provide paleoclimatic information. The minimum elevation of cirques reflects the regional snowline at the time of their formation. The predominant orientation of cirques within a region can also indicate dominant wind direction, as snow may initially accumulate, and cirques form, on sheltered lee-side slopes, especially where these have a pole-ward aspect sheltered from insolation. Where precipitation shadows occur, on larger mountain masses, cirques are likely to develop with an aspect facing the dominant source of precipitation.

In postglacial environments cirques often contain lakes in their closed basins, and these lakes may drain by overflow across the lip or sill that marks the down-slope limit of the basin. In many locations the lip or sill is erosional in origin, marking the downstream limit of glacial over-deepening of the basin. However, the feature may be created or accentuated by the deposition of moraines marking the maximum extent of corrie glaciation.

CLAMP

Introduction

That a relationship exists between vegetation and climate is indisputable. The overall appearance of vegetation (i.e., its physiognomy), but not necessarily the species composition, tends to be characteristic of the particular climatic regime in which the vegetation grows (e.g., Holdridge, 1947). This is because many plant morphologies represent particular “engineering” solutions to particular environmental constraints. Only those plants with a genome that affords certain appropriate phenotypic expressions are able to survive in particular climatic regimes. Inappropriate phenotypes are eliminated, either by the physical environment taking its toll directly, or by competition from better-adapted plants.

Although all parts of a plant throughout all stages of the life cycle contribute to the overall success or failure of the individual, it is the leaf that plays the most critical role in environmental adaptation. Its photosynthetic function demands that a leaf be efficient at intercepting light and exchanging gases with the atmosphere, while affording the minimum water loss concomitant with maintaining water flow within the plant for solute transport and evaporative cooling. All this must be achieved with the minimum of structural tissue investment because building tissue costs energy and food resources. Thus, only a limited range of architectures satisfies the often conflicting constraints present in a given set of environmental conditions. Because the unchanging laws of gas diffusion, fluid flow, and mechanics impose these constraints, these forms are

convergent in time and space and independent of taxonomic affinity (Spicer, 2000).

So pervasive is the selective premium for leaf efficiency that physiognomic “tuning” to the environment exists across plant lineages and also within and between individual plants within lineages. For example, leaves at the top of a tree crown exposed to high light and wind energies tend to be small, thick “sun leaves.” In contrast, those in the darker, more sheltered, humid sub-canopy space tend to be larger and thinner (“shade leaves”). If the environment around a tree changes with time, through removal of surrounding trees, for example, then subsequent cohorts of leaves will display different appropriate morphologies.

Plants must produce leaves that are adaptive to the entire growing season and not just to the conditions that exist at the leaf development or expansion stage. This ability to seemingly “predict” future likely conditions must be genetically predetermined through ancestral selection. For example, plants in Mediterranean climates receive abundant rainfall during the spring when the new leaf crop expands, followed by summer drought. If plants responded only to the spring rains and produced large leaves, these leaves would be non-adaptive during the summertime. Clearly, selection favors genotypes that are tuned to the overall climatic conditions and not just those experienced at the time of leaf development.

Vegetation in recently glaciated and non-glaciated parts of the Northern Hemisphere is also correlated with climate, showing that genetic and phenotypic tuning of foliar physiognomy takes place over geologically short timescales (<1 million years) as a result of taxonomic elimination and migration, as well as selection for novel genotypes that arise as the result of chance mutation or hybridization.

The method

CLAMP (Climate Leaf Analysis Multivariate Program) (Wolfe, 1990, 1993; Kovach and Spicer, 1995; Wolfe and Spicer, 1999; Spicer, 2000) is a multivariate statistical technique that decodes the climatic signal inherent in the physiognomy of leaves of woody dicotyledonous plants. It is an evolutionarily robust, accurate, and precise quantitative proxy for direct atmospheric paleoclimate determinations over land, and as such complements marine-based climate proxies (e.g., oxygen isotopes). Moreover, where it is possible to compare temperatures derived from CLAMP with those from oxygen isotopes, both proxies are in close agreement (Kennedy et al., 2002).

CLAMP calibrates the foliar physiognomy of the woody dicots using reference datasets derived from modern vegetation growing under known conditions. Using these datasets, past climatic data are determinable from leaf fossil assemblages, provided that the characteristics of the living source vegetation are well represented in the sampling of the fossil assemblage. CLAMP calibration appears robust over time and has been applied effectively to fossil floras up to 96 Ma old (Herman and Spicer, 1996; Spicer et al., 2002), but is particularly powerful and reliable for late Tertiary (Wolfe, 1995; Spicer, 2000) and Quaternary assemblages.

The statistical engine used in CLAMP is Canonical Correspondence Analysis (CANOCO) (ter Braak, 1986), as this is robust for data that do not necessarily conform to normality in the statistical sense (i.e., the variables do not have a Gaussian distribution). Most importantly, the technique does not assume independence of variables. This is essential when leaf characters are the product of functional compromise,

constructional efficiency, and a finite genome. CANOCO is a direct ordination method, used widely in plant ecology, which orders samples, in this case vegetation sites, based on a set of attributes. In CLAMP, the attributes are numerical values assigned to each of 31 different leaf character states (size, shape, margin, apex, and base features) taken from more than 20 species of woody dicots in each vegetation site. The character states have been selected both for their ability to correlate with climate, and their survivability in even poorly-preserved fossil material. CLAMP calibration is not subject to diagenetic alteration.

The vegetation sites are positioned in 31 dimensional space, such that samples with the most similar physiognomic score plot closest together. Although climate data are not used to define the position of a vegetation site, it is clear from simple inspection that the vegetation sites are ordered in terms of climate variables, principally those relating to temperature and moisture (Figure C37). Instead of using subjective positioning of climate vectors (Wolfe, 1993), CANOCO defines the positions mathematically.

The largest publicly available calibration dataset now consists of foliar physiognomic measurements and climate observations from 173 modern vegetation sites mostly in the Northern Hemisphere (Physg3ar dataset). Earlier versions used fewer modern sites (e.g., 103 in Herman and Spicer, 1996) and different datasets can be used for different purposes. For example, if initial results indicate a warm climate, then a subset of the full dataset that excludes the sites that experience significant freezing conditions (the Physg3br dataset) offers greater precision (Table C5) (Wolfe, 1993; Wolfe and Spicer, 1999). Because climate variables for these sites are known (>30 year averages are used from climate

stations proximal to the sites), vectors for each of the measured climate variables can be calibrated.

Paleoclimate variables can be quantified by scoring a fossil assemblage in the same manner as for the modern vegetation. However, the fossil site is positioned in physiognomic space in a passive manner so it does not distort the calibration by its presence. By projecting the position of the fossil site on to the calibrated climate vector, the ancient paleoclimate can be derived (e.g., Figure C38).

Table C5 Standard CLAMP climate parameters for the Physg3ar and Physg3br datasets with the standard deviations of the residuals about the regressions, and the goodness of fit of the regressions

Parameter	Physg3br		Physg3ar	
	STDEV	r ²	STDEV	r ²
Mean annual temperature (°C)	1.17	0.95	1.72	0.92
Warm month mean temperature (°C)	1.58	0.83	1.80	0.83
Cold month mean temperature (°C)	1.88	0.93	2.54	0.91
Length of growing season (months)	0.70	0.93	0.85	0.91
Growing season precipitation (mm)	335.93	0.87	317.97	0.88
Mean monthly growing season precipitation (mm)	36.91	0.86	36.66	0.86
Precipitation in the three wettest months (mm)	140.29	0.86	138.05	0.86
Precipitation in the three driest months (mm)	92.99	0.86	89.85	0.85
Relative humidity (%)	7.36	0.73	8.17	0.66
Specific humidity (g kg ⁻¹)	0.90	0.87	0.98	0.86
Enthalpy (kJ kg ⁻¹)	3.18	0.92	3.54	0.92

Scoresheets, datasets and spreadsheets for determining paleoclimates can be downloaded from the CLAMP website: <http://www.open.ac.uk/earth-research/spicer/CLAMP/Clampset1.html>

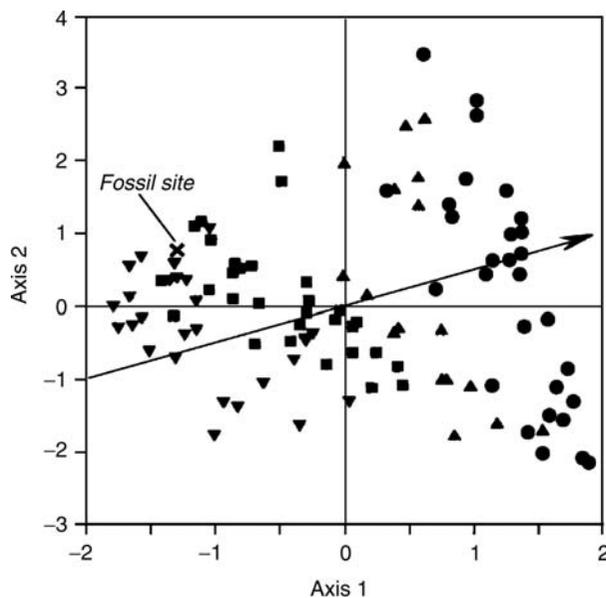

Figure C37 Plot of axes 1 and 2, the two axes of greatest variation, of the physiognomic space defined by the Physg3br CLAMP dataset. The positions of the samples are determined by the numerical description of the 31 different character states that summarize the leaf physiognomy. In this plot, the samples are coded to reflect the mean annual temperature (MAT) under which they grew: circles: 20.0–27.0°C; triangles: 15.0–19.9°C; squares: 10.0–14.9°C; inverted triangles: 4.8–9.9°C. The arrow shows the direction of the mean annual temperature vector as determined by CANOCO.

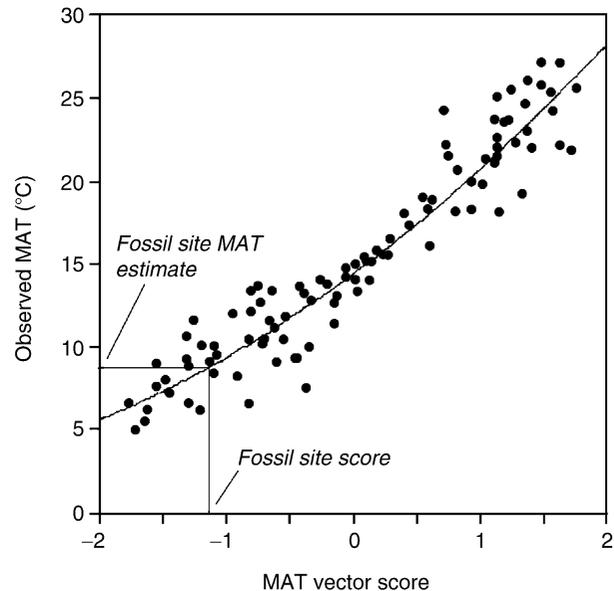

Figure C38 Mean annual temperature (MAT) vector score plotted against the observed MAT for the Physg3br dataset. The standard deviation of the residuals about the regression line is 1.17°C.

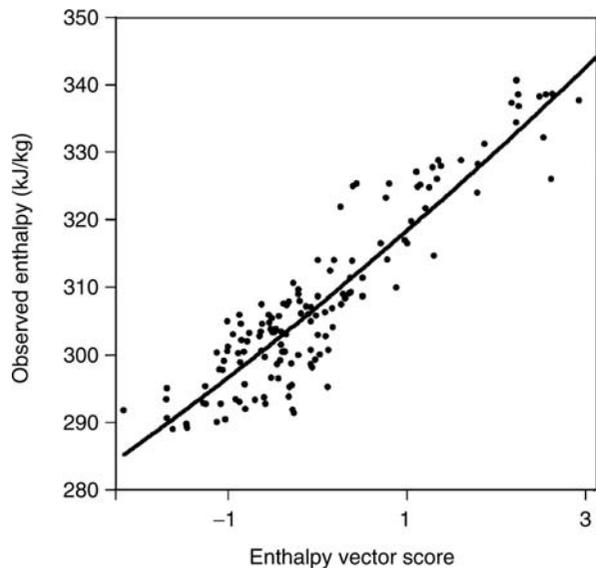

Figure C39 Enthalpy vector score plotted against the observed enthalpy using the CLAMP Physg3br dataset.

CLAMP is capable of determining not just mean annual temperature but a range of climate variables as shown in [Table C5](#).

Quantitative variables are critical for evaluating the performance of climate models but of particular importance is the ability of CLAMP to determine enthalpy. Enthalpy (H) is a function of both temperature and moisture:

$$H = c_p T + L_v q \quad (1)$$

where c_p is the specific heat capacity of moist air at constant pressure, T is temperature (in kelvin), L_v is the latent heat of vaporization, and q is the specific humidity. Leaves therefore exhibit a strong coding for enthalpy ([Figure C39](#)), with a high degree of precision.

The usefulness of enthalpy is that it can be used to determine paleoaltitude (Forest et al., 1995; Wolfe et al., 1998; Spicer et al., 2003) because the difference between two estimates of enthalpy for a given location yield an estimate of their difference in potential energy and hence height separation.

$$h = H + gZ \quad (2)$$

where h = moist static energy, g is gravitational acceleration, and Z is the altitude (see also *Energy budget climatology*, in *Encyclopedia of World Climatology*).

Limitations

Powerful as the technique is, there are some limitations. The current datasets include few vegetation/climate data for fully tropical wet regimes, continental interiors where there is a large mean annual range of temperatures, and sites in the southern hemisphere. The absence of such data currently constrains the types of paleoclimatic regimes that can be accurately retrodicted, but CLAMP development continues.

CLIMAP

Introduction

Ice ages, those times when great ice sheets spread across Northern Hemisphere continents, have been the subject of scientific and public interest for over 150 years. By the 1960s, the aerial extent of some ice ages had been established through the

mapping of the rocky debris left behind by the retreating ice and stratigraphic analyses of these deposits, which provided evidence of multiple ice advances and retreats. The accepted number of such advances was four, all occurring within the Pleistocene Epoch. Studies of deep-sea sediments, which have an advantage over the erosion-plagued record of glaciations on land because of their temporal continuity and spatial coverage, accelerated during this decade, providing further evidence of multiple major climate changes. This evidence was supplied through studies of the calcareous (limy) shells of microscopic plankton (foraminifera). When alive, these one-celled creatures are delicately adapted to the physical properties of the near-surface waters within which they live. Temperature exerts a strong influence on the geographical ranges of these species; therefore, some are restricted to the tropics while others live in the colder waters of high latitudes. Measuring warm-water species abundance variations down deep-sea cores generated qualitative estimates of ocean warming and cooling, which were interpreted as responses to ice sheet advances and retreats (Ericson and Wollin, 1968).

Laboratory studies in the 1950s had shown that the ratio of the isotopes ^{18}O to ^{16}O in the calcareous shells of some marine organisms decreases linearly with increasing temperature (Epstein et al., 1951). These changing ratios, when measured in the shells of planktonic foraminifera in deep-sea cores, were interpreted to allow measurement of changing ice age sea-surface-temperatures, with lower ratios (lighter) indicating warmer temperatures and higher ratios indicating colder temperatures (Emiliani, 1955). Doubt was cast on this interpretation, however, when it was shown that the Greenland and Antarctic Ice Sheets are isotopically light compared with seawater (Dansgaard, 1964). This is because water vapor, when moving from the tropics to high latitudes, preferentially precipitates water molecules with the heavier ^{18}O over those with the lighter ^{16}O , causing the ice sheets to be depleted in ^{18}O and enriched in ^{16}O relative to seawater. The building of ice sheets in the past could have further increased the $^{18}\text{O}/^{16}\text{O}$ ratio of seawater because the growing ice sheets preferentially leave ^{18}O behind as they move water from the ocean to the ice sheets. This in turn could increase the $^{18}\text{O}/^{16}\text{O}$ ratio in the shells of foraminifera. Thus, either cooling or ice sheet growth might have caused the increased $^{18}\text{O}/^{16}\text{O}$ ratios in the shells of foraminifera during ice ages. Regardless of which was responsible, there was no doubt that these isotopic and faunal variations recorded major climatic changes.

Hypotheses to explain these climatic changes abounded in the 1960s; Richard Foster Flint, the dean of Pleistocene geology at the time, put the number of hypotheses at 55. Some called on oscillators within the Earth's climate system (ocean, atmosphere, ice), such as the melting and refreezing of the Arctic Ocean to alternately increase and decrease the moisture supply to ice sheets bordering its rim (Ewing and Donn, 1956), or repeated surges of the Antarctic Ice Sheet, sending streams of ice into the ocean, which may have raised the Earth's albedo (reflectivity) and caused cooling (Wilson, 1964). Others called on changes outside the Earth's climate system, such as variations of solar output or variability in the concentration of interstellar dust through which the solar system traveled. The oldest idea, first proposed in the mid-nineteenth century, calls on variations in the geometry of the Earth's solar orbit, causing geographical and seasonal changes in the distribution of solar energy over the Earth's surface, and driving ice age climate change (Adhemar, 1842; Croll, 1864; Milankovitch, 1920). In the 1960s,

many thought these radiation changes were far too small to produce the great glacial advances and retreats; however, this hypothesis has advantages over others because its explicit prediction, that ice ages are periodic with periods of about 100, 40 and 23 thousand years, is testable. A period of nearly 100 thousand years should be present in the geological record if the Earth's climate system response to orbitally induced insolation changes is non-linear, as seemed likely. These specific predictions could be verified or rejected if the geological record of ice ages could be accurately dated; however, in the mid-1960s, dating of deep-sea cores was limited to the ^{14}C method, which extended back only some 25,000 ybp. Furthermore, there was no agreement on how to identify the base of the Pleistocene in deep-sea sediments, which was thought to mark the beginning of the ice ages.

The discovery that deep-sea sediments record reversals of the Earth's magnetic field (Harrison and Funnel, 1964) provided a new way to globally correlate and date deep-sea sediments. Magnetic minerals within the uppermost water-charged layer of seafloor sediment align themselves with the current direction of the field. As this layer is more deeply buried and compacted, the alignment of magnetic minerals becomes permanent. When the field reverses, the uppermost layer records the new field direction. If the field were to reverse today, an observer would see the needle of a magnetic compass swing from north to south, although it would take several thousand years to complete the swing. Geologically this is but an instant, therefore a record of a reversal in sediments is globally isochronous. Specific magnetic reversals, the last occurring some 700,000 years ago, were first dated in oceanic island lava flows (Cox et al., 1964). They can be uniquely identified in ocean sediments through their associated microfossil assemblages (Opdyke et al., 1966). Magnetic stratigraphy combined with biostratigraphy could consequently produce a global chronostratigraphy for deep-sea sediments over the last few million years (Hays et al., 1969; Opdyke and Foster, 1970; Hays and Berggren, 1971). These studies showed that there have been seven glaciations since the last magnetic field reversal and the Pleistocene's base is about 2 million years old.

Meanwhile, an ingenious technique to transform microfossil assemblage data into quantitative estimates of sea-surface temperature was being developed (Imbrie and Kipp, 1971). Factor analysis was used to identify microfossil assemblages in geographic arrays of sea-floor sediment samples and regression techniques were used to correlate the assemblage data with overlying sea-surface temperatures. In this way, equations were developed relating assemblage data to temperature. By using these equations and assemblage data from Pleistocene sediments, past sea-surface temperatures could be estimated. The technique assumes that the ecological tolerances of the selected species are little changed between Pleistocene and Recent time and the assemblage compositions are responses to physical gradients, dominated by temperature.

Finally, during the 1960s, the Lamont Geological Observatory, under the leadership of Maurice Ewing, more than tripled the size of its deep-sea core collection to more than 11,000 cores, making it a truly global collection.

The CLIMAP project

At the beginning of the 1970s, a group of young scientists trained in the study of deep-sea sediments and equipped with the new chronostratigraphic and paleoecological tools developed in the previous decade saw an opportunity to use the vast

Lamont core collection as a global climate monitoring system. Their objectives were to understand what causes ice ages and how the Earth as a whole responds to them. Through this better understanding, they hoped to predict future climate change. They called their project CLIMAP (Climate Long-range Investigation Mapping And Prediction). They were aided in this effort by a new program within the National Science Foundation, The International Decade of Ocean Exploration (IDOEO). It fostered ocean science research that included inter-institutional and international cooperation and had relevance to human needs.

CLIMAP initially proposed to study the spatial and temporal patterns of ice-age climate change in the North Atlantic, North Pacific and Antarctic. By generating seasonal maps of sea-surface temperatures at the last glacial maximum (LGM), they sought to measure the ocean's response to this most recent cooling extreme. Temporal changes were to be studied by generating time series of sea-surface temperature and other climatic indicators back to the last reversal of the Earth's magnetic field (700,000 yBP).

The project, consisting of scientists and students from Columbia University's Lamont Doherty Geological Observatory, Brown University and Oregon State University, faced challenges at its outset in 1971. The first was how to organize highly individualistic and competitive scientists, accustomed to working by themselves or with one or two others, into a cooperative productive team. This challenge was met, at least in part, by giving each investigator an individual as well as a group role. The individual roles, the study of an area of the ocean and regional time series, fed into the group task by providing regional information for the larger LGM mapping project and inter-regional comparisons of temporal climatic change. Task groups were formed to generate regional LGM sea-surface temperatures and regional time series, and others to address more general problems, e.g., the biotic index task group, under the leadership of John Imbrie, which served as a resource for regional task groups developing equations to estimate past sea-surface temperatures. CLIMAP quickly expanded to include European scientists: Drs. Shackleton (Cambridge, England), Seibold (Kiel, Germany), Dansgaard (Copenhagen, Denmark), Van der Hammen (Amsterdam, Netherlands) and Lamb (Norwich, England) were made corresponding members. These connections resulted in European conferences and a flow of students from Kiel to Lamont to work on specific CLIMAP objectives. At its peak, more than one hundred scientists and students were involved in this collaborative effort. The initial fears of internal conflict, whether because they were addressed or were ill-founded, did not materialize and the group worked together in remarkable harmony.

The second challenge stemmed from the group's commitment to generate maps of sea-surface temperature at the LGM as there was no easy way to identify this level in deep-sea cores short of ^{14}C dating at that time, and the group had budgeted insufficient funds for large numbers of ^{14}C dates. Furthermore, large areas of the ocean floor are carbonate-free, precluding ^{14}C dating. The solution to this problem happily came early in the project from a western equatorial Pacific core that just penetrated the last reversal of the Earth's magnetic field. Oxygen isotopic variations in the shells of both benthic and planktonic microfossils showed similar amplitudes throughout its length (Shackleton and Opdyke, 1973). Because ocean bottom temperatures are near zero today, they cannot get much colder during an ice age. Consequently, the large

changes in the oxygen isotopic ratios in benthic shells could not be caused by changing bottom water temperature, rather they must be caused by the changing isotopic composition of the ocean, driven by waxing and waning ice sheets. Hence, the changing isotopic composition of the ocean, due to changing ice sheet volume, must be responsible for most of the $^{18}\text{O}/^{16}\text{O}$ variations measured in foraminiferal shells. This isotopic signal mixes through the ocean within a thousand years; therefore, within this time, isotopic records from various parts of the world are synchronous. This meant that features of the oxygen isotopic record could be used to correlate deep-sea cores globally. The LGM could then be easily identified without multiple ^{14}C dates, as an isotopically heavy interval beneath the light values of the Holocene Epoch.

Criteria to identify the LGM in sediments containing biogenic silica but not calcium carbonate appeared in the form of a cosmopolitan radiolaria (*Cycladophora davisiana*) with high latitude temporal abundance changes strikingly similar to the $^{18}\text{O}/^{16}\text{O}$ record. In sub-Antarctic cores that contain both calcareous and siliceous microfossils, the abundance variations of *C. davisiana* were correlated with variations in the oxygen isotope record (Hays et al., 1976a), transferring the oxygen isotope chronostratigraphy to siliceous non-calcareous sediments in the high latitudes of both hemispheres (Robertson, 1975). Therefore, the CLIMAP team could accurately identify the LGM for their mapping task and globally correlate time series of estimated sea-surface temperature, the $^{18}\text{O}/^{16}\text{O}$ proxy for ice volume, and other climatically sensitive attributes of deep-sea cores.

Meanwhile, important advances were being made in another area that would soon intersect with CLIMAP's trajectory. The sophistication of numerical models of the atmosphere had been evolving since the early 1960s (Smagorinsky, 1963; Mintz, 1968; Sellers, 1969). These models are mathematical systems that simulate climatic states by solving equations representing physical processes. By the early 1970s, General Circulation Models (GCMs) could simulate the global distribution of such atmospheric properties as pressure, temperature, wind, and precipitation that are in equilibrium with a limited set of earth surface conditions (Gates, 1976). These surface conditions include sea-surface temperature, sea-ice extent, albedo, sea level and land elevation. CLIMAP was already reconstructing some of these for parts of the world ocean. If it expanded its LGM map to cover the world ocean, reconstructed the great continental ice sheets and estimated continental albedo, land elevation and sea level, it could model the LGM atmospheric circulation with the latest generation of GCMs.

The CLIMAP team quickly seized this opportunity and added a glacial geologist (George Denton) as well as an ice modeler (Terry Hughes) to the team, for if the perimeter of the great ice sheets could be determined and the assumption of ice sheet equilibrium (snow accumulation = ice ablation) accepted, ice sheet thickness could be modeled. The Denton-Hughes team recruited European scientists and together produced a book describing for the first time the area and thickness of all the great ice sheets at the LGM (Denton and Hughes, 1981). Dr. George Kukla, a student of the great dust deposits (loess) that accumulated on large areas of Eurasia during the last ice age, agreed to lead a group that would reconstruct continental albedo.

By 1975, under the leadership of Andrew McIntyre and Theodore Moore, the compilation of the first global LGM sea-surface temperature map for the month of August was complete and by the end of the decade, the group had doubled the

number of glacial maximum sea-surface temperature estimates and compiled maps for the months of February and August. These maps were merged, under the supervision of John Imbrie, with maps of continental albedo, land elevation, shorelines and the extent and thickness of the great ice sheets (Figure C40) (CLIMAP Project Members, 1976, 1981).

When compared with today, the LGM oceans showed large increases of winter sea-ice in both hemispheres and equator-ward expansion of polar water with pronounced steepening of temperature gradients across the polar fronts of both hemispheres. These changes were most dramatic in the North Atlantic, with this ocean's Polar Front shifting from its present position near the east coast of Greenland to a position running near Cape Hatteras to Spain. Temperatures were significantly colder in the tropical upwelling zones and along the western coasts of Africa, South America and Australia, probably in response to both increased upwelling and advection from higher latitudes. Temperatures within the great subtropical gyres, however, were little changed from today. On average, the ocean's surface temperature was 2.3 °C colder than today.

On the continents, immense ice sheets covered northern North America and Northern Europe. In North America, the

ice extended south to the present locations of New York City in the east, Seattle in the west and southern Illinois in the mid continent area. The northern European Ice Sheet extended into northwest Siberia; however, there was little or no ice on northern Alaska and northeast Siberia. The southern Andes generated expanding glaciers that spread to the lowlands of Patagonia. In general, there were huge differences in land ice extent in the Northern Hemisphere but very little difference in the Southern Hemisphere. This project produced the first reconstruction of Earth's surface conditions at a time that was climatically very different from today.

These surface conditions were then used as input to the two-level Mintz-Arakawa GCM. The model generated cooler and dryer continents, with the zone of westerly winds displaced southward near the great ice sheets. The mean temperature of the Earth's surface during the month of August was estimated to be on average nearly 5 °C lower than today's mean August temperature (Gates, 1976).

A modeling effort by the Geophysical Fluid Dynamics Laboratory of Princeton University focused on the simulation of tropical climate (Manabe and Hahn, 1977). CLIMAP's higher reconstructed LGM continental albedos produced greater negative departures of continental temperatures from

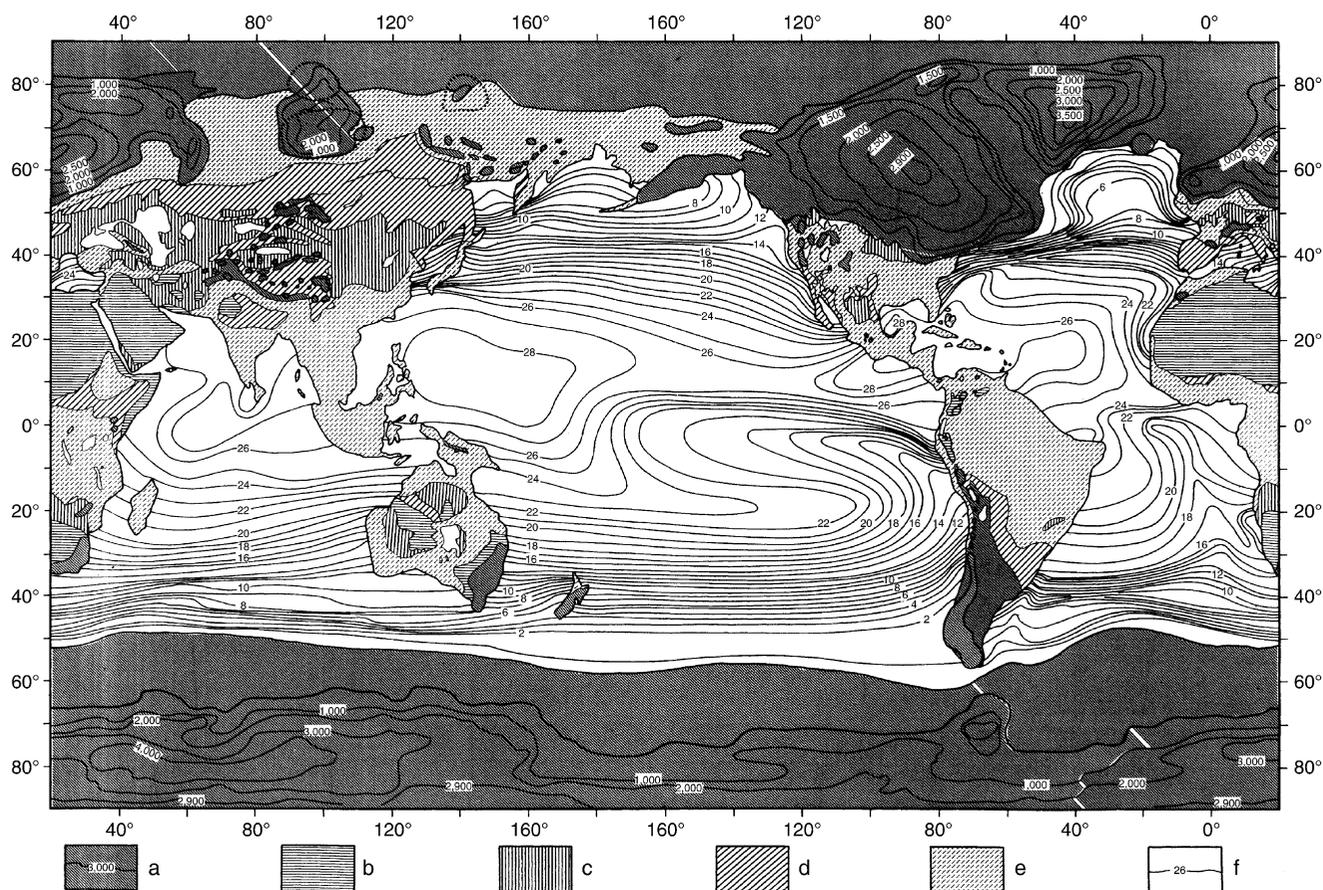

Figure C40 Surface of the ice age Earth in August 18,000 years ago. Contours are 1 °C for isotherms and 500 meters for ice elevation. Shorelines represent an 85 meter lowering of sea-level. Albedo values are given by the key; (a) snow and ice, albedo >40%, (b) sandy desert, patchy snow and snow-covered dense coniferous forests, albedo 30–90%, (c) loess, steppes and semi deserts, albedo 25–29%, (d) savannas and dry grasslands, albedo 20–24%, (e) forested and thickly vegetated land, albedo 15–18%, (f) ice-free ocean and lakes albedo <10% (modified from CLIMAP Project Members, 1984).

today's temperature than do air temperatures over the ocean. The model consequently predicts stronger surface outflows from the continents (or less surface inflow), resulting in increased tropical continental aridity. Evidence of such aridity was provided by mineralogical studies of tropical deep-sea cores (Damuth and Fairbridge, 1970). Manabe and Hahn (1977) also showed that an ice age increase in continental albedo over Tibet contributed to a weakening of the simulated Asian monsoon.

By the mid 1970s, CLIMAP had generated numerous time series in both hemispheres, some reaching back to the last reversal of the Earth's magnetic field (Cline and Hays, 1976). Because CLIMAP had demonstrated that oxygen isotopic variations (especially in benthic species) in deep-sea cores are primarily a response to changing Northern Hemisphere ice volume, Southern Hemisphere cores now offered a special opportunity to test the synchronicity of climate change between the two hemispheres. If local Southern Hemisphere temperatures could be estimated through faunal analysis in the same samples as oxygen isotopic ratios (reflecting Northern

Hemisphere ice sheet fluctuations) were measured, then the relative timing of climate change in the two hemispheres could be compared in the same core. Cores raised from the Indian Ocean sector of the sub-Antarctic region contained both siliceous and calcareous microfossils. Sea-surface temperature estimates, using siliceous microfossils, oxygen isotope measurements and measurements of the relative abundance of *C. davisiana*, showed that climatic change on ice age timescales is nearly in phase between the two hemispheres (Figure C41) (Hays et al., 1976b). This is not what the orbital theory of ice ages predicts; however, two cores from the sub-Antarctic sector of the Indian Ocean that together span more than 400,000 years (RC11-120 and E49-18) have sediment accumulation rates sufficient to resolve climate changes with periods of less than 20,000 years, which is adequate for a frequency test of the orbital theory. Spectral analysis of the three records yielded three spectral peaks in each record, centered at about 100,000, 41,000 and 23,000 years, very close to the orbital periods (Figure C42) (Hays et al., 1976b). The peak representing a period near 23,000 years is bimodal with power

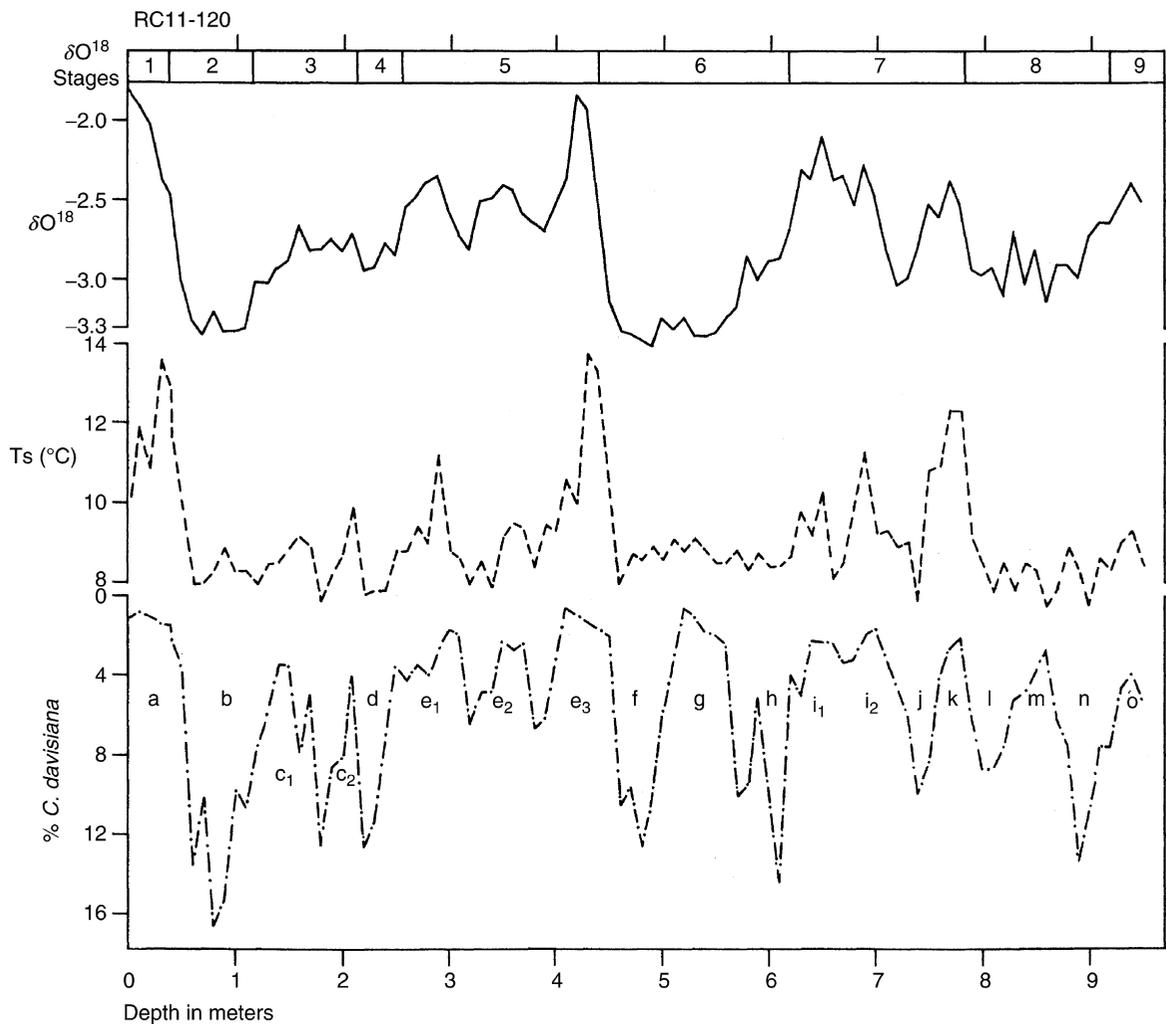

Figure C41 Depth plots of three records in sub Antarctic core RC11-120, from top to bottom: $\delta^{18}O$ a measure of the $^{18}O/^{16}O$ ratio, estimated sea-surface temperatures based on faunal analysis and % *C. davisiana* (after Hays et al., 1976b).

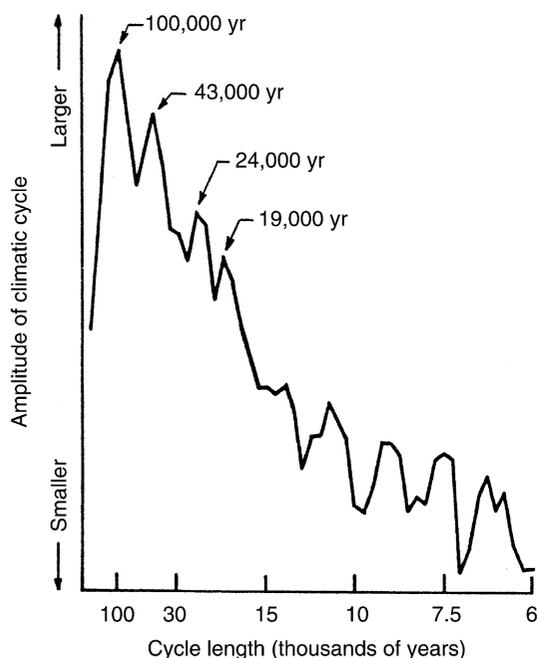

Figure C42 Periods in Northern Hemisphere ice volume variations during the last half million years (after Hays et al., 1976b).

centered near 23,000 and 19,000 years. Almost simultaneously with this study, André Berger, a Belgian scientist recalculated the orbital parameters and discovered that indeed there was also significant power in precession with a period near 19,000 years (Berger, 1977). The filtered 41,000 and 23,000-year signals show a constant phase relationship with tilt and precession over an interval of 300,000 years. These analyses provided convincing evidence that orbital variations are responsible for the timing of major glacial interglacial fluctuations, as had been suggested years before (Adhemar, 1842; Croll, 1864; Milankovitch, 1920). Why had CLIMAP succeeded in demonstrating the connection between orbital variations and climate change when many previous attempts had failed? – Emiliani, 1955, 1966; van den Heuvel, 1966; Kemp and Egger, 1967; Broecker and van Donk, 1970; Imbrie and Kipp, 1971. The clear reason is that by the time the CLIMAP team made their assessments, and very much due to their efforts, the knowledge of the age of geological features in deep-sea cores within the last half million years had improved to the point that it was sufficient to demonstrate the correlation between orbital variations and the geological record of climate change (Ninkovich and Shackleton, 1975; Hays and Shackleton, 1976; Shackleton and Opdyke, 1976; Thierstein et al., 1977).

CLIMAP workers then used the chronological information in the orbital calculations to more precisely date the geological record, first for the last 400,000 years (Hays et al., 1976b; Martinson et al., 1987) and then for the last 700,000 years (Kominz et al., 1979; Imbrie et al., 1984). The Kominz et al. (1979) work is noteworthy because, using orbital chronology mapped into an oxygen isotope record, they estimated the age of the last magnetic field reversal as 728,000 years and not 700,000 years, as had previously been thought. In the same year, additional K/Ar dates on lava flows confirmed this older age (Mankinen and Dalrymple, 1979). These nearly coincident

ages arrived at by independent methods were further confirmation of the orbital theory of ice ages as well as validation of the efficacy of mapping orbital chronological information into geological records.

The successful test of the orbital theory encouraged efforts to model the climatic consequences of radiation variations caused by precession and obliquity changes. Suarez and Held's (1976, 1979) energy balance model generates estimates of snow cover and temperature variations that, in a qualitative way, follow changes in temperature estimated from a North Atlantic core (Sanchetta et al., 1973). Imbrie and Imbrie (1980) using another model with orbital input generated variations in ice volume, which simulate the record of ^{18}O variations from deep-sea cores, and predicted future ice sheet variations.

CLIMAP's last major effort was the reconstruction of conditions at the last interglacial roughly 122,000 years ago, a time similar to the present day (CLIMAP Project Members, 1984). The group used the oxygen isotope record to identify the last interglacial and estimated temperatures through a time range of some 10,000 years. In this way, the temporal relationship between the melting of glacial ice before and re-growth after could be compared with the warming and cooling of sea-surface temperatures. In general, the sea-surface temperatures at the height of the last interglacial were not significantly different from those of the modern ocean. The project demonstrated that the oceanic sea-surface temperature change in much of the Southern Hemisphere precedes Northern Hemisphere ice volume change by several thousand years, while the reverse is true in the North Atlantic.

Conclusions

The CLIMAP project came to an end in 1981 but gave birth to project SPECMAP. Through the publication of more than 100 papers, CLIMAP contributed much to the nascent fields of paleoclimatology and paleoceanography. A few of its major contributions are listed below:

1. Presented the first detailed quantitative global reconstruction of the surface of the Earth at a time other than the present, i.e., the maximum of an ice age.
2. Through 1 (above), provided the boundary conditions for a global simulation of Earth's atmospheric circulation.
3. Provided the first quantitative measurement of how much the Earth cooled during an ice age.
4. Established a global chronostratigraphy for deep-sea sediments during the last 700,000 years with a resolution of less than a few thousand years.
5. Demonstrated that variations in the geometry of the Earth's orbit around the sun control the timing of ice age cycles.
6. By demonstrating that chronological information could be mapped from calculations of Earth's orbital variations to the climatic record in deep-sea sediments, it provided a new and accurate way to date deep-sea sediments.

CLIMATE CHANGE, CAUSES

To summarize evidence discussed elsewhere in this volume, past climate change can be detected on time scales of decades to hundreds of millions of years. Theories as to the causes for such changes extend back almost as far as the observations. James Croll (1867) was the first to seriously examine the role

of changes in the Earth's orbit, through their contribution to the waxing and waning of Pleistocene ice ages. In the early twentieth century, Alfred Wegener, in conjunction with the geographer Köppen (Köppen and Wegener, 1924), discussed how continental drift could explain the great Permo-Carboniferous ice age discovered in different parts of Gondwanaland. The tree ring laboratory at the University of Arizona was instituted in part to test hypotheses as to whether changes in the output of the sun may be responsible for decadal scale changes in drought in the western United States. In perhaps the first comprehensive assessment of the problem, Brooks (1926) estimated that there were already 56 different explanations for the ice ages.

Although many of the above ideas are still alive and well, one of the most significant advances in paleoclimatology in the last half century has been a considerable increase in quantifying past climate change, and in determining the chronology of past climate change. This last contribution is exceedingly important and sometimes either overlooked or taken for granted. As John Imbrie once remarked, "Stratigraphy is 90% of geology." By this, he meant that no sound testing of a cause is possible without a precise and accurate knowledge of the time relationships between different sources of forcing and the responses in the climate system.

The testing of hypotheses has also benefited greatly from the development of large-scale models of the atmosphere and ocean circulation and ice sheets, and the coupling of these models with both the biosphere and biogeochemical systems. One of the most significant advances by climate scientists in the last 30 years has been the recognition that not all climate change is related to some external type of forcing (e.g., volcanoes, solar and/or orbital insolation variations, motions of the continents, etc.). Rather, fluid systems can generate their own internal variability because of the different response times of different parts of the system, and this variability can account

for a very large part of the entire observed variability in the climate record.

The basic idea behind "internal variability" is that there are different time constants for different parts of the climate system – days to weeks for the atmosphere, months to years for the surface ocean (i.e., ocean mixed layer), centuries to a thousand years for the deep ocean circulation, thousands of years for ice sheets, and millions of years for continental drift. These time scales are not independent. Small, essentially random, variations in weather can sometimes store or remove heat temporarily from the ocean mixed layer. Because the ocean mixed layer has a heat capacity about 60 times that of the atmosphere, the time constant for integrating the atmospheric effects is longer in the surface ocean. Thus, there may be "decadal scale" climate variations driven simply by these random variations. In addition, planetary Rossby waves in the ocean can have time scales of years to a decade, so the propagation of these waves through the upper ocean can generate a more organized type of variability on decadal time scales. The great subtropical ocean gyres also have a time scale of a decade or two with respect to their transport of energy in the different ocean basins.

Given an infinite amount of time, the ocean would return any stored heat to the atmosphere, so that the long-term average exchange would be zero, but for finite periods, temperature can vary by 0.1–0.3 °C with respect to global mean temperature. In fact, all control runs of coupled models of the ocean-atmosphere circulation simulate such variability, which in one case has been extended to more than 10,000 model years. This variability is typically illustrated by variance versus frequency plots, which show increasing variance as the frequency of any forcing decreases (e.g., Figure C43). This pattern is known as a "red noise spectrum" and can be found in virtually all geophysical time series, including climate time series in the geologic record. The slope of the background spectrum is often in the range of -1 to -2 (the greater the slope, the greater the

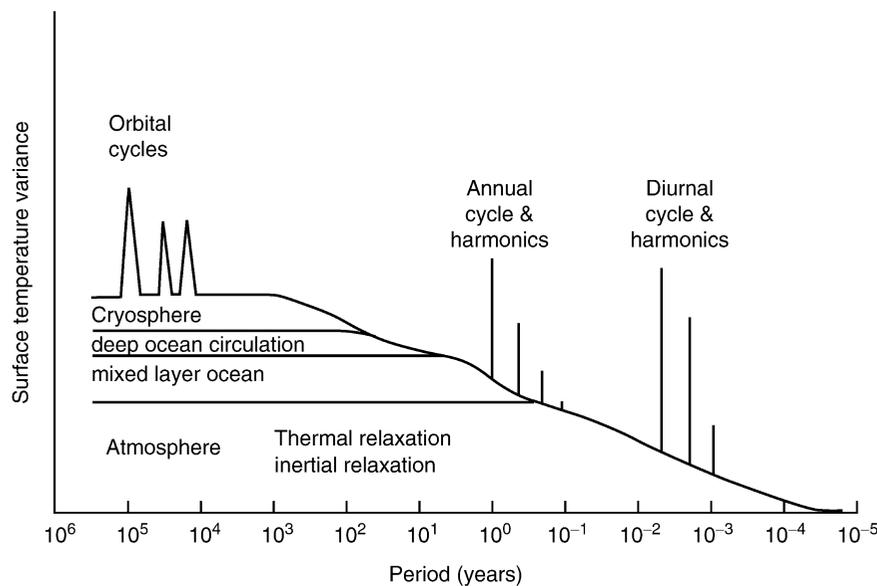

Figure C43 Schematic variance spectrum of the surface temperature versus frequency, f , (labeled in terms of period, which equals f^{-1} in years), illustrating the timescale for different components of the climate system and the relation between the background "red noise" variance and externally forced oscillations at distinct periods. (Modified from Crowley and North, 1991).

coupling between different time scales). This is the actual shape and range of slopes observed when high quality geologic observations have been used.

Only spectral peaks exceeding two standard deviations above the local background “red noise spectrum” require some type of additional explanation as to their origin, and even these must be checked with repeat analyses from other records as there is still a 5% chance that, in a fine length time series, a given peak can occur by chance alone above the 2-sigma level. These “stochastic” variations of climate should not be confused with chaos in the climate system. The latter can occur where random perturbations lead to some threshold “state change” in the system, after which there may be an abrupt change in system state. Such changes are inherently nonlinear, but the stochastic processes emphasized above are, to a large extent, linear processes.

The importance of the above discussion cannot be overemphasized, because there seems to be an inherent tendency to attribute any climate fluctuation, past or present, to some change in external forcing. However, the null hypothesis is to interpret the changes as being of internal origin unless there is some compelling evidence suggesting otherwise; for example, a strong correlation between an observed response and an external forcing term. Another, related test would be whether the observed response has a spectrum significantly different from the background climate spectrum. This is clearly the case for the annual cycle of temperatures and some of the climate changes on time scales of tens of thousands to hundreds of thousands of years that have been linked to periodic variations in the planet’s insolation.

Tectonic timescale

As indicated in Figure C44, the maximum variance in the paleoclimate system occurs on the tectonic time scale – millions to tens of millions of years. Here, the change is between times of little or no ice and times of major continental glaciation. Direct evidence of glaciations (striated rocks and pebbles, sedimentary deposits of likely glacial origin) indicates that there have been three main phases of major continental glaciation in the last 600 million years – in the late Precambrian (Neoproterozoic, ~600 Ma [million years ago]), the Permo-Carboniferous (~270–360 Ma), and the late Cenozoic (0–35 Ma). There are shorter glaciations (1–10 million years?) in the Late Ordovician (~440 Ma), in the mid-Devonian (~365 Ma) and perhaps in the middle Jurassic (~180 Ma). The magnitude and duration of the latter two is not well established, but it is likely they were less extensive in time and space than the late Cenozoic, Permo-Carboniferous, and Neoproterozoic glaciations. In total, direct evidence for glaciation occurs in about 25% of the record over the last 600 million years.

Changes in geography due to plate tectonic changes have long been explored as a mechanism of causing the “grand cycles” of Phanerozoic climate change (Donn and Shaw, 1977). However, in the early 1980s, paleoclimate-modeling exercises by Barron and Washington (1984, 1985) suggested that, although the climate effects of plate tectonic changes were significant, it was not possible to explain long-term changes in ice cover solely by this process (One exception is Greenland, where model results suggest that cooling could have been due to the northward migration of the landmass through the last 100 million years, plus deceased summer warming due to opening of the Greenland-Norwegian Seas (Crowley et al., 1986)). However, Barron and colleagues discovered that if

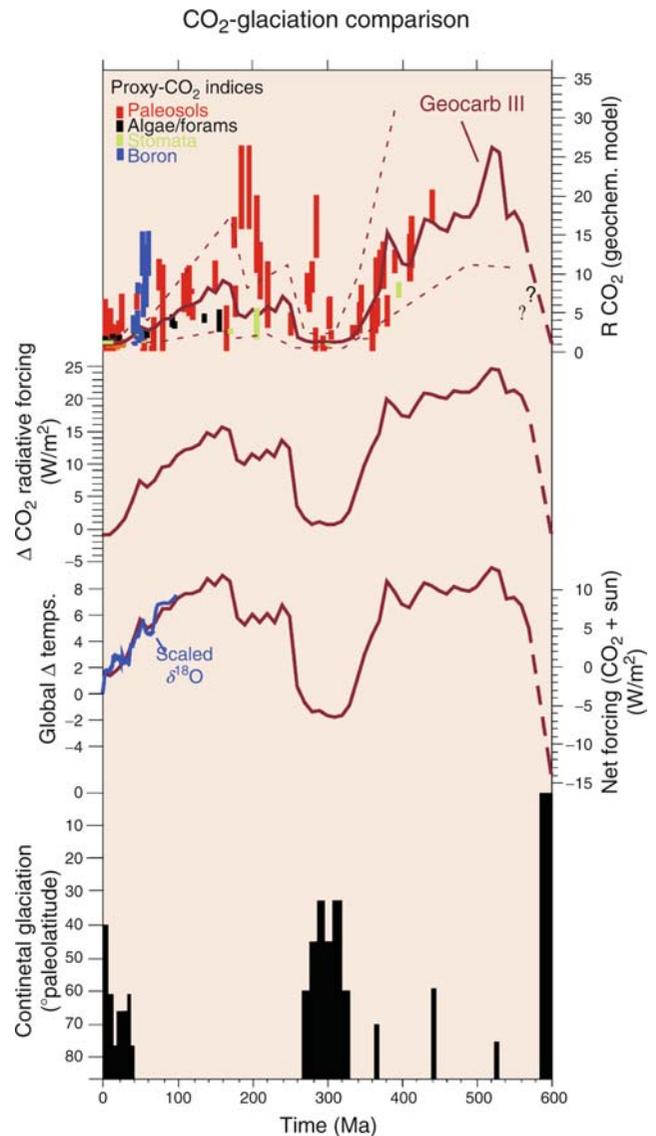

Figure C44 Comparisons of carbon dioxide changes from a geochemical model with various indices of climate change. From the top, comparison with various proxy CO₂ indices of the last 600 million years; next, adjusted radiative forcing after taking into account the logarithmic relation between CO₂ concentration and radiative forcing; second panel from bottom, radiative forcing after factoring in the evolution of solar output over the last 600 million years. On the left hand side of this panel is the oxygen isotope record of climate change for the last 100 million years, scaled to global temperatures. Bottom panel, comparison with best-documented evidence for continental glaciation. (Modified from Crowley and Berner, 2001).

carbon dioxide levels were changed, then a closer agreement between models and paleo-data could be obtained.

The results of Barron and colleagues meshed very well with independent studies of geochemistry. Berner et al. (1983) published a geochemical model suggesting that there could have been major changes in the natural CO₂ content of the atmosphere due to changes in the balance of sources and sinks of atmospheric CO₂ (e.g., outgassing from volcanoes, weathering,

and carbon burial). Changes in the latter two draw down CO_2 in the atmosphere. Changes in weathering can be related to uplift of landmasses, CO_2 -enhanced increases in weathering, and phases in the evolution of terrestrial life. For example, the present version of this model (Berner and Kothava, 2001; Figure C44) predicts a major period of high CO_2 levels in the early-mid Paleozoic (~ 300 – 540 Ma) followed by a significant decline in the later Paleozoic due to the evolution and expansion of land plants (which create an extra carbon sink of reduced carbon and also produce organic acids in the soil that accelerate the breakdown of silicate minerals). A later rise persists into the mid-Cretaceous period (~ 80 – 100 Ma) after which there is a slow decline to values at or near present by about 30 Ma.

Although considerable questions have been raised about this geochemical model, a separate line of testing, using geochemical analyses of various sedimentary constituents to derive “proxy” CO_2 estimates, agrees well with the model predictions to the first order. The calculated CO_2 levels also agree (to first order) with the amounts required by climate models to fit the paleo-data. On the 10-million year timescale (the resolution of the geochemical model), there is a good agreement (Figure C44) between the timing of CO_2 lows and major glaciation. On this timescale, it is necessary to factor in the evolution of solar irradiance due to the ever-increasing fusion-related conversion of hydrogen to helium in the sun’s core. The estimated increase amounts to about 1% per 100 million years. One also has to consider that radiative forcing from CO_2 changes is logarithmically related to CO_2 concentration because of the increased “saturation” of CO_2 absorption bands at high atmospheric CO_2 levels. Combining these two factors, and assuming for simplicity that the Earth’s planetary albedo of 30% remains constant with time, yields an estimate of net irradiance changes versus time that explains $\sim 50\%$ of the variance of continental glaciation on a time scale of 10 million years. There has been a separate but less conclusive line of discussion suggesting that CO_2 levels during the Neoproterozoic glaciation may also have been low. If so, about 60% of the major climatic variance over the last 600 million years can be explained by natural variations in the CO_2 content of the atmosphere.

There are still times when the simple CO_2 –ice relationship does not seem to hold – particularly in the Late Ordovician (~ 440 Ma) and the mid-Jurassic (~ 180 Ma). However, even these time intervals may not be totally at odds with the CO_2 model, for a number of climate modeling studies (Crowley and Baum, 1995) indicate that there is a small area of parameter space that allows high CO_2 and ice buildup. This parameter space is related to the configuration of the continents. When landmasses are close to the poles, the presence of open water suppresses the summer warming on these landmasses. Even small topographic highs can form permanent ice caps under such scenarios. Some preliminary work also suggests it may apply to the small ice advances in the Jurassic.

One peculiar feature of the above CO_2 –climate relationship is that the ocean appears to play a minor role in regulating the long-term global changes in climate. This is not to imply that the ocean did not change. The development of the Antarctic Circumpolar Circulation, after the opening of the Drake Passage (~ 20 – 30 Ma?), must have had a significant effect on the ocean circulation – at the minimum causing enhanced mixing between the deep and surface waters as the surface barriers disappeared. Modeling and observational studies (Maier-Reimer et al., 1990) suggest that final closure of the Central

American isthmus around ~ 3 Ma had a very significant effect on poleward heat transport in the Atlantic Basin (Figure C45). However, convincing links to the onset of late Cenozoic glaciation are surprisingly hard to establish. Enhanced poleward ocean heat transport in the North Atlantic since ~ 3.0 Ma coincides closely in time with the spread of Northern Hemisphere ice, but it is unclear why the ice would grow in the presence of greater warmth (summer temperatures seem more important than winter moisture as a limiting factor for ice initiation).

A more important role for the ocean response to higher CO_2 levels seems to involve the redistribution of heat on the planet. Geological data consistently indicate a very significant reduction in the equator-pole temperature gradient during times of extreme warmth. These reductions cannot be convincingly simulated with the present generation of climate models. This discrepancy represents perhaps the single largest uncertainty with respect to our understanding of how the Earth responded to past changes in forcings, and raises questions as to whether some unexpected changes may occur in the future due to society’s emissions of greenhouse gases into the atmosphere.

A related discrepancy between models and observations involves indications that winter warming in high latitudes appears to be greater than simulated by models with increased CO_2 and even a forced change in the polar temperature gradient. However, the disagreements may not be disastrous and could simply be explained by higher CO_2 levels in the atmosphere, or uncertainties in the paleo-latitude of the fossil sites.

In addition to modeling the steady-state nature of warm climates, some work has been done on the changes in climate through the Phanerozoic. In some cases, there are relatively abrupt transitions between states that imply either a rapid change in the forcing or instabilities in the climate system. In addition to the spectacular asteroid impact at the end of the Cretaceous (66 Ma), three noteworthy examples of shorter-term climatic

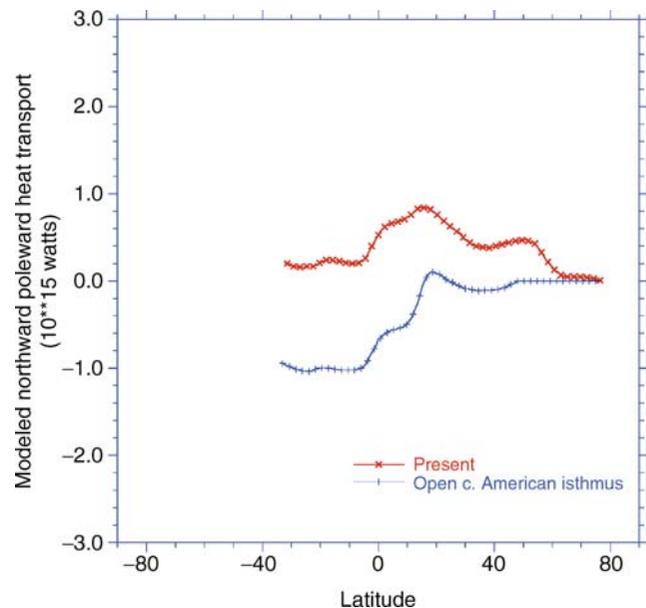

Figure C45 Comparison of polar heat transport in the Atlantic for an ocean model simulation with the present geography and with an open central American isthmus (based on results from Maier-Reimer et al., 1990).

events on long time scales (Zachos et al., 2001) involve an abrupt warming event that appears to have marked the warmest period of the Cenozoic around 55 Ma, the rapid expansion of ice on Antarctica around ~34 Ma, and another rapid climate change around 14 Ma. The first event (Paleocene-Eocene Thermal Maximum, or PETM) is associated (Zachos et al., 2003) with a rapid warming (order 10^3 – 10^4 year), a poleward expansion of subtropical biota, and abrupt warming of the deep-sea, which caused an extinction of some benthic organisms, an abrupt increase in global weathering rates, and a carbon isotope excursion that seems to be best explained by a sudden emission of methane clathrates buried on ancient continental margins (methane is a greenhouse gas that is rapidly converted to CO_2 in the atmosphere). This signal dissipated after about 200,000 years but may be the closest analog in the geologic record to how the climate system might respond to the current anthropogenic CO_2 perturbation.

The abrupt cooling around 34 Ma has long been known. It occurred over about 100,000 years and has been linked to an expansion of the Antarctic Ice Sheet and significant cooling of the deep oceans. Some recent modeling results (DeConto and Pollard, 2003) suggest that the rapid expansion of ice on Antarctica may reflect an unstable system response to slow decreases in atmospheric CO_2 . The third abrupt transition at about 14 Ma has been less examined. It has long been known from oxygen isotope records that an abrupt transition, perhaps as short as a few tens of thousands of years, occurred at this time and was associated with a further cooling of deep ocean waters. However, the precise nature of the triggering mechanism has been neither examined nor modeled.

As to reasons for the abrupt transitions, much effort over the last 20 years has been devoted to explaining and modeling abrupt climate shifts as a function of rapid reorganizations in the ocean-atmosphere system. However, for over 35 years, climate scientists have shown, first with simple energy balance models (Budyko, 1969) and later with more complex models, that it is also possible for models to rapidly evolve to a new climate state due to an instability related to the snow/ice albedo feedback. As temperatures cool due to, for example, CO_2 decreases, snow area either increases or (in the case of some regions) may be first preserved in summer. This new snow patch has much higher albedo (reflectivity) and further cools the system until it reaches a new equilibrium with significantly expanded ice area. General circulation model (GCM) experiments for the Permo-Carboniferous ice age (Crowley et al., 1994) provide some support for the idea that slow decreases in radiation (due to, for example, changes in CO_2 levels) result in a rapid increase in snow area at some critical point in the model (Figure C46). Further experiments linking GCMs to ice sheet models suggest that the abrupt change near the Eocene-Oligocene boundary (~34 Ma) may also be explained by this mechanism. Although still not widely accepted in the geological community, the snow-ice instability seems to be a very viable explanation for abrupt changes in ice extent in Earth history.

Glacial-interglacial timescale

For 50 years, it has been known from deep-sea records that there were numerous glacial-interglacial fluctuations in the late Pleistocene (Emiliani, 1955). With the advent of the Ocean Drilling Program, the record of glacial-interglacial fluctuations, as characterized by the oxygen isotope record of marine planktonic and benthic organisms, has been extended back millions of

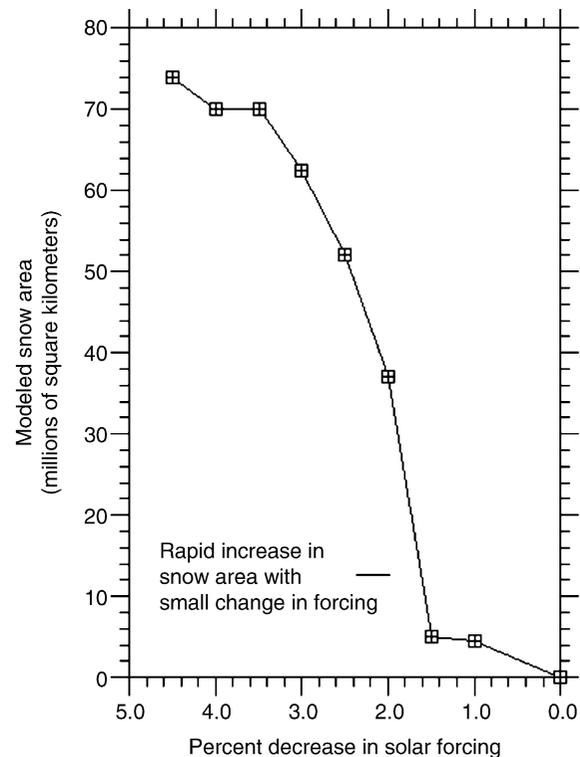

Figure C46 Model result illustrating the snowline instability. The figure shows the response of a snow cover in a general circulation model run for the Carboniferous ice age, versus changes in solar forcing (this is a conventional diagnostic tool for analyzing the response to any change in radiative forcing). Note that a decrease in solar radiation below a certain point results in rapid expansion of snow cover that would be associated with abrupt climate change, and glaciation, in the Earth record. (Modified from Crowley et al., 1994).

years. The records consistently show (Shackleton and Opdyke, 1976) that the expansion of Northern Hemisphere glaciation was a stepwise process, with Greenland glaciating first, then “small” ice sheets fluctuated at a ~41,000 year period, and in the last million years, very large ice sheets fluctuated primarily at the 100,000 year period.

It has now been established beyond a reasonable doubt that the primary factor responsible for the waxing and waning of the major ice sheets has been periodic seasonal variations of the Earth’s insolation due to orbital perturbations primarily from the gravitational fields of the Sun, moon, and Jupiter. This is the so-called Milankovitch Hypothesis or the Orbital Theory of Glaciation (Milankovitch, 1930) that was first convincingly demonstrated in an important paper by James Hays, John Imbrie, and Nicholas Shackleton (Hays et al., 1976). A key feature of this paper is that continental ice volume responds almost linearly to the orbital perturbations on shorter periods of ~41,000 years (obliquity or tilt of the Earth’s axis) and ~23,000 years (precession), while on the 100,000 year time scale the response to eccentricity variations is nonlinear. Another historic contribution comes from the Vostok (Antarctica) ice core (Figure C47), which indicates that CO_2 and Antarctic temperatures fluctuated almost in parallel for the last 400,000 years, with both strongly influenced by orbital variations (Petit et al., 1999). This result again implicates CO_2 variations as a major amplifying factor of past climate change.

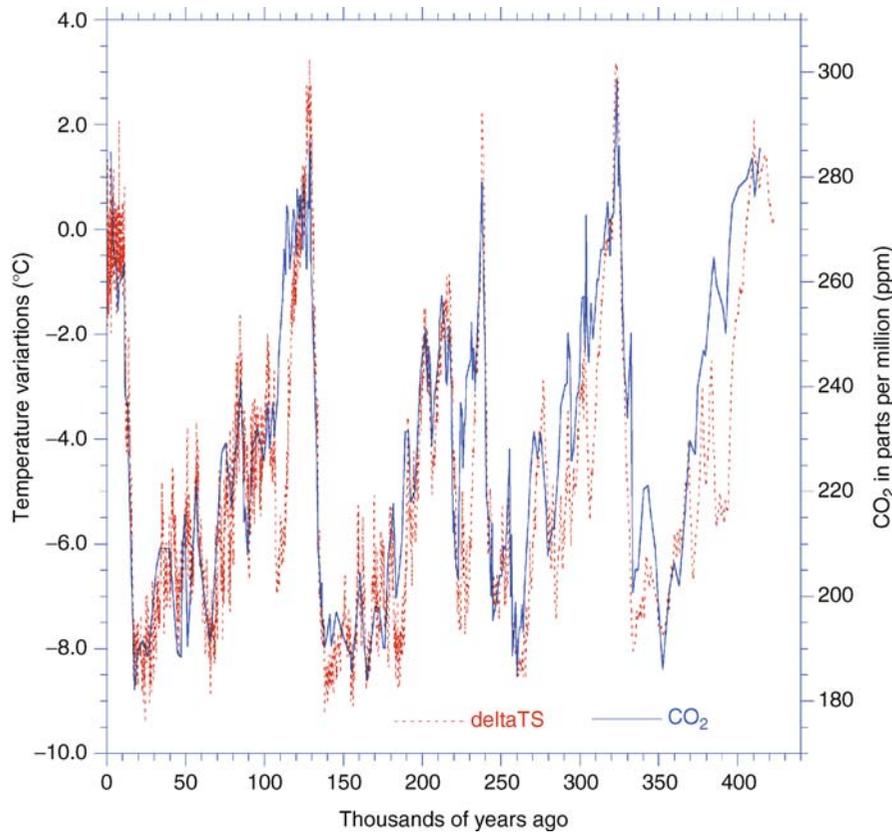

Figure C47 Comparison of carbon dioxide and deuterium temperature record from the Vostok ice core, illustrating a very tight coupling between the two records (the disjoint relationship in the oldest interglacial may reflect sampling problems at the bottom of the core). (Modified from data in Petit et al., 1999).

Since the Hays et al. (1976) paper, the principal modeling efforts have been associated with explaining how the ocean-atmosphere system translates orbital perturbations into ice volume fluctuations of the observed magnitude. A virtual mathematical zoo has been proposed as possible explanations for the 100,000 year cycle. Unfortunately, there has been little effort to cull among the different hypotheses, comparing predictions that can be falsified. Nevertheless, the dominant thinking at present is that the inherent nonlinearities associated with ice sheet dynamics are somehow responsible for the amplified response at the 100,000 period (e.g., Saltzman and Sutera, 1987). One example of how this process works is that, following an interglacial period, low summer insolation during a “cool summer orbit” leads to preservation of permanent snow fields, which over time build up into an ice sheet and flow into lower latitudes. At full glacial maximum conditions, the ice buildup depresses the Earth’s crust by as much as 1 km (Figure C48).

During a subsequent “warm summer orbit” configuration, melting of the ice sets in. Because the elastic rebound of the Earth’s crust is slower than the thinning of the ice sheet, the ice sheet is essentially “trapped” at low elevations, leading to catastrophic melting. The very rapid wastage in the time domain is translated into more power in the frequency domain at 100,000 year periods. CO₂ represents an important amplifier for the whole process. Application of a model of this type (Tarasov and Peltier, 1997) to the evolution of the last glacial cycle (Figure C49) suggests results in quite good agreement;

however, a fuller explanation for Pleistocene climate change requires understanding the origin of the CO₂ changes and further testing of the “ice trapping” model.

As with the tectonic timescale, there is also a great deal of interest in the role of abrupt climate instabilities facilitating the glacial-interglacial oscillations. For example, the first rapid melting of ice starting at about 19,000 calendar yBP seems to have occurred within a few centuries and caused about a 15 m increase in global sea level. A second phase of rapid melting began about 14,500 calendar yBP. This step was preceded by a slow but steady CO₂ increase, to about half of its Holocene value. There was also an abrupt increase in the overturning of the North Atlantic circulation that started at 14,500 yBP. Since the North Atlantic circulation provides substantial heat to the high latitudes in the strong overturning mode, this feedback presumably contributed to the rapid wasting of ice.

Some mechanism is needed to explain the rapid change in the state of the North Atlantic system. As Hays, Imbrie, and Shackleton demonstrated in 1976, some of the first signs of warming at the end of a glacial period occurred around Antarctica – perhaps because Antarctic sea ice has a far lower thermal inertia than the great northern hemisphere ice sheets. A number of recent studies now suggest that changes in the ocean circulation around Antarctica may have altered the production rate of Southern Ocean deep water, which, when it upwells in the North Atlantic, influences the production rate

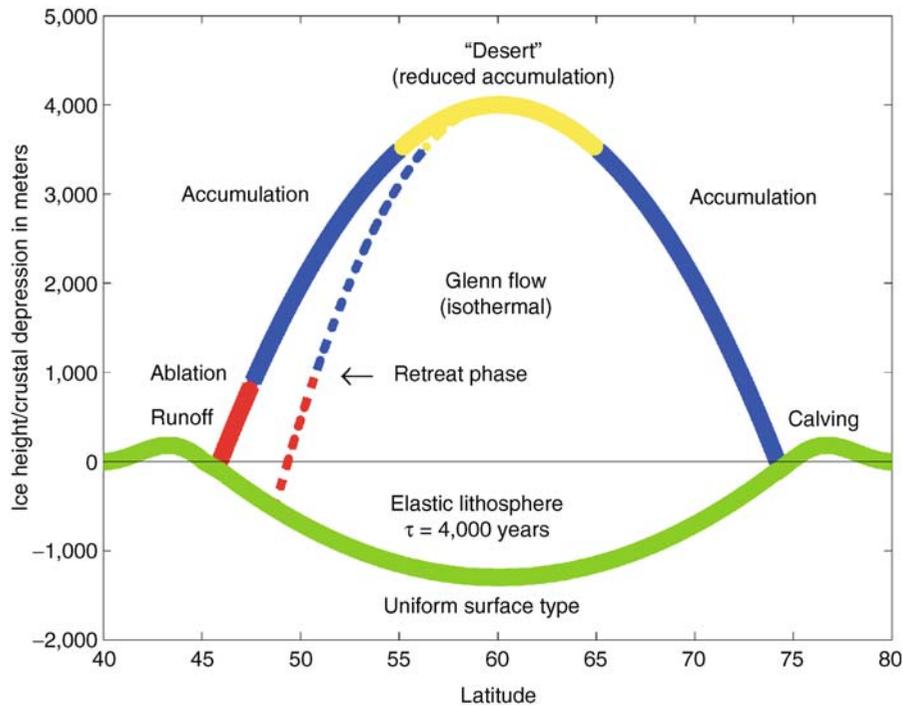

Figure C48 Schematic cross-section of Pleistocene ice sheets, illustrating zones of ablation and accumulation, and isostatic depression of the crust by the ice sheet. During times of rapid melting the ice will lay “trapped” in the depression due to the long response time of mantle rebound, resulting in rapid deglaciation (figure courtesy of William T. Hyde).

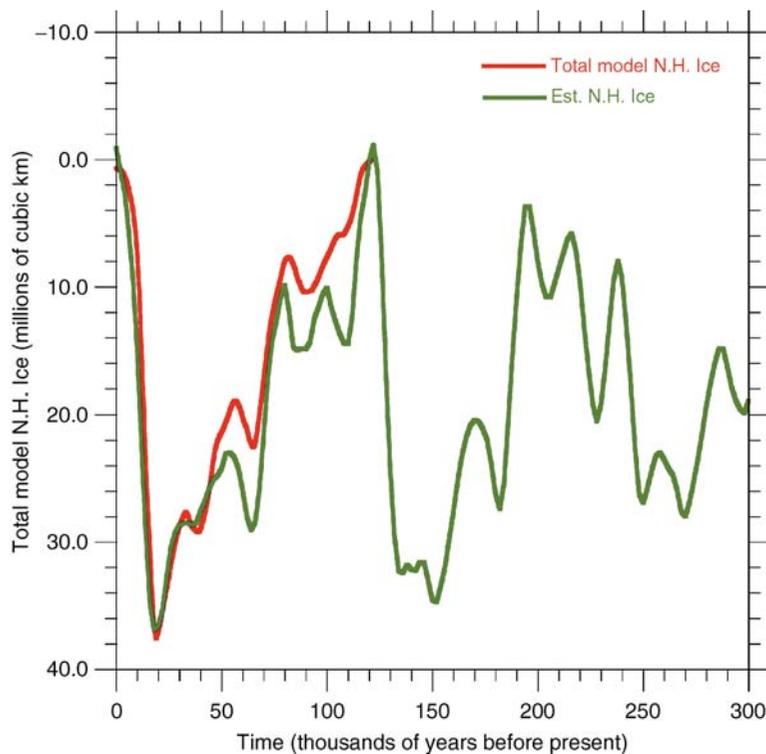

Figure C49 Comparison of modeled and observed Northern Hemisphere ice volume for the late Pleistocene. Observed variations based on marine oxygen isotope measurements converted to ice volume. Model result for the last glacial cycle based on the University of Toronto ice sheet model, which was driven by orbital forcing, CO_2 changes and variations in North Atlantic heat transport (model result courtesy of William Hyde).

of North Atlantic Deep Water. A sudden reduction of deep water formation around Antarctica might then have caused an abrupt “switch on” of the North Atlantic (Mikolajewicz, 1998). It is presently debated whether early CO₂ increases may have triggered the Antarctic changes around 19,000 BP, but the timing of the changes is sufficiently close to suggest such a possibility.

There has also been a great deal of interest in smaller but rapid changes in the ocean-atmosphere system during the “interstadial” period preceding the last glacial maximum. Records from Greenland ice cores, the North Atlantic, Eurasia, North America, and parts of the tropical regions of the South American-Indian Ocean sector indicate a fairly close correlation between the timing of abrupt changes in different regions that may reflect in part rapid and abrupt oscillations of the North Atlantic Deep Water circulation. The triggering link for the North Atlantic changes may involve some episodic outbursts of melted ice-rafted material from the continents that change the ocean salinity and short-circuit the overturning circulation.

The millennial and orbital scales cannot be viewed in isolation. It is clear that orbital forcing is virtually omnipresent in all paleoclimate records of at least the last million years. It is also clear that the system has undergone abrupt transitions. The relation between the two presumably involves the fact that, for glacial and interglacial transitions, slow changes in orbit forcing results in threshold responses in ice growth (e.g., snowline or thermohaline instabilities discussed above) and possibly CO₂. The system then goes through an abrupt transition on

its eventual trajectory to a state determined by the longer term forcing. The details of how these steps occur have yet to be elucidated.

Centennial-millennial timescale

Records primarily of the last 10,000 years provide information on shorter timescale climate that enable placement of the twentieth century warming in a longer-term perspective. Such data are also valuable in assessing different mechanisms for decadal-millennial climate change. Reconstructions (e.g., Figure C50) from the last 1,000 years of tree rings, ice cores, and corals provide a general picture of warm Middle Ages followed by a cold “Little Ice Age” that began in the late thirteenth century and persisted until the middle of the nineteenth century. Composites of such fluctuations generally agree with the lower resolution record derived from studies of the advance and retreat of alpine glaciers.

In addition to refining estimates of the magnitude and timing of past climate change, new paleotemperature reconstructions enable more precise estimates of the relative importance of different mechanisms for climate change. It has long been postulated that changes in the frequency of intense volcanic eruptions may have influenced climate on this time scale. Similarly, changes in the output of the Sun have also been postulated. Finally, there were small changes in the CO₂ content of the atmosphere during the Little Ice Age that have been recorded in ice cores, and also a long-term increase in trace gas concentrations for the last few thousand years.

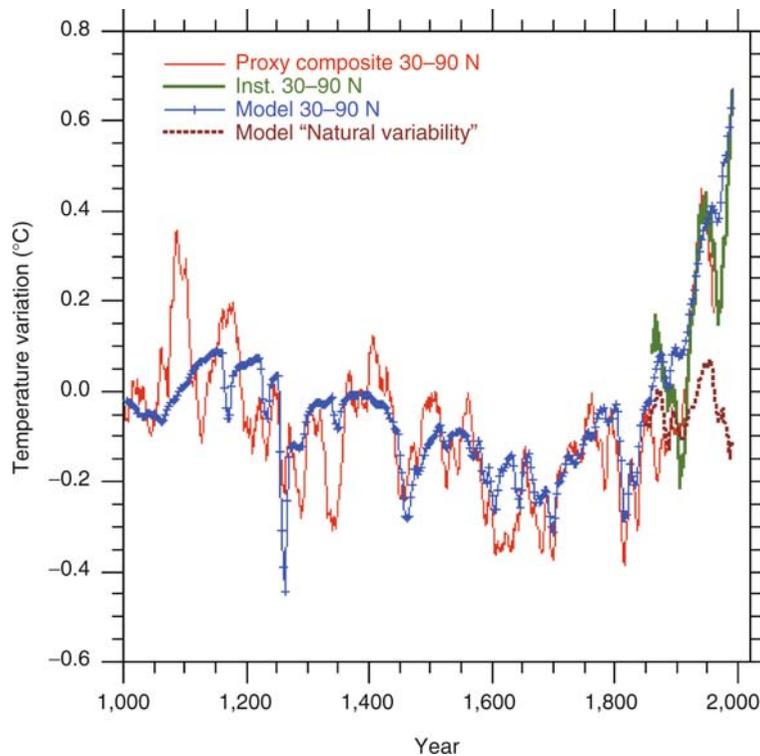

Figure C50 Sample comparison of model simulations of climate change over the last 1,000 years with observations from both the instrument and paleoclimate records. Reconstructed temperatures are for 30–90° N, where most of the long records are preserved. Model results driven by changes in greenhouse gases, volcanism, and output of the sun. Pulses of volcanism primarily account for climate change in the “Little Ice Age” (~1250–1850). Note that although the model does a good job of explaining about half of the decadal variance prior to about 1850, only the addition of greenhouse gases of anthropogenic origin can explain the late twentieth century temperature rise. (Modified from Crowley et al., 2003).

Reconstructions of volcanic, solar, and greenhouse gas forcing have enabled testing of the relative importance of different mechanisms for climate change. The volcanic reconstructions are based on sulfate deposited in Greenland and Antarctic ice cores. Solar variability can be inferred from variations of the cosmogenic isotopes ^{14}C and ^{10}Be . Trace gas concentrations are derived from ice cores. Experiments with both simple and complex climate models indicate that there is a surprisingly large forced response in the decadal-centennial band (Figure C50). More detailed analyses indicate that changes in volcanism can explain about 40% of the variance in the interval 1,000–1,850, i.e., prior to the enhanced disturbance of the system following the industrial revolution (Crowley et al., 2003). By contrast, solar variability and trace gas changes play only a secondary role on the largest scale (Hegerl et al., 2003); although there is some evidence that solar variability may occasionally be proportionately more important on smaller space scales.

The importance of solar variability seems to increase on the millennial timescale (Figure C51). There are a number of known millennial scale climate fluctuations that have long been identified as punctuating the generally warm time of the Holocene. In particular there are changes at about 5,500 BP (calendar years before present), 4,500 BP, and 2,700 BP. In the North Atlantic basin, these and other Holocene fluctuations bear a striking correspondence to solar forcing as inferred from variations of ^{14}C and ^{10}Be . These data suggest that the importance of solar forcing may be timescale-dependent – it is relatively weak on the decadal-centennial scale, but proportionately more important on the millennial scale. The general explanation for

such a frequency dependency may involve the fact that there is generally more variance at lower frequencies in geophysical systems. A weak solar signal at decadal-centennial scales may become sufficiently strong at the centennial-millennial scale to leave a clearer imprint on geologic records, especially since there is much less evidence in support of any millennial variability in volcanism.

The above analysis can explain the quasi-cyclical millennial scale oscillations of the Holocene that appear to be influenced by solar activity. However, volcanic activity in the last millennium has had a major effect on the system response during this time and has exerted a great influence on multi-decadal time scale fluctuations. This could explain why the Little Ice Age was the most extreme climate cooling of the last 1,000 years. This analysis therefore suggests that solar forcing may only reach significant levels for climate fluctuations greater than about a century in length.

The clarification of the relative importance of different types of natural forcing has enabled better understanding of the twentieth century trends in the instrumental record. Natural forcing alone, which can explain much of the pre-industrial interval, accounts for only a fraction of the twentieth century record. Viewed from the paleoclimate perspective (Figure C50), the recent temperature increase appears to be much more clearly driven by the anthropogenic greenhouse gas perturbation. Such a conclusion is consistent with an increasing body of analyses of instrumental records and points to the likelihood that the greenhouse perturbation has already manifested itself in the climate system.

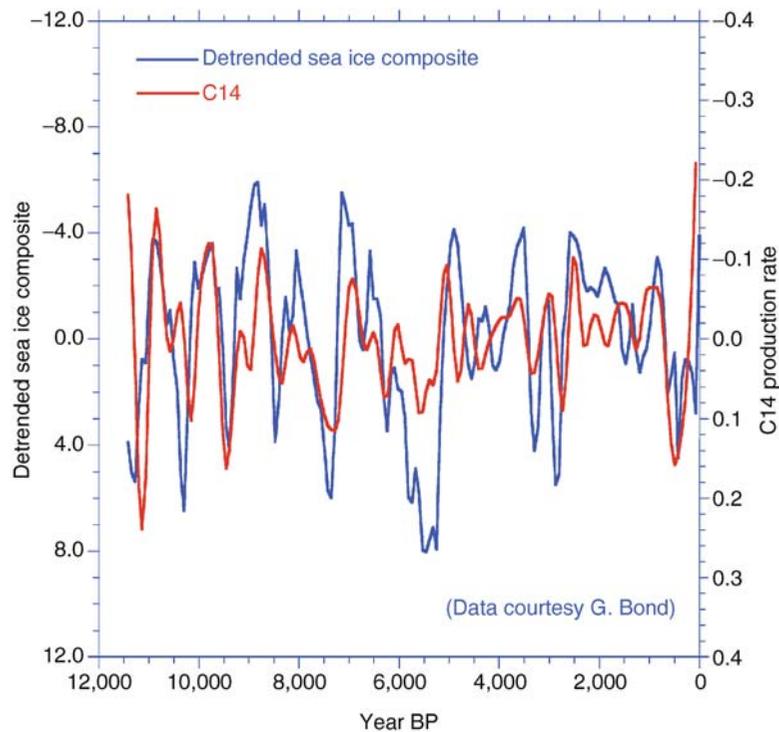

Figure C51 Comparison of atmospheric residual carbon-14 variations of the last 11,000 years with a record of sea ice variations in the subpolar North Atlantic. Positive values on the left axis indicate expansion of sea ice; positive values on the right axis indicates increase in C-14 production rate, which has been associated with a decreased output of solar irradiance. On century-millennial timescales, changes in solar variability may explain a proportionately larger amount of variance than volcanism in climate records (based on results from Bond et al., 2001).

Summary

A great deal has been learned about the causes of past climate change. CO₂ appears to play perhaps the dominant role as the first-order “driver” of climate change on tectonic timescales. However, CO₂ cannot explain everything. In particular, the altered planetary temperature gradient during warm time periods indicates a response of the ocean-atmosphere system that represents perhaps the most prominent difference between models and observations in the paleoclimate record. Understanding this response may enable more confident predictions of greenhouse model simulations of the future.

A second important consideration of climate change on tectonic timescales involves the rapid transitions to ice cover at various times in the Phanerozoic. Models suggest that this transition may be explicable by a snowline instability due to albedo discontinuities at the snow-ice edge. This instability has received much less attention than changes in the ocean circulation, but is fully deserving of equal prominence as a mechanism for rapid climate change.

On ice-age timescales, orbital forcing plays an important role in “pacing” the timing of glacial and interglacial advances. Instabilities appear to play a crucial role with respect to both ice advance and decay; the snowline instability may be more important for ice growth, but ocean changes coupled with ice sheet dynamics may be necessary to explain deglaciations. CO₂ is at the minimum an important amplifier of these responses and for deglaciation may play a fundamental and necessary role in driving the system to full interglacial conditions. Even after almost 25 years since its discovery, the cause of the ice age CO₂ changes continues to elude a satisfactory, consensus explanation.

Volcanism and solar variability appear to play the most important roles on decadal-millennial time scales. Solar variability appeared to have some influence on centennial-scale cooling events in the Holocene. However, the most severe cooling in the last 8,000 years – the Little Ice Age – may have resulted from a wave of volcanism superimposed on a modest cooling of solar origin. Projections of “natural forcing” into the twentieth century indicate that only a fraction of the observed warming can be explained by these processes; anthropogenic greenhouse warming appears to have established itself above the noise level of the geologic record. Future warming projections suggest that conditions comparable to the Pliocene-Miocene warm periods could occur by the end of the twenty-first century. Full utilization of the fossil fuel reservoir could drive temperatures up to levels not experienced since the Eocene warm period, 50 million years ago.

The greatest remaining issues involve:

1. Explanation for the altered equator-pole temperature gradient during past warm time periods.
2. Coupling between low-frequency orbital forcing and abrupt responses in the ocean-atmosphere system on ice age time scales.
3. The origin of ice age CO₂ changes.

CLIMATE FORCING

Climate forcings are usually thought of as being small, sustained changes that are externally imposed on either the solar or thermal component of the planet's radiation energy balance, thereby driving the climate system to a new thermal equilibrium. Climate change is frequently associated with changes in atmospheric circulation that alter the prevailing precipitation and temperature patterns. However, since the atmospheric circulation is ultimately driven by temperature contrasts, the climate forcings are ultimately radiative in nature.

Regarding climate forcings that are relevant to current climate, the gradual increase of greenhouse gases such as CO₂, CH₄, N₂O, CFC₃ and CF₂Cl₂ has the effect of strengthening the terrestrial greenhouse effect, and thus leading to enhanced global warming. Other contributors to current global climate change include changes in the amount and vertical distribution of ozone as well as the increase of both absorbing and non-absorbing aerosols whose differing radiative properties partially cancel each other's radiative forcing effects. Periodically, large volcanic eruptions inject large amounts of sulfur-bearing gases into the stratosphere. These gases become globally dispersed and are converted photochemically into sulfuric acid droplets, which block the incoming solar radiation and cool the ground surface until the aerosols fall out from the stratosphere. Changes in solar luminosity also contribute to climate forcing, although the observed variations in solar luminosity are small and coincide with sunspot activity during the course of the 11-year sunspot cycle. Larger changes in solar luminosity are believed to occur over longer time scales and are thought responsible for unusually cold periods such as the Little Ice Age during the Maunder Minimum in the seventeenth century, when sunspot activity had virtually ceased.

A change in radiative forcing does not necessarily have climatic consequences. Large changes in solar illumination occur as part of the diurnal cycle and large seasonal changes in solar heating take place in the polar regions. This produces largely repetitive short-term temperature fluctuations that are nevertheless part of what we regard as the prevailing equilibrium climate. The bona fide climate forcings are radiative forcings that are sufficiently large in magnitude, and/or are sustained enough to overcome the large heat capacity of the

ocean, land, and atmosphere, and thus produce a change in the annual mean radiative energy balance of the Earth sufficient to move the prevailing climate away from its reference norm.

Cataclysmic climate forcings

Astrophysical models of solar evolution indicate that the luminosity of the Sun was about 25% less than its present value in the early days of the solar system (see *Faint Young Sun Paradox*). This would have been a very large climate forcing, which, if applied to the present atmospheric composition, would quickly produce a solidly frozen planet from equator to pole. The fact that the Earth has maintained a viable biosphere for billions of years implies that a strong CO₂ greenhouse effect must have been operating at that time to have sustained temperatures that were sufficiently moderate for liquid water to exist in the environment. This also implies that, over the geological time frame, the biosphere of the Earth was able to successfully navigate the gradual reduction of atmospheric CO₂ to present-day levels as solar luminosity was increasing, thus avoiding the runaway greenhouse catastrophe that befell Venus and rendered it inhospitable to life.

The geological record is also punctuated by catastrophic climate forcings that are very likely the result of major comet or asteroid impacts, which in some cases have been linked to mass extinctions. Of these, perhaps the best documented is the end of Cretaceous mass extinction 65 million years ago, in which the dinosaurs and many other animal species of that time perished. This mass extinction has been associated with the multi-ringed, Chicxulub Crater, roughly 100 miles in diameter, which is located on the northern coast of the Yucatan Peninsula in Mexico, and which is believed to have been formed by the impact of a comet or asteroid perhaps ten miles in diameter. Another notable mass extinction occurred at the end of the Permian period 245 million years ago when 95% of the living species were wiped out. The geological record suggests that major extinctions have occurred roughly at intervals of 25–30 million years, a periodicity that according to one hypothesis has been associated with oscillations of the solar motion through the galactic plane. Encounters with the denser media of the galactic plane are thought to disturb the Oort Cloud of comets surrounding the Sun, causing an increased number of comets to drop down into the inner parts of the solar system, thereby "loading the dice" for catastrophic encounters. Such comet and asteroid impacts can release enormous amounts of energy; sufficient to vaporize hundreds of cubic kilometers of solid rock, which if dispersed globally would produce extensive clouds of light scattering particles high in the stratosphere. The initial firestorm of the impact would deposit a great deal of heat in the atmosphere, at least locally, and would be followed by prolonged global cooling that would last for several years until the dust settled out. This would have enormous climatic consequences; first by overheating the environment, then by blocking solar radiation from reaching the ground, stopping photosynthesis, and eliminating entire species unable to cope with the climatological consequences.

Geological scale climate forcings

Other climate forcings that have had a profound impact on climate are the changes in topography and continental layout that occur very gradually on a timescale of many millions of years. High mountain ranges such as the Andes and Himalayas strongly affect the local climate via altitude of the land. They also affect the atmospheric circulation and determine where

precipitation will fall and where arid conditions will prevail. Similarly, as the continental layout changes with continental drift, the ocean currents readjust and produce climate change. Absence of land in the polar regions to anchor potential ice sheets is believed to have been instrumental in maintaining the relatively mild temperatures during the Mesozoic period.

Another type of climate forcing and one that is responsible for the classical shifting of global climate between cold ice ages and warm interglacial periods over the past several million years is known as the astronomical or Milankovitch theory of climate change. This involves slow variations of the Earth's orbital parameters due to the gravitational influence of other planets. As a result, the tilt of the rotational axis of the Earth with respect to the orbital plane wobbles by more than a degree with a period of about 41,000 years. This affects the amplitude of the seasonal temperature change. Furthermore, because the orbit of the Earth is not fully circular, the Earth moves closer in and farther away from the Sun during the course of the year. At present, the closest point of approach, or perihelion, occurs in January, at which point the Earth receives about 7% more solar energy as compared with July when the Sun-Earth distance is at its maximum. The seasonal timing of perihelion occurrence is associated with the precession of the equinoxes, which takes about 22,000 years for a full cycle. In addition, the degree of oblateness of the Earth's orbit varies on a timescale of roughly 100,000 years. These perturbations have little effect on the annual mean solar energy that strikes the Earth, but they do alter the geographical and seasonal distribution of solar illumination by as much as 10–20%, being particularly effective in the polar regions.

Precisely how these slow variations in geographical and seasonal insolation act to produce an ice age climate is not yet fully understood. Ice core analysis of trapped air bubbles in the Antarctic and Greenland Ice Sheets indicates that atmospheric CO₂ levels 20,000 years ago were roughly half of present day concentrations. Climate model simulations of ice age climate show that the radiative forcing characteristic of ice age climate was about 6 W m⁻² less than for the current climate, due primarily to the effect of vast continental ice sheets that account for about 3.5 W m⁻², and to the decreased amount of greenhouse gases (CO₂, CH₄, and N₂O), which contribute about 2.5 W m⁻². This amount of radiative forcing was sufficient to maintain a global mean temperature 5 °C colder than the present global mean, consistent with the global mean temperature that has been inferred from polar ice core δ¹⁸O isotope ratios. This implies a climate sensitivity of nearly 1 °C global mean temperature change per 1 W m⁻² of radiative forcing for ice age climate, which is basically the same sensitivity that is obtained from climate model simulations conducted for current climate.

Nevertheless, a careful analysis of the ice core record shows that the observed temperature changes tend to precede the CO₂ and CH₄ changes by 500–1,000 years. This implies that the observed changes in CO₂ and CH₄ may be positive feedback responses by the ocean and the biosphere to the Milankovitch forcing. Just how this CO₂ and CH₄ feedback response might operate has not been fully demonstrated. The distinction between what constitutes a climate forcing and a climate feedback is not a clearly defined concept and depends on the timescales that are involved. On the one hand, there are fast feedback processes such as the evaporation and condensation of water vapor and the seasonal melting and freezing of snow and ice. These feedback processes respond quickly to changes

in radiative forcing and provide a positive feedback magnification of the original forcing. This is because water vapor is a strong greenhouse gas and the addition of more water vapor to the atmosphere produces more greenhouse warming. The melting of snow and sea ice lowers the albedo of the Earth and allows more solar radiation to be absorbed. Clouds also fall in the category of fast feedback processes, but are more complicated in that an increase in high-altitude cirrus would provide a positive feedback because of their strong greenhouse effect, while an increase in low-level clouds would increase the planetary albedo and thus provide a negative feedback. On the other hand, slow geophysical processes such as the growth and decay of continental ice sheets, changes in vegetation cover, and the gradual change in atmospheric CO₂ and CH₄ levels, may operate as feedback processes on geological timescales but act as radiative forcings on short (decadal) timescales.

The susceptibility of the Earth to ice age climate appears largest when alignment of the orbital parameters is most favorable for cold Northern Hemisphere summers. However, in climate model simulations, the Milankovitch forcing alone is not enough to initiate an ice age. It appears that a triggering mechanism, such as strong global cooling from a series of large volcanic eruptions, or a temporary decrease in solar luminosity, may be necessary to ensure that the winter snowfall accumulation does not melt during the following summer and becomes instead the foundation of a new continental ice sheet. However, once established, ice age climate is stable in the sense that the prevailing colder global temperature is in equilibrium with the combined radiative forcings due to the continental ice sheets and the depleted greenhouse gases.

A closer look at the geological temperature record based on isotope ratios found in Antarctic ice cores shows a complex time series of global mean temperature fluctuations. For most of the past 4 million years, the time series is characterized by a cold ice age climate. The warm interglacial periods appear to be relatively brief and tend to occur at intervals of roughly 100,000 years, and last perhaps 10,000–20,000 years. There are slow periodic fluctuations where the global temperature undergoes changes of more than several degrees on timescales of 10,000 years, on which are superimposed faster oscillations of less than 1,000 years in duration with amplitudes smaller than 1 °C. This only serves to illustrate the limitations of present day climate models, which appear capable of calculating the direct impact of radiative forcings with reasonable accuracy and in estimating the magnitude of feedback responses of the fast feedback processes but do not possess the necessary physics to model the full ice age cycle of climate change.

There may be additional uncertainties and non-linear effects involved in these slow-process climate forcings as suggested by the asymmetric nature of the more or less slow and steady growth of continental ice sheets followed by a more rapid ice sheet decay. The extent to which an ice sheet will grow or decay is determined by a complex balance between snow accumulation over the ice sheet relative to ice loss due to melting and ablation. A strong hydrological cycle is needed to supply ample moisture for ice sheet growth, and sufficiently cold summer temperatures are needed to sustain the accumulation of snow over the ice sheet. Ice sheet melting, however, is not simply the reverse process of ice accumulation. During ice sheet decay, ice dynamics aided by ice-melt lubrication injected via ice crevasses may undermine the ice sheets and lead to an accelerated breakup, processes that would not be operating during ice sheet buildup.

Radiative nature of climate forcings

The purely radiative aspects of climate forcing have been more thoroughly studied and can be described more quantitatively. As illustrated in Figure C52, the atmospheric temperature decreases steadily with height, due partly to radiative cooling by atmospheric gases but also due to the convective and dynamic transport of energy within the troposphere, which acts to maintain a global mean temperature gradient of about $5.5\text{ }^{\circ}\text{C km}^{-1}$. About half of the incident solar radiation is absorbed by the ground surface, from where the absorbed energy is transported upward in the form of latent and sensible heat and mixed throughout the troposphere by convective motions. For an atmosphere that is in radiative-convective equilibrium, convective heat transport along with longwave cooling by atmospheric water vapor, CO_2 , clouds, and other gases, work together to balance the atmospheric heating due to absorbed solar radiation. Convective heat transport also acts to bind the tropospheric temperature profile to the ground surface and to the very large heat capacity of the ocean. The stratosphere on the other hand is in a state of purely radiative equilibrium where the local heating due to the absorption of solar UV radiation by ozone is balanced by the longwave cooling due primarily to CO_2 . It is the local maximum concentration of ozone above the tropopause that produces the characteristic temperature profile in the stratosphere.

For the current climate, the global mean surface temperature is about 288K ($15\text{ }^{\circ}\text{C}$). The Earth has a planetary albedo of 0.3, because of which, the global mean solar energy absorbed is 239 W m^{-2} . For the Earth in radiative equilibrium, this dictates an effective Planck radiating temperature to space of 255K . The difference between the surface temperature and the effective radiating temperature ($33\text{ }^{\circ}\text{C}$) defines the total greenhouse strength of the Earth's atmosphere. This means that if the atmosphere of the Earth were totally transparent to all radiation (and if the Earth still had a global albedo of 0.3), the global mean surface temperature would be 255K ($-18\text{ }^{\circ}\text{C}$) instead of 288K . The point within the atmosphere where the physical temperature is equal to the effective radiating temperature is determined by the vertical distribution of the longwave

absorbing gases (H_2O , CO_2 , O_3 , CH_4 , N_2O) and clouds, and coincides with the point where the effective longwave opacity (as viewed from space) is unity. For the current climate, this point occurs at about a height of 6 km.

As illustrated in Figure C52a, the simplest measure of radiative climate forcing is the instantaneous forcing ΔF_i (W m^{-2}). When a radiative forcing such as doubled CO_2 is applied, the longwave fluxes change throughout the atmosphere. By evaluating the instantaneous radiative flux change at the tropopause, a reasonably good estimate of the eventual change in equilibrium surface temperature is obtained. This is because the tropospheric temperature profile is strongly bound to the surface temperature via convective heat transport, so that evaluating the flux imbalance at the tropopause gives a good estimate of the radiative forcing that is applied to the troposphere-ground system. A better estimate of the expected surface temperature change is obtained from the adjusted forcing, ΔF_a , whereby the stratosphere is allowed to adjust to its new radiative equilibrium before evaluating the radiative flux difference. This provides a more accurate measure of the radiative flux imbalance that actually drives the climate system. Because the heat capacity of the stratosphere is very small, the stratosphere will reach radiative equilibrium in a matter of months, long before the surface temperature has had a chance to respond appreciably.

Figure C53 shows the equilibrium surface temperature change, ΔT_o , which is obtained after the ocean, with its large heat capacity, has fully responded to the applied forcing, ΔF_a , in the artificial case that no feedback processes are allowed to operate. As might be anticipated, ΔT_o and ΔF_a , differ only by a relative scale factor where $\Delta T_o(^{\circ}\text{C}) \sim 0.3\Delta F_a$ (W m^{-2}), with the exact value of the constant depending somewhat on the latitudinal, spectral, and height distribution of the applied forcing. As indicated, instantaneous doubling of CO_2 increases the longwave opacity of the atmosphere. This forces the effective radiating level (the point where longwave opacity is unity) to a higher altitude where the temperature is colder; therefore, less thermal energy is radiated to space, thereby trapping the amount ΔF_a . Since the solar heat input remains fixed, the

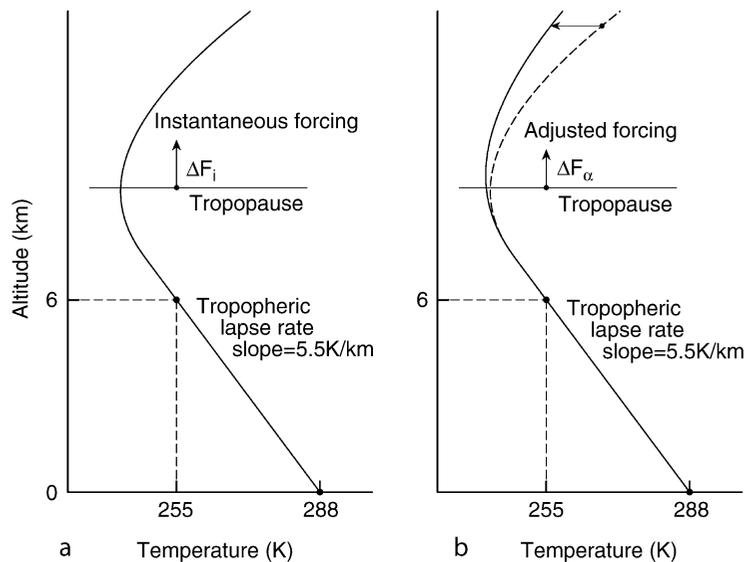

Figure C52 Schematic global mean temperature profile of the Earth. (a) Instantaneous forcing ΔF_i evaluated at the tropopause. (b) Adjusted forcing ΔF_a after allowing stratosphere to cool.

trapped thermal energy forces the atmospheric and surface temperatures to increase until radiative energy balance is restored.

When feedbacks are allowed to operate, there is a further increase in atmospheric temperature, as is shown in Figure C53b. This is because the initial warming of the atmosphere by the amount ΔT_o due to doubled CO_2 forcing induces more evaporation of water vapor, causes additional melting of snow and sea-ice, increases the amount of high-altitude cirrus, and decreases low-level clouds – all of which act to magnify the original temperature change of the initial radiative forcing perturbation.

The all-feedback response, ΔT_s , can be thought of as being the sum of the applied no-feedback forcing, ΔT_o , plus a contribution, ΔT_f , that arises entirely due to feedbacks, such that $\Delta T_s = \Delta T_o + \Delta T_f$. In typical doubled CO_2 climate experiments, $\Delta T_o = 1.2^\circ\text{C}$, with the global mean temperature change attaining $\Delta T_s = 4.0^\circ\text{C}$ at equilibrium. The ratio f , by which the no-feedback forcing is magnified, is called the climate feedback factor, such that $\Delta T_s = f\Delta T_o$, which for current climate yields $f = 3.3$.

The strength of the climate feedback response is given by the ratio $g = \Delta T_f / \Delta T_s$, which is also called the feedback gain

factor, and for current climate is about 0.7 (see *Albedo feedbacks*). From this we see that the feedback gain factor is related to the feedback factor by $f = (1 - g)^{-1}$. In this formulation, the relative strengths of individual feedback processes can be directly compared because the gain factors for water vapor, snow and ice, and cloud feedbacks combine linearly in the form $g = g_w + g_s + g_c$. Thus, the climate system of the Earth is seen to operate with a strongly positive overall feedback so that a relatively small change in the gain efficiency of any one of the feedback processes can have a disproportionately large effect in magnifying an applied radiative forcing.

The largest uncertainty in estimating the climate system response to an applied radiative climate forcing is associated with determining the strengths of the various feedback processes, which depend on complicated physical interactions that are difficult to model. Radiative forcings, on the other hand, can be calculated with good accuracy and can be expressed in terms of either the adjusted forcing, ΔF_a , or the no-feedback forcing response, ΔT_o . The radiative forcing due to changes in atmospheric CO_2 is shown in Figure C54a, and in Figure C54b for CH_4 and N_2O .

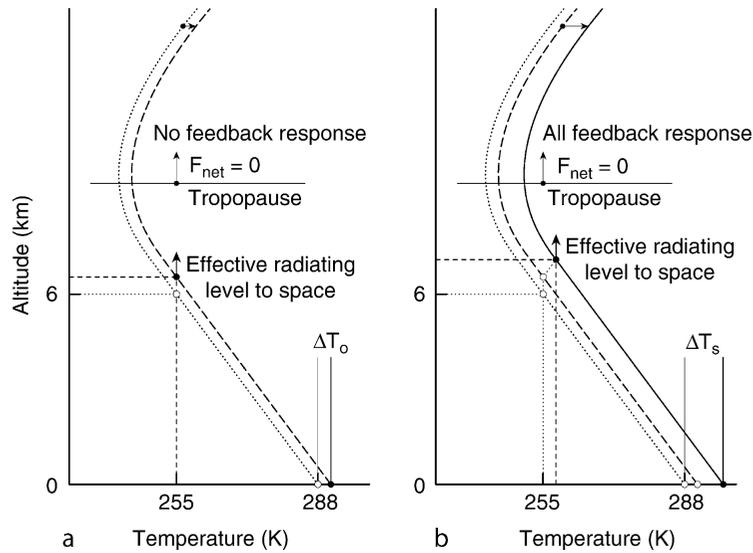

Figure C53 Schematic illustration of equilibrium response to doubled CO_2 . (a) No-feedback forcing response ΔT_o . (b) All-feedback response ΔT_s .

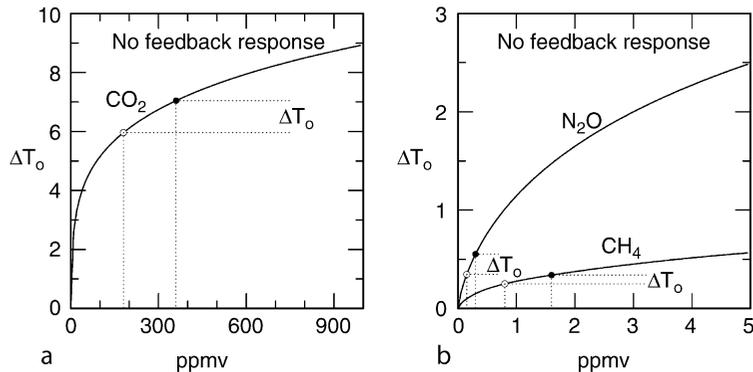

Figure C54 No-feedback forcing ΔT_o for (a) CO_2 , and (b) CH_4 and N_2O . Filled circles represent current atmospheric amounts. Open circles show ΔT_o for half of the current concentrations.

These no-feedback forcings show considerable saturation with increasing absorber concentration, particularly for CO₂. The curves are roughly logarithmic in nature; hence, the radiative forcing for a doubling of the gaseous concentration is not overly sensitive to the precise reference point. Also of note, if all CO₂ were removed from the atmosphere, the radiative forcing would be $\Delta T_0 \sim 7^\circ\text{C}$, and if we include also the radiative forcings for the current atmospheric amounts of CH₄, N₂O, the CFCs, and ozone, we obtain an additional $\Delta T_0 \sim 3^\circ\text{C}$. Together, the greenhouse forcing due to these non-volatile greenhouse gases (i.e., greenhouse gases that will not condense and precipitate from the atmosphere in response to temperature change) is approximately $\Delta T_0 \sim 10^\circ\text{C}$. The total greenhouse effect of the Earth's atmosphere (given by the difference between global mean surface temperature and the effective radiating temperature of the Earth) is $\Delta T_s \sim 33^\circ\text{C}$, which includes the contributions from all greenhouse gases, including water vapor, and also the greenhouse contribution due to clouds. From this, it follows that the ratio $f = \Delta T_s / \Delta T_0$, of the total terrestrial greenhouse effect to the total no-feedback forcing due to the non-volatile greenhouse gases, yields a climate sensitivity feedback factor of $f \sim 3.3$ for the entire atmosphere of the Earth, which is fully consistent with the feedback sensitivity that is obtained in climate change studies for relatively small climate forcings such as doubled CO₂.

CLIMATE VARIABILITY AND CHANGE, LAST 1,000 YEARS

Geologists and paleoclimatologists study the past on all time-scales as a basis for future predictions. The past is therefore highly relevant to modern climate change. It is essential to document past large-scale climate changes in order to place recent climate change in a longer-term context. The primary boundary conditions on the climate (e.g., Earth's orbital

geometry and global ice mass) have not changed appreciably over the past millennium. The variations in climate observed over this timeframe are hence likely to be representative of the natural climate variability that might be expected in the absence of any human influence. Placing modern climate change, including recent global warming, in a longer-term context can thus help establish the role of anthropogenic forcing (human greenhouse gas concentration increases and aerosol production) on past and future climate changes.

Approaches to estimating past changes

Instrumental meteorological records can only document large-scale climate changes over roughly the past 100–150 years. Relatively few instrumental records are available back into the eighteenth century. Several distinct approaches nonetheless exist for describing climate variations over a timeframe of roughly the past millennium. One such approach is the use of theoretical models of the climate system that are driven by estimated changes in external parameters or “forcings,” such as greenhouse gas concentrations and solar output, which tend to warm the climate, and the frequency and intensity of explosive volcanic eruptions, which tend to cool the climate through injecting reflective sulfate aerosol into the atmosphere (Free and Robock, 1999; Crowley, 2000; Gerber et al., 2003). This approach to reconstructing climate history is limited by the imperfectly known history of these changes in forcing, which are typically estimated indirectly from trapped gas, radioisotopes, and volcanic dust signals left behind in ice cores. Moreover, the reconstruction is limited by any uncertainties in the model's representation of actual climate processes and responses. Finally, the approach only indicates the forced component of climate change; it cannot estimate the possible role of internal dynamics (e.g., natural changes in ocean circulation) in the actual climate changes in past centuries, which are, in part, unpredictable from a model simulation.

Human documentary evidence provides another source for reconstructing climate in past centuries. Records of frost dates, droughts, famines, the freezing of water bodies, duration of snowcover, and phenological evidence (e.g., the dates of flowering of plants, and the ranges of various species of plants) can provide insight into past climate conditions (Wigley et al., 1981; Bradley, 1999). Furthermore, human accounts of mountain glacier retreats and advances during past centuries, widespread historical documentation of weather conditions, and even a handful of several centuries-long thermometer measurements are available in Europe for more than 1,000 years. Plentiful human documentary evidence is limited, however, to those regions (primarily Europe and Eastern Asia) where a written tradition existed. They are thus not useful for documenting truly global-scale climate variations. Human documentary records must furthermore be interpreted with caution, as they are not equivalent in their reliability to actual instrumental measurements of meteorological variables. Typically, these records provide indirect and potentially biased snapshots in time of potentially climate-related phenomena.

We must thus turn to more widespread, quantifiable measures of climate to document the large-scale climate variations of past centuries. Geological evidence from terminal glacial moraines indicating the advance of mountain glaciers in past centuries can also provide inferences into past climate changes. However, owing to the complex balance between local changes in melting and ice accumulation, and the effects of topography, all of which influence mountain glacier extents, it is difficult to

ascertain the true nature of temperature changes simply from evidence of retreat of mountain. Both increased winter precipitation and cooler summer temperatures can lead to the growth of a glacier, and large or even moderate glaciers respond slowly to any underlying climate changes (Folland et al., 2001). Estimates of long-term ground temperature trends from temperature profiles retrieved from terrestrial borehole data over the globe can also provide complementary large-scale information regarding ground-surface temperature trends in past centuries. However, impacts of changes in seasonal snow cover, land-surface changes, and other factors unrelated to surface air-temperature changes may complicate the interpretation of these data (Folland et al., 2001; Mann and Jones, 2003).

“Proxy” climate reconstruction

The most reliable estimates of climate changes in past centuries are provided by “proxy” indicators of climate change. These indicators are natural archives of information that, by their biological or physical nature, record climate-related phenomena. Certain proxy indicators, including most sediments cores, ice cores, and preserved pollen cannot record climate changes at high temporal resolution, and are thus generally not useful for reconstructing climate changes on centennial or shorter timescales. However, high-resolution, annually and/or seasonally resolved proxy climate records such as growth and density measurements from tree rings, laminated sediment cores, annually resolved ice cores, and isotopic information from corals can be used to describe year-to-year patterns of climate in past centuries (Jones et al., 2001; Mann, 2001). These indirect measurements of climate change vary considerably in their reliability as indicators of long-term climate. While tree-ring data are the most widespread source of annual proxy climate information, they are limited in a number of ways. They only provide information on sub-polar terrestrial regions, and generally, only extratropical species are useful for climate reconstruction. Thus, tree ring data are poorly representative of the full surface of the globe. The issue of how best to estimate climate variability on multi-centennial timescales from tree ring data, moreover, remains unresolved (Briffa and Osborn, 2002; Esper et al., 2002; Mann and Hughes, 2002), rendering long-term estimates based solely on tree ring data somewhat perilous. Coral information (e.g., oxygen isotopes and chemical species ratios that

respond to both temperature and salinity changes near the ocean surface), in contrast, offer information regarding tropical and subtropical climate changes, represent maritime regions, and continuously sample their environment over the full year. However, very long, multi-century records are rare, and the nature of the possible influence of “vital effects” (e.g., non-climatic influences on the coral’s biochemistry) has not yet been confidently established. Ice cores typically provide information from polar regions (and, in some cases, high-elevation tropical and extratropical environments), so that they are spatially complimentary to tree-rings and corals, but they sample a very small fraction of the global surface. An incontrovertible interpretation of ice-core oxygen isotopes in terms of e.g., atmospheric temperature variability, moreover, remains elusive, and precise annual dating is difficult. However, when taken together, and particularly when combined with historical documented information and the few long instrumental climate records available, these various proxy sources can provide a mutually complementary, global sampling (Figure C55) of climate changes in past centuries.

Such “multiproxy” assemblages of data can be used to reconstruct past large-scale patterns of surface temperature change, drought, and atmospheric circulation, by establishing a statistical relationship between the proxy data network and modern instrumental climate records (Mann, 2001). Indices of modes or patterns of climate variability, such as the El Niño/Southern Oscillation or ENSO and the North Atlantic Oscillation (NAO), which may play an important role in determining patterns of past climate variability, can also be reconstructed in a similar manner (see e.g., Jones et al., 2001 for a summary). This approach has also been used to reconstruct annual patterns of surface temperature change in past centuries (Mann et al., 1998; Briffa et al., 2001). Hemispheric or global mean surface temperature estimates can be derived by spatial averaging of such estimates of past large-scale patterns of surface temperature change. It is most meaningful to estimate the average surface temperature changes for the Northern Hemisphere, where considerably more widespread past data is available (e.g., Figure C55).

Climate history of the past 1,000 years

Climate reconstructions from proxy data networks have allowed for reconstructions of large-scale temperature patterns

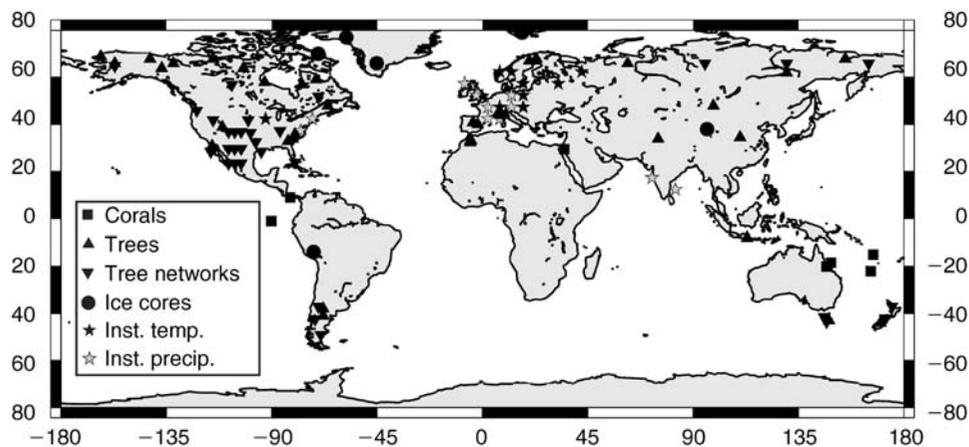

Figure C55 Geographic distribution of “proxy” and historical/instrumental indicators used in large-scale annual surface temperature reconstructions back to AD 1400 (adapted from Mann et al., 1998).

over roughly the past millennium. The detailed spatial patterns of these reconstructions provide insights into the underlying governing factors. For example, substantial patterns of warming and cooling over the extratropical Northern Hemisphere that vary from year-to-year appear to relate to the influence of the North Atlantic Oscillation (NAO) or Arctic Oscillation (AO) atmospheric circulation pattern. A related pattern of climate variability that appears to have an origin in internal, natural variations in the North Atlantic ocean-atmosphere system (Delworth and Mann, 2000) also appears to be important on multidecadal and century timescales. Other patterns of surface temperature variability appear to be associated with the global impacts of the El Niño/Southern Oscillation phenomenon. The complexity of the resulting regional variations in temperature trends underscores the premise that it is perilous to draw conclusions regarding hemispheric or global temperature trends from isolated regional information.

Different estimates of Northern Hemisphere mean temperature changes over the past millennium have been made, using different sources of proxy data, some of which are representative of the full Northern Hemisphere, and others which are more indicative of the extratropical regions of the Northern Hemisphere. These reconstructions can also be compared with model estimates of forced Northern Hemisphere mean temperatures changes over the past millennium (Figure C56). These various estimates indicate relatively modest variations in Northern Hemisphere mean temperature over the past 1,000 years, prior to the marked warming of the twentieth century. Hemispheric mean temperatures appear, for example, to have been slightly higher (by a couple of tenths of a degree Celsius) during the period AD 1000–1400 relative to the later, colder period AD 1400–1900 (associated, respectively, with the often-used labels of “Medieval Warm Period” and “Little Ice Age”). However, even the early interval of relative warmth does not approach the magnitude of the hemispheric warmth

of the latter twentieth century. The modest estimated changes in Northern Hemisphere average temperatures are consistent with evidence of the amplitude of natural (pre-anthropogenic) changes in the carbon cycle estimated from long-term carbon dioxide measurements (Gerber et al., 2003).

Some reconstructions of hemispheric temperature changes based on extratropical, continental tree-ring data suggest wider swings in temperature, including greater cooling during the seventeenth to nineteenth century than is evident in the instrumental, model, or other proxy-based estimates (Esper et al., 2002). The greater variability in this case probably arises from the emphasis on extratropical continental regions and the exclusive use of summer-temperature-sensitive tree ring chronologies (Mann, 2002). While European temperatures, for example, indicate a distinct cold phase from the seventeenth to nineteenth centuries, most hemispheric estimates (Figure C56) suggest a relatively steady, long-term cooling. It is probable that greater cooling in continental regions such as Eurasia and North America during the “Little Ice Age” resulted from changes in the NAO atmospheric circulation pattern. Recent evidence suggests that the NAO can be altered, for example, by changes in the output of the Sun (Shindell et al., 2001). Such changes may have led to enhanced winter cooling in Europe during the eighteenth century, when solar output was slightly weaker, and winter atmospheric circulation patterns in Europe appear to have been significantly altered, favoring exposure to cold, dry, Siberian air masses. Other complications arise from the use of summer temperature-sensitive tree-ring proxy information alone, which may exaggerate the cooling response to volcanic eruptions, which is greatest both over the continents and during summer (Mann, 2002).

Ground temperature changes estimated from boreholes in past studies (Huang et al., 2000) appeared to conflict with the hemispheric temperature trends evident in the instrumental and proxy-based estimates shown in Figure C56. Recent work has shown, however, that once these estimates are adjusted

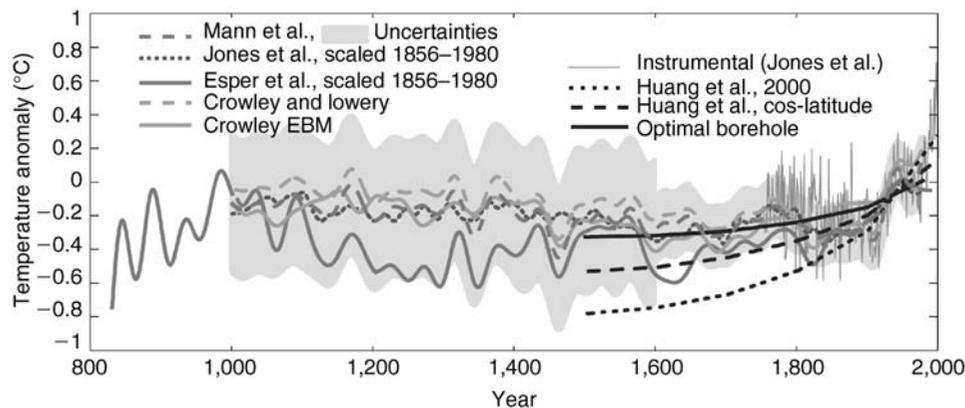

Figure C56 Comparison between various estimates of Northern Hemisphere temperature changes in past centuries. Annual mean Northern Hemisphere surface temperatures are reconstructed from proxy data (Crowley and Lowery, 2000; Mann et al., 1999) and theoretical energy balance models (Crowley, 2000), as well as *warm-season, extratropical Northern Hemisphere* temperature trends (Esper et al., 2002; Jones et al., 1998), scaled to match the *full Northern Hemisphere annual* temperature record for direct comparison (Jones et al., 1999). The smoothed reconstructions highlight variations on timescales greater than 40 years; uncertainties (95% confidence interval) in the smoothed Mann et al. (1999) reconstruction are also shown, as are the instrumental Northern Hemisphere temperature records through the mid eighteenth century (Mann and Jones, 2003). Estimates of ground surface temperature changes from terrestrial borehole data based are also shown, based on (a) a simple (unweighted) arithmetic average of available borehole data (Huang et al., 2000), (b) an areal-weighted average of the borehole data, and (c) statistically optimal hemispheric surface temperatures from available borehole data (Mann and Jones, 2003).

for spatial sampling biases (Briffa and Osborn, 2002; Mann and Jones, 2003) and the influence of factors unrelated to annual mean surface temperature changes, such as changes in the extent and duration of seasonal snowfall (Mann and Jones, 2003), the borehole estimates come into reasonable agreement with the other proxy and model-based estimates (Figure C56).

Implications

Recent research seeking to reconstruct and model climate changes of the past 1,000 years highlights the importance of taking into account regional variations in estimating climate changes in past centuries. While reconstructions of Northern Hemisphere temperature changes in past centuries, for example, confirm other (e.g., human documentary) evidence of the phenomenon of a 1–2 °C cooling in the winter during the “Little Ice Age” of the seventeenth to nineteenth centuries in Europe, they do not indicate a continuous period of similar magnitude cooling that is synchronous with cold conditions in Europe. The best current estimates suggest modest amplitude changes (considerably less than 1 °C) at the hemispheric scale, prior to the twentieth century warming trend. While internal climate factors are important in describing regional patterns of climate change, most of the observed variations in hemispheric mean temperature are consistent with the response of the climate to external forcing including volcanic and solar influences and, during the twentieth century in particular, anthropogenic influences. The comparisons between estimated and modeled changes imply a sizeable sensitivity of the climate system to anthropogenic influences of roughly 2 °C warming for a doubling of carbon dioxide concentrations from their pre-industrial levels.

COAL BEDS, ORIGIN AND CLIMATE*

Introduction

Coal is defined in the Glossary of Geology (1997, p. 122) as follows:

“A readily combustible (sedimentary) rock containing more than 50% by weight and more than 70% by volume of carbonaceous material, including inherent moisture, formed from compaction and induration of variously altered plant remains similar to those in peat. Differences in the kinds of plant materials (type), in degree of metamorphism (rank), and in the range of impurity (grade) are characteristic of coal.”

Although coal, by definition, may be composed of nearly 50% mineral matter, most commercial-grade coal in the United States is mined from coal beds that generally contain less than 20% mineral matter by weight (excluding mineral partings), and commonly less than 10% by weight. The U.S. Geological Survey excludes impure coal/coal material containing more than 33% ash by weight from resource/reserve estimates (Wood et al., 1983, p. 8). Coal with these grade characteristics can develop only under very limited conditions of peat formation. Grade characteristics indicate that resource-quality coal beds are derived from peat that formed in environments that were relatively free of dissolved solids and mineral content.

*All rights reserved

Furthermore, in order to form commercial grade coal beds, the concentration of mineral matter in the original peat must have been relatively low, because metamorphism following burial of peat tends to increase mineral content. The heat and pressure involved in the transformation (metamorphism or “coalification”) of peat to coal liberates significant amounts of the original organic matter in the form of carbon dioxide, methane, and water. The liberation and loss of organic matter during this transformation (metamorphism) of peat to coal may effectively double the mineral content. For example, 25% mineral matter in peat (dry basis) may be concentrated to 50% mineral matter when peat is transformed (coalified) to a medium volatile rank coal.

Climate and peat/coal formation

Although modern wetlands containing organic-rich sediment occur in a variety of climate settings around the world, only those deposits that contain less than approximately 25% (dry basis) mineral matter should be considered as precursors for coal. Other organic-rich deposits where mineral matter concentrations are greater than 25% will become carbonaceous shale or marl following burial and metamorphism. Cecil et al. (1985) pointed out a relation between climate and modern precursors of most commercial-grade coal. These modern coal precursors occur predominantly in two types of peat-forming environments, designated as type A and type B (Table C6 and Table C7), which can be differentiated, respectively, by selected parameters and conditions of peat-formation.

The primary variables that control the mineral matter content of peat (i.e., peat quality) are nutrient availability and pH of peat-forming environments. Thus, the highest quality peat/coal precursors have the lowest mineral matter content, and

they tend to have both a low pH and a low nutrient status (oligotrophic conditions). Oligotrophic peat deposits occur under humid to perhumid climates (see Cecil, 2003 for climate definitions), where relatively high precipitation causes intense chemical weathering (leaching) and removal of soluble mineral matter from peat. These climates also cause removal of nutrients and alkaline materials from mineral soils (pedogenesis) that are spatially and temporally associated with peat formation. Mesotrophic peat deposits tend to occur where the climate is marginally humid. The quality of mesotrophic peat is marginal as a precursor to coal because nutrients are available that promote microbial decay of organic matter. Furthermore, the nutrients tend to remain sequestered in peat as mineral matter through ion exchange processes. Eutrophic peat deposits, by definition, have a relatively high nutrient status and they generally contain relatively high concentrations of alkaline materials, which result in a near neutral pH that is conducive to high rates of microbial degradation of organic matter. These deposits tend to occur in climates that are moist subhumid or sometimes in drier climates, where soluble salts are enriched in surficial waters through evapotranspiration. As a result, eutrophic peat is invariably enriched in mineral matter to the extent that the peat would become very impure coal or carbonaceous shale upon burial and metamorphism.

In the modern world, the distribution of peat deposits (as precursors of coal beds) empirically illustrates climate controls on peat formation. Laterally extensive, high quality (low ash) peat deposits form predominantly in regions where monthly precipitation approximates or exceeds evapotranspiration (humid to perhumid climates). These regions include certain global climatic belts and regions that have maritime climates. The most widespread modern global climate belt of peat formation

Table C6 Parameters and conditions that control peat formation for the two predominant types of peat-forming environments (modified from Cecil et al. (1985) with climate terminology from Cecil, 2003)

Parameter	Type A condition	Type B condition
Climate	Perhumid	Humid
Water source	Ombrogenous (rain)	Topogenous (rain water, surface water, and ground water)
Nutrient availability	Oligotrophic (impoverished)	Oligotrophic to mesotrophic to eutrophic (impoverished to rich)
pH	<4	4 to ~7
Eh	?	?
Microbial activity	Low (cellulose preserved)	High (cellulose degraded)
Mechanism of degradation	Primarily chemical	Primarily microbial

Table C7 Descriptors and relative characteristics of peat-forming environments (modified from Cecil et al., 1985)

Descriptors of peat environments	Type A characteristics	Type B characteristics
Surface morphology	Domed	Planar
Flora communities	Low diversity; Zoned distribution; Xeromorphic physiognomy	High diversity; Random distribution; Luxuriant physiognomy
Ash content	Uniformly low	Low to high
Sulfur content	Uniformly low	Low to high
Nitrogen content	Uniformly low	Low to high
Cation exchange capacity	High	High
Specific conductivity	Low	High
Base saturation	Low	High
[Ca ²⁺]	Low	High
Fiber content	Fibric	Hemic to sapric
Bioorganic sulfide	Low	High
Bioorganic methane	Low	High

occurs in the vicinity of 60° North latitude along the edge of the atmospheric polar front. Polar fronts result from high atmospheric pressure and descending air at the poles that moves out from the polar region where it is then overridden by warmer and moister air in the vicinity of 60° latitude. The cooling of the warmer and moister air as it rises results in condensation and precipitation at the polar front. Even though precipitation is not particularly high in the region of polar fronts, the climate is humid to perhumid because cool summer temperatures and often freezing winter temperatures inhibit evaporation. At 60° South latitude, however, the absence of landmasses precludes widespread peat at this latitude in the Southern Hemisphere.

Areally extensive peat deposits also occur in certain equatorial regions. Thick (up to 13 meters) and extensive (over 50 km across) modern deposits of domed peat occur in equatorial Indonesia and Malaysia. Domed peat deposits, whose moisture source is exclusively precipitation, form in this region in response to a perhumid climate. The perhumid climate results from the presence of the nearly permanent low pressure, induced by the rising air of the intertropical convergence zone (ITCZ). In addition, a maritime effect occurs as moisture-laden weak winds cool as they move inland and rise over the island landmasses, thus causing precipitation that supplements rainfall associated with the low pressure of the ITCZ.

Further examples of peat formation controlled by maritime climate can be found in the British Isles where prevailing westerlies from the Atlantic Ocean cool as they rise upon reaching landmasses. The cooling of the westerly winds results in precipitation that contributes to the formation of peat deposits that blanket upland slopes. The climate in this cool temperate region is humid to perhumid because humidity and precipitation (in the form of fog, mist, and rain) are relatively high, whereas evapotranspiration is relatively low. Although it is highly unlikely that blanket peat deposits in upland areas can be preserved in the rock record, such deposits nevertheless serve to illustrate the relation between peat formation and wet climates.

Summary and conclusions

Modern peat deposits that could be precursors of resource-quality coal beds occur predominantly under humid to perhumid climatic conditions (Cecil, 2003; Cecil and Dulong, 2003). By analogy, coal beds containing less than approximately 30% ash must have been derived from peat that formed under humid to perhumid climatic conditions. Although some coalified terrestrial organic matter may have been deposited in sedimentary strata that were deposited under a wider range of climatic conditions, resource-quality coal beds that are discrete and areally extensive accumulated under humid to perhumid paleoclimate conditions.

COASTAL ENVIRONMENTS

Introduction

The coastal zone, extending from ca. 10 m depth on the inner shelf to the landward limit of tidal action in rivers, occupies a small fraction of the Earth's surface. Despite this, coastal deposits are an important component of the stratigraphic record because they contain a large amount of information about the environmental conditions that prevailed during deposition. The geomorphology of the coastal zone (Figure C57) and the characteristics and stratigraphic architecture of the corresponding deposits (Figure C58) are influenced by many interdependent factors. The most notable of these are: (a) the history of sea (or lake) level, which, together with sediment input, determines whether the coastline is migrating landward (i.e., transgressing) or seaward (i.e., regressing or prograding); (b) the relative influence of waves, tidal currents, and river outflow, which determines the nature of the resulting facies; (c) the geologic setting, which controls the uplift or subsidence history and the resulting stratigraphic stacking pattern of coastal deposits; and (d) the climate, which determines the sea-level history, the intensity of wave action, the amount of fluvial runoff, the presence of ice, and the role of plants and animals. The interaction of these many factors produces enormous geomorphic variability and complexity in both modern coastal environments (Bird, 2000; Woodroffe, 2002) and their ancient counterparts (Pratt et al., 1992; Reading and Collinson, 1996).

Relative sea-level history

The direction of shoreline movement is the single most important control on the geomorphology and preserved stratigraphic expression of coastal environments (Boyd et al., 1992). Regressive situations are associated with the seaward growth of deltas (Figure C57a, b), the development of strandplains (also called beach-ridge plains) by prograding beaches and shorefaces, and the seaward build-out of open-coast tidal flats (Figure C57c). On the other hand, barrier islands, lagoons, and estuaries (Figure C57d) exist only where there is, or very recently has been, transgression. Thus, such environments are particularly common along modern coasts because of the post-glacial sea-level rise. Here, we follow the geological definition of "estuary" proposed by Dalrymple et al. (1992), in which an estuary is a transgressive coastal embayment (usually a drowned river valley) that receives sediment from both river and marine sources. This definition is preferred to the salinity-based formulation of Pritchard

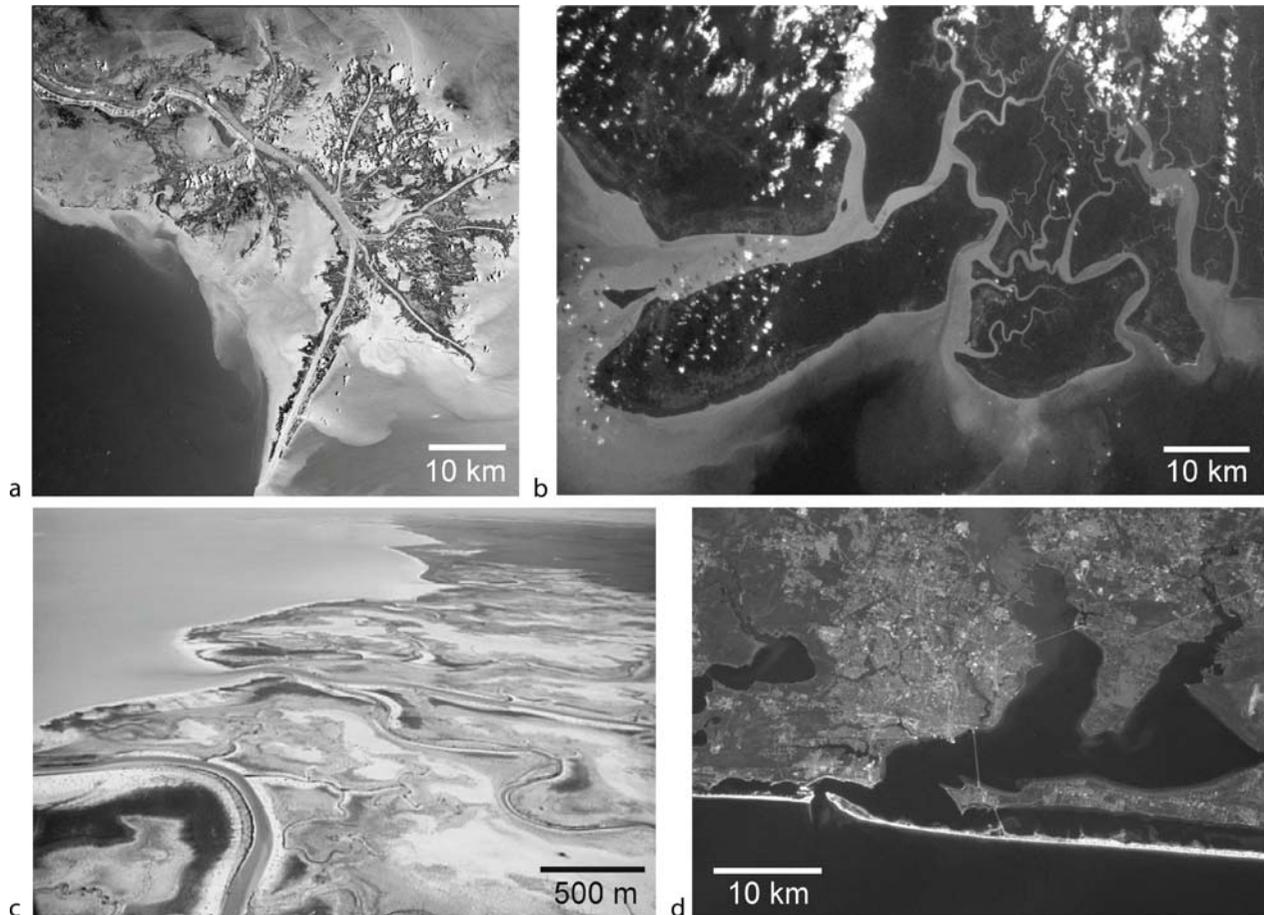

Figure C57 Typical examples of modern coastal environments. (a) The presently active birdsfoot delta of the Mississippi River, United States. Note the elongate distributary channels, flanked by levees and separated by shallow bays and marshes. (b) Subaerial plain of the tide-dominated Rajang River delta, Malaysia. Note the complex network of sinuous tidal channels. (c) Muddy, carbonate tidal flats, cut by meandering tidal channels, Andros Island, Bermuda. (d) Transgressive coast with barrier islands, tidal inlet, back-barrier lagoon, and drowned river-mouth estuaries (upper right), Pensacola, Florida, United States. The elongate area of land immediately behind the modern barrier is an older barrier island formed during a late Pleistocene highstand of sea level (all photos except c courtesy of NASA; c courtesy of N. P. James, Queen's University).

(1967), which considers any semi-enclosed coastal area with brackish water an estuary, regardless of whether it is regressive or transgressive.

The distinction between regressive and transgressive coasts is reflected in the vertical stacking pattern of coastal facies: shallower-water facies overlay deeper-water deposits in regressive settings, and the reverse in transgressive successions. Regressive successions are usually more or less complete and gradational (Figure C58a) because the shoreline is migrating into deeper water. Only in situations where regressions occur under conditions of falling sea level (i.e., a forced regression; Posamentier et al., 1992) is it common to generate a succession that may contain an erosion surface, with sandy, shallow-water facies lying abruptly on muddy, offshore deposits (Figure C58a). By contrast, transgressive successions are almost everywhere punctuated by one or more discontinuities (Figure C58b,c) at which the deposits of a more seaward environment lie abruptly on a more landward facies (e.g., brackish-water lagoonal mud overlying fluvial deposits). Such discontinuities are called flooding surfaces; if there is significant erosion, such as occurs where the shoreface migrates landward, they are also termed a ravinement surface (Figure C58a,c).

Physical processes

River currents, waves, and tidal currents are responsible for the geomorphology of coastal environments (Hayes, 1975; Wright, 1985; Boyd et al., 1992) and the nature of the associated deposits. Consequently, coastal environments and their ancient counterparts are commonly classified as river-, wave- or tide-dominated.

River-dominated coastal environments occur at the mouths of rivers, in settings where wave and tidal influence are not important, and generally consist of deltas with either a birds-foot or lobate morphology (Figure C57a; Wright, 1985). Distributary mouth bars occur directly seaward of the river mouth(s) and consist of a succession that passes upward from prodeltaic mud to the sand of the mouth bars. Interdistributary bays are developed between the distributary mouths (Figure C57a) and are sites where muddy and organic-rich sediments accumulate.

Wave-dominated coasts are generally straight or cusped, and are fronted by beaches that pass seaward into the shoreface and offshore shelf (Figure C57d). In progradational settings, progressive seaward migration of the coast produces a strandplain, on

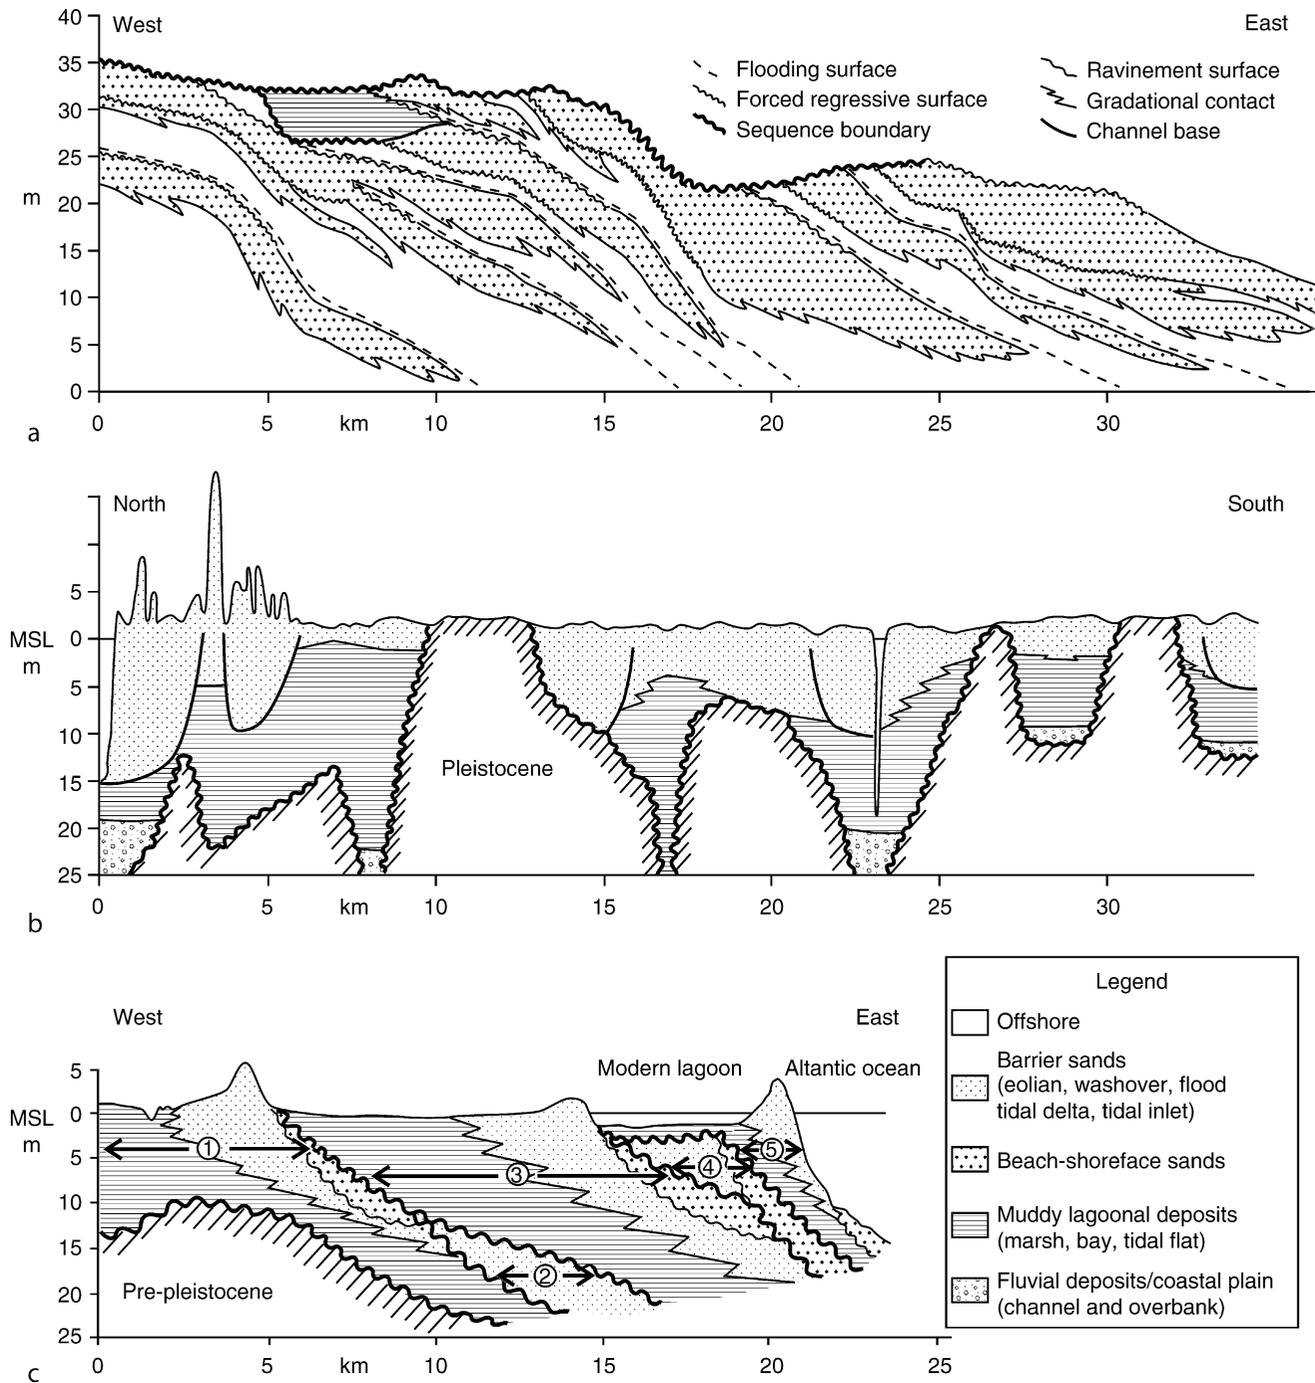

Figure C58 Vertical cross sections showing typical stratigraphic expressions of coastal deposits. (a) Prograding, wave-dominated shoreline, formed during a time of “greenhouse” climate. Note the episodic vertical offset of sandy beach-shoreface deposits, caused by small-scale sea-level changes. Iles Formation (Cretaceous), northwestern Colorado, United States (after Crabaugh, 2001, figure 2.8). (b) Coast-parallel section, Delaware, United States. The valleys cut during the last glacial maximum have been filled by a transgressive succession of fluvial, estuarine/lagoonal, and barrier-island deposits. All deposits above the -6 m level will be removed by landward migration of the shoreface, which will generate a ravinement surface (after Kraft et al., 1987, figure 3). (c) Coast-normal section perpendicular to **b**, showing the stacking and amalgamation of coastal deposits of five sea-level highstands during the Pleistocene. Each lowstand generated a through-going unconformity termed a sequence boundary. Each sequence (numbered oldest to youngest) contains a transgressive stacking of back-barrier mud and barrier-island sand. Note the erosional truncation of barrier sands in more down-dip areas. Most of this erosion is caused by transgressive shoreface ravinement. The greater degree of stratigraphic complexity relative to **a** is a result of the high-amplitude sea-level changes that characterized the “icehouse” conditions of the Pleistocene (after Demarest and Kraft, 1987, figure 4).

which eolian dunes may be important. The deposits generated by coastal progradation consist of a succession that coarsens upward from offshore mud into shoreface sand (Figure C58a). Such successions are abundant in the stratigraphic record and may be stacked on each other, reflecting repeated transgression and regression of the paleo-shoreline. Each upward-coarsening succession, termed a parasequence (Van Wagoner et al., 1988), is separated from the next one by a flooding surface, across which offshore shale rests abruptly on more nearshore deposits.

Transgressive, wave-dominated conditions are very common along modern coasts. Where the hinterland is low lying, as would be the case in most ancient sedimentary basins, the coastline is fronted by barrier islands that are separated by tidal inlets (Figure C57d). Drowned river-valley estuaries and lagoons lie behind these sandy islands. In such back-barrier areas, tidal action is commonly the dominant physical process. Tidal channels radiate from the tidal inlets, cutting through the flood-tidal deltas that lie immediately landward of inlets. Tidal flats rim the lagoons and estuaries; muddy deposits accumulate in the deeper-water areas. Bayhead deltas, which typically exhibit a river-dominated morphology, may be developed at river mouths. Such wave-dominated estuaries display a characteristic tripartite facies zonation, from sandy sediments at the barrier, through muddy lagoonal deposits, to more sandy sediments in the bayhead area, and are a common component of valley-fill successions (Figure C58b). The more seaward portions of the estuary, including the sandy barrier and related environments, are rarely preserved, however, because they are eroded by the landward passage of the shoreface, which generates a ravinement surface (Figure C58b).

Tide-dominated coastal environments most commonly occur in macrotidal areas (i.e., tidal ranges >4 m). At locations where there is a significant coast-normal tidal flux, a network of tidal channels is generally developed (Figure C57b,c). The migration of these channels produces an architecturally complex succession of lateral-accretion deposits. These deposits are commonly very heterolithic because of the high suspended-sediment concentrations. Tide-dominated sedimentation is favored in transgressive settings, because the flooding of an irregular topographic surface (i.e., a sequence boundary) generates many embayments that are sheltered from wave action and enhance the influence of tidal currents. However, large tidal ranges and tidal dominance can occur at any point in a relative sea-level cycle because tidal resonance is dependent on instantaneous, regional-scale basin morphology.

Geologic setting

The geologic setting creates the general context for the coastal zone. Coastal zones in tectonically active areas (e.g., coastlines on subducting or strike-slip continental margins, or in young rift basins) tend to be bordered by rugged hinterlands, especially if the location of the coastline is determined by an active fault. As a result, they are typically fed by small rivers that supply relatively coarse-grained sediment. The extent of estuarine environments is minimized because the steep fluvial gradient limits the intrusion of salt water and tidal action. Coastlines along passive continental margins or in foreland or intracratonic basins generally have lower gradients and may be fed by a smaller number of large rivers (Wright, 1985). The sediment reaching the river mouth is typically relatively fine-grained. Slow subsidence in tectonically stable areas causes transgressive coastal erosion to have a more profound influence than in areas of high subsidence rates. Thus, coastal deposits

will tend to be truncated to a greater degree, leading to a more fragmentary record of sea-level variations than in more rapidly subsiding areas (Figure C58c).

Influence of climate

Climate also influences the general context in which coastal environments exist. For example, the frequency and intensity of storms, which determine the intensity of wave action, is a function of the climatic belt. Mid-latitude coasts are subject to frequent storms, which favors the occurrence of high-energy, wave-dominated shorelines. By comparison, areas approximately 30° north and south of the equator tend to have low average wind speeds, with infrequent but intense hurricanes.

Humid climates have significant river flow, which delivers large amounts of sediment and fresh water to river mouths. This favors the development of deltas and prograding coastal environments, as well as the widespread occurrence of brackish-water conditions. Coastal vegetation is generally abundant and vegetated salt marshes are widespread in the upper intertidal zone (Luternauer et al., 1995). In tropical to sub-tropical settings, mangroves grow into the intertidal zone. Arid climates with high evaporation rates promote the development of hypersaline conditions in areas with limited tidal circulation (e.g., coastal lagoons and estuaries). Terrestrial vegetation is sparse and evaporite minerals such as gypsum and halite can grow in the surficial sediments of the intertidal zone. Caliche (also called calcrete) is commonly present in paleosols formed in areas with a semi-arid climate.

Organically produced carbonate sediment is abundant in areas with limited freshwater input and a consequent scarcity of terrigenous-clastic sediment. The nature of these carbonate sediments is strongly controlled by water temperature, as well as the availability of nutrients (James, 1997). In tropical and subtropical areas where water temperatures are higher than ca. 20°C, the fauna today is dominated by corals and calcareous algae that produce reefs. These reefs, together with the associated shallow carbonate platform, damp wave action and allow tidal flats to develop along many shorelines (Figure C57c). The repeated progradation and transgression of these flats produces stacked successions of upward-shallowing packages, typically 1–3 m thick, separated by flooding surfaces (Pratt et al., 1992). In temperate and polar areas, by contrast, reef-producing organisms do not thrive. Sediment-production rates are low and gently sloping offshore ramps occur instead of flat-topped platforms. Because of this, wave energy can reach the shoreline more readily, causing beaches to be more widespread than in tropical areas.

Polar areas experience seasonal or permanent growth of sea ice that limits the impact of wave energy. As a result, coastlines tend to be of lower energy and muddier than might be the case otherwise. Soft-sediment deformation caused by the grounding of ice pushed onshore by winds may be significant (Dionne, 1985). Permafrost is also an important constraint on coastal morphology.

Climate change at Milankovitch frequencies has had a profound influence on modern coastal areas because of the frequent, high-amplitude, sea-level cycles that have occurred throughout the “icehouse” conditions of the Quaternary. Each of the last few interglacial highstands has reached approximately the same elevation (Chappell et al., 1996), leading to the amalgamation and superposition of coastal deposits of significantly different ages but similar facies (Figure C58c). Significant time gaps (i.e., sequence boundaries) occur between these packages because of non-deposition and/or erosion

during the sea-level lowstands. For example, along much of the east and southern coasts of the United States, Holocene barrier-lagoon complexes lie only a short distance seaward of similar deposits of late Pleistocene age (Figure C57d; Demarest and Kraft, 1987). This leads to enormous stratigraphic complexity, especially in areas of low sediment supply. Sea-level oscillations with a similar period but much reduced amplitude probably occurred during “greenhouse” times such as the Cretaceous. Coastal deposits formed under these conditions may not show as much complexity because a smaller number of significant unconformities will be present (Figure C58a).

Summary

The coastal zone is arguably the most complex environment on earth because of the many independent factors that influence its characteristics. Pronounced spatial gradients in the intensity of the main physical processes (river currents, waves, and tidal currents) create complex assemblages of facies, which are then stacked in complex stratigraphic successions because of the migration of the shoreline in response to sea-level change and sediment addition or removal. The geologic setting and climate have less direct, but nevertheless important, influences on the nature of coastal environments. As a result of the interplay of these many factors, coastal deposits are a rich source of information about past environmental conditions.

COCCOLITHS

Coccoliths are an important group of microfossils much used in paleoceanographic studies. They are minute (typically 1–10 μ) calcite platelets that are produced by unicellular planktonic algae, coccolithophores. In life, the individual coccolithophore cell is typically almost entirely covered by coccoliths, forming an exoskeleton or coccosphere. In the fossil record, coccoliths are often accompanied by nannoliths, i.e., similar sized calcite fossils of uncertain affinities (e.g., discoasters, nannoconids). Geologists study coccoliths and nannoliths together and refer to them as calcareous nannofossils.

Coccolithophores belong to the algal division (phylum) Haptophyta, which also includes many non-calcifying taxa (e.g., *Phaeocystis*, *Prymnesium* and *Pavlova*). Haptophytes are distinguished from other algae by their possession of two smooth flagella and a unique third flagellum-like organelle, the haptonema. Molecular genetic research has confirmed that the Haptophyta are a discrete clade that probably diverged from other protists in the Early Paleozoic and subsequently

acquired chloroplasts by endosymbiosis, possibly in the Early Mesozoic. Non-calcifying haptophytes, especially *Phaeocystis*, are important in shelf environments but coccolithophores are predominant in oceanic environments and the only group with a fossil record. The coccolithophore *Emiliana huxleyi* produces spectacular blooms with very high abundances of loose liths, which are readily identified by satellite (Figure C59).

Haptophytes typically have a life-cycle with discrete haploid and diploid phases, both of which are capable of indefinite asexual reproduction (Billard, 1994). In coccolithophores, the two phases produce different coccolith types. The haploid phase is usually motile and if it calcifies, it produces coccoliths formed of numerous euhedral crystallites; these “holococcoliths” are very small and rarely preserved. The diploid phase is often non-motile (i.e., flagella and haptonema are not developed) and produces more robust coccoliths formed of a few radial cycles of elaborate-shaped interlocking crystal units – “heterococcoliths” (Young et al., 1999). Both life-cycle stages are fully planktonic and there is no cyst-stage in the life cycle. The alternation between two life-cycle strategies may, however, aid adaptation to the open-marine environment – the haploid holococcolith-bearing phase typically occurs in shallower and more oligotrophic environments than the diploid heterococcolith-bearing phase. The haploid phase may also be mixotrophic. In any case, it is clear that coccolithophores are particularly well-adapted to oligotrophic open-ocean conditions and they often dominate the phytoplankton in such areas. In more eutrophic areas, coccolithophore numbers may increase but they become subordinate to the much more abundant diatoms. Similarly, coccolithophore blooms usually occur later in the seasonal succession than diatom blooms (Winter and Siesser, 1994).

In the fossil record, coccoliths are very important as open ocean sediment formers. They are usually the dominant calcareous component of pelagic deposits, including both Late Cretaceous chalks and modern deep sea oozes. They have proven invaluable as biostratigraphic marker fossils in such sediments and are the prime means of dating sediments recovered by the DSDP and ODP projects (Bown, 1998). Despite the minute size of coccoliths, such studies are usually carried out by light microscope, since the high birefringence of calcite means they are readily identified in cross-polarized light. Electron microscopy is only used for special studies. Numerous studies of nanofloral change have elucidated responses of coccoliths to oceanographic change and they can provide key constraints to hypotheses of change in the phytoplankton

based on indirect geochemical evidence – e.g., an inference of productivity change based on carbon isotopes can be tested by determining if concomitant change occurs in the phytoplankton. However, reliable quantitative nanofloral proxies and transfer functions are still at a relatively early state of development. The most important coccolithophore-derived geochemical proxy is the uk37 alkenone paleothermometer. There has also been much recent study of stable isotope and Sr/Ca records from coccoliths.

COHMAP

Introduction

Climate change is global in scope, multivariate in character, and varies both temporally and spatially. Single investigator studies of sediment cores can provide individual data points for studying past climate, but as CLIMAP (Climate: Mapping and Prediction) demonstrated, it takes internationally and inter-institutionally organized groups of interdisciplinary investigators to compile the global data sets and models needed to construct a global view. Patterned after CLIMAP (1981), COHMAP (Cooperative Holocene Mapping Project) featured researchers who assembled continental-to-global data sets primarily of radiocarbon-dated pollen and lake-level data and analyzed these data to produce time series of maps of estimated climate variables that show the changing synoptic patterns of climate change during the late Quaternary. During its 18 years of existence from 1977 to 1995, COHMAP evolved from four principal investigators focusing on mapping late Quaternary climates in eastern North America to over 30 cooperating scientists who together were mapping and modeling the temporal changes in spatial patterns of climate from all continents but Antarctica, and from the Atlantic, Pacific, and Indian Oceans (Wright et al., 1993). Starting with the Last Glacial Maximum (LGM) at 21,000 calendar years ago (or 18,000 radiocarbon yBP), COHMAP members twice made a sequence of model runs that showed the simulated impact of the changing boundary conditions on late Quaternary climates (Kutzbach et al., 1993, 1998) and then thoroughly checked the model results against the data (COHMAP, 1988; Wright et al., 1993; Webb,

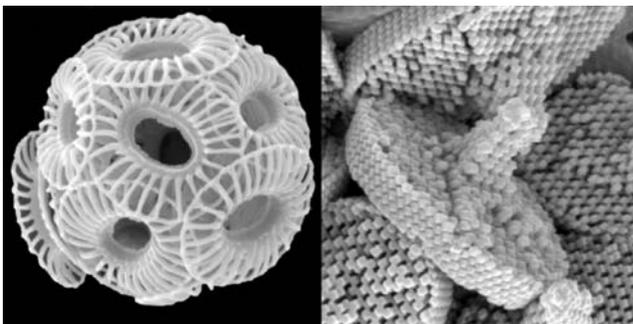

Figure C59 Left: Coccosphere of *Emiliana huxleyi* heterococcoliths. Right: Several *Helicosphaera carteri* holococcoliths.

1998). A key finding was the direct impact of orbitally forced changes in seasonal insolation on monsoon climates in Africa and southern Asia (Kutzbach, 1981; Kutzbach and Street-Perrott, 1985), which demonstrated how the climate forcing postulated by Adhemar, Croll, and Milankovitch (Imbrie and Imbrie, 1979) affected tropical climates without ice sheets being involved. By formulating a mechanism involving the enhancement and weakening of monsoons and then testing its plausibility with models and data, COHMAP investigators discovered one way for orbital forcing to affect global climates throughout Earth history. Geological evidence showing periodic frequencies on orbital time scales is abundant from the Permian, Triassic, Cretaceous, and other geological periods (DeBoer, 2004).

History, investigators, and meetings

COHMAP was a group of active researchers interacting and collaborating in productive ways (Wright and Bartlein, 1993). The group began as the brainchild of H. E. Wright and E. J. Cushing, established Quaternary geologists and paleoecologists, and J. E. Kutzbach and T. Webb III, meteorologically trained paleoclimatologists, who were both students of R. A. Bryson from whom they gained training in climate history and climate dynamics. In initial discussions at the 1974 AMQUA (American Quaternary Association) meetings in Madison, WI, these researchers identified a major opportunity to compile radiocarbon-dated pollen data into continental data sets for mapping and climatic reconstructions (Webb and Bryson, 1972). By 1977, when they were first funded by the National Science Foundation (NSF), the project had the potential to check the results of general circulation models (Peterson et al., 1979). Within a year, they began collaborating with F. A. Street-Perrott, who was developing a global lake level database and had good dated coverage in Africa and other tropical areas where pollen data were sparse (Street and Grove, 1979). Street-Perrott soon became a member of the executive committee along with paleoceanographers W. Ruddiman and W. Prell, who provided a CLIMAP perspective and SST estimates from the Atlantic, Pacific, and Indian Oceans, where sedimentation rates were high enough to allow resolution within the Holocene. In the early 1980s, P. J. Bartlein added his climatic, statistical, and cartographic expertise to the leadership group. By then, Kutzbach (1980, 1981) had developed methods for estimating precipitation from lakes levels and had begun using general circulation models (GCMs) to simulate the impact of orbital forcing of Holocene climates. The modeling studies evolved into a time series of runs in 3,000 year intervals from 18,000 radiocarbon years ago to present (Kutzbach et al., 1993). With a goal of global mapping of pollen and lake level data for data/model comparisons, the COHMAP executive committee recruited regional experts for acquisition, quality control, and interpretation of the pollen and lake-level data (COHMAP, 1988; Wright et al., 1993). A policy of subsidizing the radiocarbon dating of pollen data from critical areas encouraged many North American palynologists to contribute their data to the North American database.

Key to research planning and coordination was regular meetings involving either just the executive committee members or all cooperating scientists. At these meetings, investigators shared their expertise and educated each other across their diverse disciplines. They gained a common understanding of the global controls on the climate system and its spatio-temporal nature of variation. With a sophisticated view of the climate system, they used climate-modeling results to simulate possible changes in circulation patterns and teleconnections that helped explain

why the timing and magnitude of changes in the data differed among regions. They also used their continental-to-global data sets to test the accuracy of the model simulations. The meetings allowed both the modelers and the data compilers to learn from each other and to formulate productive plans for mutual research. Root and Schneider (1995) cited COHMAP as a model for “cooperative SCS (strategic cycle scaling)-like research” because of its integration of modeling and data analysis and its “interdisciplinary multi-institutional research” and education.

Key methods, findings and new concepts

In the beginning, COHMAP researchers aimed to compile and add to sets of modern and fossil pollen data for climate calibration and mapping in eastern North America. The goal was to map geographic patterns of vegetation and climate variables that show how and perhaps even why past climates had changed. Fieldwork was central to the project in order to fill gaps in the data networks, especially in critical regions. The Radiocarbon Laboratory directed by Margaret Bender at the Center for Climatic Research in Madison, Wisconsin, provided many dates to improve chronologies within sites with fossil pollen data. Two sets of pollen data were compiled. One was a calibration data set of over 900 sites with modern pollen data collected from surface sediments. When combined with the modern climate data for each site, these data were used to calculate transfer functions and later response surfaces that provided estimates of climate variables from the fossil pollen data (Bartlein et al., 1984, 1986). The fossil pollen data were in the second data set, which included site information, the pollen counts, and depth-date files for constructing chronologies. These data sets are now archived

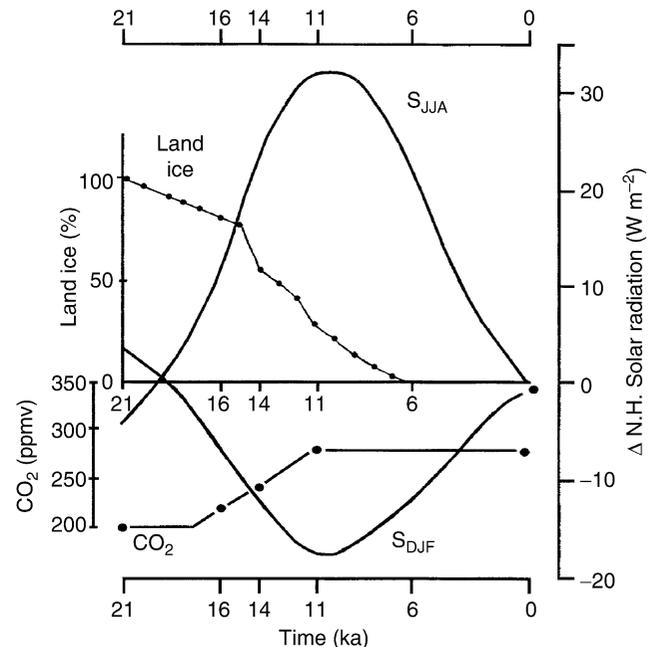

Figure C60 Changes in key climate controls during the last 21,000 years including (1) percentage coverage by terrestrial ice sheets, (2) concentration of atmospheric carbon dioxide, and (3) orbitally controlled insolation at the top of the atmosphere for the northern hemisphere for summer (June, July, and August) and winter (December, January, and February) (modified from Kutzbach et al., 1998).

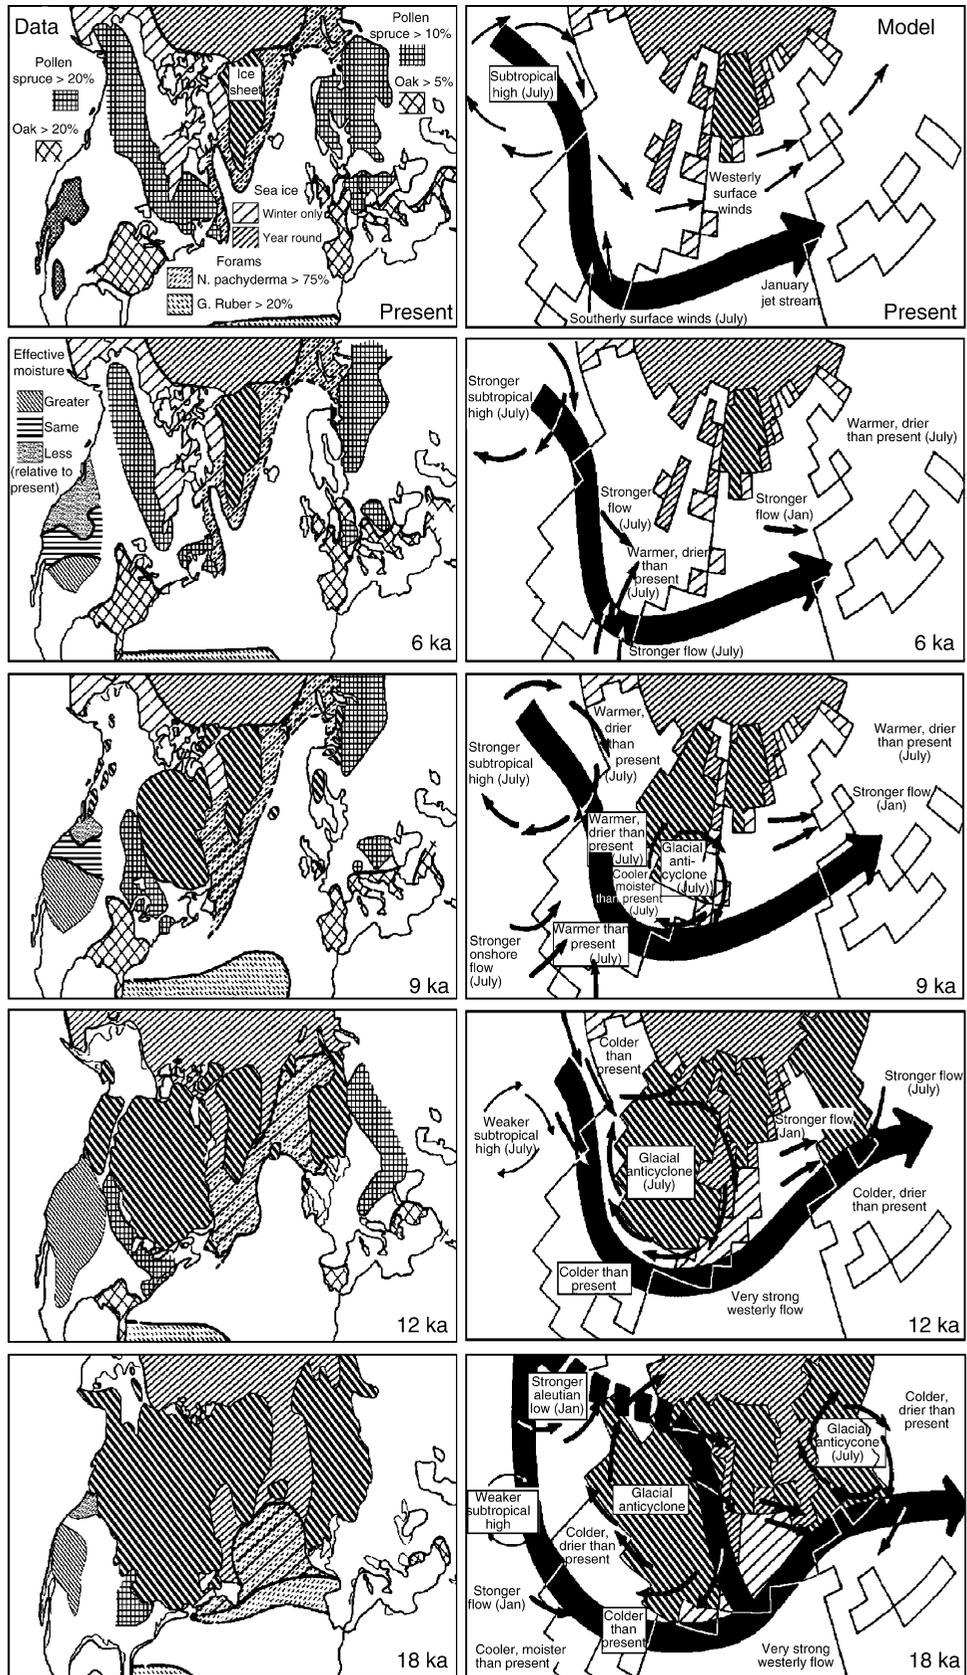

Figure C61 Continued.

and in active use at the NOAA World Data Base (<http://www.ngdc.noaa.gov/paleo/napd.html>).

With the addition of climate modeling, lake level data, and pollen data from other regions, the COHMAP effort expanded to a global program with a focus on comparing maps and time series of the model results with the data (Wright et al., 1993). CLIMAP's modeling of the LGM at 18,000 radiocarbon years ago or 21,000 calendar years ago was expanded by Kutzbach et al. (1993, 1998), who ran a global climate model to equilibrium with the boundary conditions at each 3,000-radiocarbon- or 5,000-calendar-year-interval between the LGM and present day (Figure C60). The climate model allowed COHMAP researchers to show the regional climatic impact of the broad-scale controls, such as ice sheet size, seasonal insolation, and greenhouse gas concentrations. The modeling results aided development of conceptual models for late Quaternary climate changes by illustrating mechanisms and circulation changes, and provided results that could be compared and thus tested by the data (Figure C61). Because the successful testing of the model results was key to their use in helping to explain late Quaternary climate changes, COHMAP researchers developed several methods for comparing the data to the model results. For each method, regional to continental-wide data sets were essential because of the 500-by-700-km gridding for the model results, which meant that only the broadest scale patterns could be compared.

In one approach, calibration data sets were used to calculate multiple regression equations and response surfaces that turned fossil pollen data into temperature and moisture estimates that, when mapped, could be compared to comparable maps of the model simulations. Hydrological models were also used to obtain moisture-balance estimates from lake-level data. In a second approach, response surfaces were used to turn model-simulated temperature and moisture values into maps of pollen or P-PE (precipitation minus potential evaporation) values that then could be compared to the pollen and lake-level data. In a final, more heuristic approach, cartoon-like maps illustrated the main features of the data and model simulations and allowed these visual representations to be compared (Figure C61). Such visualizations combined information from many diverse sets of data on the maps and brought focus to regions where the climate estimates from the data were robust.

COHMAP (1988) illustrated the first results of data-model comparisons in the context of time-series model simulations, as described in Wright et al. (1993). For the LGM over North America, these show that, in the model simulations, the high Laurentide Ice Sheet forced the winter jetstream southward over California, where winter storms brought moisture to fill the pluvial lakes (Figure C61). At the same time, the simulated glacial anticyclone produced anomalous easterly winds that created drier-than-present conditions in the Pacific Northwest just south of the ice sheet. As the ice sheet retreated, the jet and glacial anticyclone shifted in position, which altered the

pattern of moisture conditions across the west. In the east, much colder-than-present temperatures at the LGM favored spruce trees growing where oaks grow today. Then, the retreating ice sheet delayed the timing of peak warm temperatures during the Holocene in northeastern North America compared with the northwest and MacKenzie Delta areas. For the monsoonal regions of Africa and southern Asia, the climate model simulations showed an immediate (vs. delayed) response to orbital forcing and a much enhanced monsoonal circulation from 12,000 to 6,000 radiocarbon years ago when the contrast in seasonal insolation was greatest. Raised lake levels and steppe and savannah vegetation from western Africa into southern Asia fit well with the pattern of changes there.

These initial modeling results used version 0 of the NCAR Community Climate Model (CCM0), for which sea-surface temperatures needed to be prescribed. COHMAP researchers then updated the results using CCM1 with a mixed-layer ocean for a second set of time series runs (Kutzbach et al., 1998). They also used calendar-year calibrations for the radiocarbon dates and an ice sheet reconstruction that estimated a lower height for the Laurentide Ice Sheet at the LGM. The new simulations showed no split jet over North America in winter for the LGM, but showed most of the other main results (described above) to be robust and in good agreement with the data (Webb, 1998). A global biome model provided a new approach for data-model comparisons, and several papers illustrate its use to good effect. The simulated surface energy balance was also analyzed in detail and helped COHMAP researchers to separate dynamic from thermodynamic controls of regional climates (Bartlein et al., 1998). The data and model results showed clearly that climate changes vary spatially in magnitude as well as in timing and that phenomena like the "hypsithermal" were not globally uniform, either in magnitude or timing. With the patterns in moisture variations and seasonality varying along with temperature, no simple description of late Quaternary climates is possible.

Conclusions

Besides the key synthesis work (COHMAP, 1988; Wright et al., 1993; Webb, 1998), COHMAP results appear in over 200 journal articles and in edited books and journal issues by Wright (1983), Webb and Dubois (1985), Ruddiman and Wright (1987), and Huntley and Webb (1988). COHMAP research showed the broad impact of orbital forcing on late Quaternary climates and provided a background of forced changes onto which the many millennial-scale changes can be superimposed. Subsequent work has led to the mapping and modeling of Younger Dryas age climates; a study of possible feedbacks that affect the magnitude, pattern, and timing of late Quaternary climates; and an understanding of how climate patterns unlike any today have resulted in vegetation assemblages unlike any today.

Thompson Webb III

Figure C61 Changes in the atmosphere, geosphere, and biosphere that accompanied the transition from glacial to interglacial conditions during the past 18,000 years (18 ka), as illustrated by geological and paleoecological evidence (*left panels*) and features of the climate-model simulations (*right panels*). The maps of the data show the extent of ice sheets and of year-round and winter-only sea ice. For 18 ka, sea level lowering resulted in a broadened land area. The distributions of oak and spruce are inferred from pollen data, and the status of effective moisture (relative to present) in western North America is inferred from lake level records. The present region where annual precipitation is less than 300 mm is shown on the map for Present. The maps for the model simulations show the distribution of ice sheets and sea ice that served as boundary conditions for the simulations. *Thin black arrows* show the surface winds and *thick black arrows* show the jet stream position. The *broken line* for 18 ka over Alaska indicates a weakened jet (modified from color version in COHMAP, 1988).

CONTINENTAL SEDIMENTS

Introduction

Continental sediments can be very sensitive paleoclimate indicators because they are commonly deposited either in direct contact with the atmosphere or in close proximity to it. Relative to marine sediments, however, terrestrial sedimentary records of paleoclimate can be more difficult to interpret, due to incomplete preservation, fluctuating rates of sedimentation that commonly include significant periods of erosion, and post-depositional modification by bioturbation or diagenesis. This chapter first focuses on the broad association of various continental depositional systems (glacial, lacustrine, fluvial, and eolian) with specific climatologic settings. Following, several important paleoclimatologic indicators common to continental sediments are discussed.

Continental depositional systems and paleoclimate Glacial systems

The preservation of pre-Quaternary and Quaternary continental glacial deposits indicates that the Earth's climate has oscillated between an "icehouse" (i.e., glacial) and a "greenhouse" (i.e., interglacial) mode. Observations of modern glacial systems,

theoretical studies of glacial dynamics, and documentation of Quaternary glacial sediments form the basis for development of glacial system depositional models. However, because of the difficulty in examining modern subglacial processes and the fact that glacial environments are not at present extensive, the detailed environmental interpretation of ancient continental glacial sediments is not always straightforward. What is clear is that widespread deposition of glacial sediments on the continents, particularly in low latitude situations, indicates periods of significant global cooling.

Terrestrial glacial systems range in scale from local, alpine glaciers to continent-scale ice sheets. Glacial systems of all scales contain a variety of subenvironments that may be recognizable in the ancient sedimentary record. Among the most important are subglacial settings (under the glacier) and proglacial settings (in front of or adjacent to the glacier). Both environments may involve ice contact. Supraglacial settings (on top of the glacier) and englacial settings (within the glacier) have low preservation potential and will not be discussed here.

Subglacial ice contact deposits typically include some sort of glacial till – characterized by its very poor sorting and abundance of angular clasts, some of which may be glacially striated. Three till types are commonly recognized in ancient continental glacial deposits. Lodgement till typically forms by basal slip of the glacier against the sediment substrate. It is typically rather compacted and characterized by weak clast imbrication. More common is deformation till that forms through subglacial sediment shearing and is characterized by extremely poor sorting, random clast orientation, and evidence of soft-sediment deformation. Also common is melt-out till that usually contains evidence of subglacial water-reworking of sediment.

Although their sedimentology is not well documented, subglacial lakes of significant volume and longevity may be present beneath continental glaciers because of the insulation effects of the ice and internal heat of the underlying crust. For example, glacial Lake Vostok is estimated to be 70 km long and to have existed for up to 20 million years under the Antarctic Ice Sheet (Siegert et al., 2001). Although not a universally accepted idea, some workers have speculated that large subglacial lakes may have contributed significantly to glacial outwash flows, particularly during periods of deglaciation (Shaw et al., 1999).

Proglacial lakes can provide some of the best evidence for ancient glaciation because they commonly contain a variety of easily recognizable sedimentary structures. Perhaps most important are glacial-lacustrine rhythmites. Many (though not all) such rhythmites result from annual seasonal changes in sediment flux. Typically, glacial varves are characterized by a sharp base, corresponding to the onset of spring melt-out, overlain by relatively coarse-grained sediment deposited during spring and summer, followed by decreasing sediment sizes during the return to winter conditions. Sedimentation rates in proglacial lakes in which varves are being formed can be extremely high – commonly cm yr^{-1} (Ashley, 1975). In addition to rhythmites resulting from seasonal changes, proglacial lake environments are commonly characterized by widespread sediment gravity flow deposition, including overflows, interflows, and underflows (Gustavson, 1975). These result mainly through introduction of sediment by subglacial currents as well as through remobilization of sediments from lake margins. Ice-rafted debris (IRD), another common attribute of proglacial lake systems, consists of randomly-oriented coarse clasts (pebbles, cobbles, boulders) that are encased in

deeper-water glacial lake sediments (Levish, 1997). In the absence of association with other glacial sediments, IRD may be difficult to distinguish from poorly-sorted sediment associated with other sedimentary environments (e.g., some mud-rich debris flows).

In addition to lakes, proglacial settings can contain a spatially complicated suite of environments that may include bedload-dominated streams (glacial outwash) and eolian environments. Bedload-dominated streams associated with glacial outwash are difficult to distinguish from those not associated with glacial settings and thus are not by themselves good indicators of glaciation. Widespread eolian deposits in proglacial settings are commonly produced by adiabatic winds flowing off continental ice sheets. Proglacial eolian deposits can include both sand dunes and silt-sized loess, commonly occurring in paired dune-loess systems. Loess deposits typically consist of tabular beds of well-sorted silt that may contain included ventifacts and well-developed paleosols.

Lake systems

Lakes can contain some of the highest resolution sedimentary records of paleoclimate preserved in continental settings, because many of the physical, chemical, and biological processes that directly control sediment type and flux in lakes are driven by seasonal changes. Importantly, the preservation potential of lakes is generally high because lakes commonly form in areas where tectonic subsidence is significant.

Rates of lake basin infill by sediment and water are a function both of climate (e.g., effective precipitation rates) and tectonics (e.g., rate of subsidence of the lake basin bottom). This important relationship led Carroll and Bohacs (1999) to classify modern and ancient lakes as underfilled, balanced-filled, and overfilled. This is a useful classification because it can be readily applied to ancient lacustrine basins without the need for paleogeomorphic reconstructions. Underfilled lake basins typically reflect the inability of the delivery rate of sediment plus water to keep up with tectonic subsidence. Such lakes are typically closed and commonly retain some evidence of water column stratification, reduced bottom oxygen levels, and increased salinity levels. Overfilled lakes are usually open and reflect the inability of the subsidence rate to keep up with the delivery rate of sediment plus water. Such lakes are usually well-oxygenated and are characterized by progradation of deltas into the lake and a non-stratified water column. As the name implies, balanced-filled lakes occur in settings where subsidence and the rate of lake-basin infill by sediment and water are co-equal.

Climate records in lake sediments can be reflected by a multitude of sedimentologic, biologic, and geochemical characteristics that change over timescales ranging from 10^0 to 10^5 years. Annual seasonality may be faithfully recorded in lake sediments in the form of varve laminations that are controlled by seasonal environmental changes, such as variations in sedimentation flux, lake chemistry, or biology (Nuhfer et al., 1993). At longer time scales, oscillations in climate have been interpreted from a variety of sedimentologic characteristics in which some element of cyclicity is preserved. For example, Olsen (1990) described a series of upward-shoaling cycles within lake sediments from the Triassic rift basin of the eastern US. Applying spectral analysis to the temporal variations in relative lake depth, Olsen (1990) demonstrated that the frequency of water depth variation was consistent with that expected from astronomically-driven changes in the Earth's orbital parameters

(i.e., Milankovitch cyclicality). In a second example, Trauth et al. (2001) studied variations in sedimentology, diatom assemblages, and geochronology from East African lakes and concluded that the lakes alternated between deep freshwater conditions and shallow highly alkaline conditions on a 23-kyr-frequency band that is consistent with Milankovitch-driven cyclicality.

In addition to interpretation of orbitally-forced Milankovitch cyclicality in ancient lake deposits, lake sediments have proven useful in revealing the presence of other cyclic frequencies that may reflect atmospheric or coupled oceanic-atmospheric processes that are as yet poorly understood. For example, Munoz et al. (2002) studied laminated lake sediments from Spain and concluded that cyclic sedimentation reflected climate variations due to the El Niño Southern Oscillation (ENSO) and the North American Oscillation (NAO).

Three types of end-member lake types have been recognized as having particular paleoclimatologic significance. These are glacial lakes, playa lakes, and organic-rich lakes. Glacial lakes are discussed above. Playa lakes are shallow, closed lakes formed in areas of low effective precipitation and high rates of evaporation. Playa lakes usually have alkaline or saline water chemistries. Common characteristics include: (a) deposition of evaporites or alkaline minerals such as dolomite, various zeolites, and Mg-rich clays; (b) organic-rich laminated mudrock in the central part of the lake basin; and (c) abundant mudcracks – particularly in lake margin facies. The margins of saline or saline, alkaline lakes commonly interfinger with alluvial fan sediments, indicating the important role of tectonics not only in creating the lake basin, but also in the production of orographic climate effects (e.g., rain shadows) in some cases. Organic-rich lakes occur in a variety of tectonic and climatologic settings, so it is typically necessary to supplement climate interpretations based on sedimentary character with those from other data sets such as organic geochemistry or the composition of diatom assemblages. Organic-rich bottom sediments are commonly deposited in lakes with permanent thermal or salinity stratification, and anoxic bottom conditions develop in tropical climates with low seasonality and high humidity. For example, organic-rich lakes are common in equatorial Africa (Talbot, 1988) – an area characterized by little seasonality but abundant rainfall. In contrast, organic-rich lakes also are common in temperate North America (between 42° N and 55° N latitude) where seasonality is strong but annual productivity is high (Anderson et al., 1985).

River and alluvial fan systems

River system dynamics are controlled by a large number of variables that may be influenced by climate but may also reflect other external controls such as rates of subsidence and sedimentation. Unfortunately, the geomorphology of ancient fluvial systems is rarely preserved in the rock record. As a result, paleoclimatologic interpretations of ancient fluvial systems typically have focused on documenting the nature and geometry of sand bodies deposited by riverine processes and on determining whether ancient streams were ephemeral (i.e., not flowing continuously) or perennial (flowing continuously).

Use of fluvial sand body geometries to infer paleoclimate, though qualitative, usually focuses on distinguishing between mud-dominated streams that are inferred to be meandering, and bedload-dominated streams that are inferred to be more braided. Although both stream types can occur in a wide variety of climate settings and both are controlled by numerous factors other than climate – tectonics in particular – the implication is

that mud-dominated streams usually represent a more humid climate than bedload-dominated streams. Meandering stream channel sands tend to be isolated, with well-preserved channel forms and relatively few internal scours, a relatively fine overall grain size, and common preservation of lateral accretion surfaces within channel deposits. Paleocurrent indicator directions tend to be widely dispersed. Overbank regions are characterized by abundant evidence of plant colonization and, commonly, the occurrence of coal. Braided river deposits are usually characterized by sand bodies that are multistoried and multilateral, an abundance of cut and fill scour surfaces, relatively coarser and less well sorted sediment, and common planar and trough cross-bedding. Individual channels are rarely preserved, the ratio of sand to mud is higher than meandering streams, and evidence of plant colonization is less common. Overbank regions commonly contain well-developed calcsol (caliche) horizons (Miall, 1992, 1996).

Distinguishing between ancient ephemeral and perennial stream flow may be a somewhat more reliable means of interpreting paleoclimate than determining whether ancient streams were mud- or bedload-dominated, although both forms of interpretation are qualitative assessments of paleoclimate. Generally, ephemeral streams are more likely to represent dry climates than perennial streams. Common features of ancient ephemeral streams include: (a) relatively small sandstone bodies with upper flow regime structures produced by short but powerful flash floods; (b) abundant reworked sand and mud intraclasts, suggesting short duration flows; (c) common desiccated mud drapes and/or interbedded eolian deposits; (d) abundant root traces within the channel system, and (e) well-developed calcsols in overbank regions (Parrish, 1998). In contrast, perennial streams are typically characterized by larger sandstone bodies and low flow regime sedimentary structures, such as subaqueous dunes and current ripples, which are interpreted to reflect lower velocity and more sustained flows.

Alluvial fans are generally not regarded as good indicators of paleoclimate, although specific climatologic indicators (e.g., evaporites, coal) can be associated with alluvial fan systems. Alluvial fans are generally more useful as evidence of tectonic activity, because steep topographic gradients are required for alluvial fan formation. Nevertheless, climate can be an important influence on fan sedimentation. For example, Blair and McPherson (1994) described alluvial fans in terms of two end-members: debris-flow dominated fans, generally associated with more arid climate regimes; and sheet flood dominated fans, generally associated with more humid climate regimes. In many ancient cases, alluvial fans are indistinguishable from braided river deposits. Although this similarity might imply that alluvial fans are mostly associated with arid environments, fans are also common in well-watered environments as, for example, proglacial outwash fans, which commonly occur downstream from alpine glaciers.

Deserts and eolian systems

Deserts are generally defined as areas characterized by low rates of precipitation and high rates of evaporation. More specifically, the definition depends on the ratio of actual precipitation (P) to evaporation and evapo-transpiration (E_t). Deserts are usually characterized by P/E_t ratios of 0.2 (Parrish, 1998). Modern deserts generally occur in three different settings, each of which is characterized by air masses that retain moisture as they heat up, thereby inhibiting atmospheric condensation and resulting precipitation. The largest modern deserts (e.g., the Sahara) occur at lower middle latitudes (~30° N and 30° S) where dry,

descending upper-atmospheric flow heats up, inhibiting precipitation and enhancing evaporation. Deserts are also common in coastal areas where cool offshore air is brought onshore, where it heats up and retains excess moisture. The Namibian and Atacama Deserts are good examples. Lastly, deserts can be produced by orographic effects such as rain shadows (e.g., the Great Basin, western USA).

Modern and ancient deserts contain a variety of recognizable sedimentary facies that are good indicators of low effective moisture. Among the best of these are eolian sands. Eolian sands are readily recognizable in the ancient rock record because they are typically well sorted, commonly contain frosted grains produced by elastic grain-to-grain collisions in air, and usually include grain flow, grain fall, and wind ripple sedimentary structures (Kocurek and Dott, 1981). Grain flows result from avalanching of grains down the steep, lee side of sand dunes. Grain flow deposits are typically only a few cm thick, usually massive, and thin towards the bottom of the dune. Grain fall deposits, on the other hand, result from eolian transport of grains and deposition as a thin drape over pre-existing topography. Grain fall deposits are usually rather thin (1–2 mm thick) and are somewhat finer-grained than surrounding deposits. Wind ripple deposits are particularly diagnostic of eolian environments because wind ripples form by a fundamentally different process to subaqueous ripples and bear correspondingly different internal architectures. Wind ripples form by ballistic impacts of saltating grains on the bed surface. These ballistic impacts tend to organize the bed into ripples characterized by coarser grain populations (so-called “creeping population”) on ripple crests and in relatively protected ripple lee sides, and finer grain populations in ripple troughs and in less protected windward sides of ripples. As wind ripples migrate downwind and aggrade vertically, they leave behind mm-scale laminations of sand that typically coarsen upward as coarser-grained ripple crests migrate over finer-grained ripple troughs. Interfingering of wind ripple deposits with grain flow deposits at the base of dunes is generally regarded as unequivocal evidence of eolian sedimentation.

In addition to eolian sands, eolian systems commonly contain a variety of other environments that can yield important paleoclimatologic information. Most important of these are interdune depressions. Interdune depressions can be the sites of playa lakes, deflation flats, or ephemeral fluvial systems. The presence of interdune playa lakes is commonly controlled by the elevation of the water table relative to the dune surface. Although water table elevation can fluctuate out of phase with climate, it commonly provides some indication of moisture availability. For example, elevated water tables that tend to stabilize interdune areas commonly reflect greater availability of moisture (Havholm et al., 1993). In “wet” eolian systems, the area represented by interdune areas may be greater than that represented by eolian sandy bedforms. In dry eolian systems where the water table elevation is considerably below the bedform surface, interdune flats may be absent altogether (Herries, 1993).

In addition to their utility as indicators of low effective moisture, eolian sand deposits may be the best indicators of paleowind direction. Modern and ancient eolian sands typically accumulate in a variety of dune morphologies. Although not always straight-forward, the internal architectural elements of these dunes can provide direct evidence of paleowind direction. For example, unimodal wind directions commonly produce transverse dunes. As these dunes migrate, sand is eroded from the windward side of the dune and accumulates near the crest

of the dune. This accumulation eventually destabilizes and flows down the steep front side of the dune, producing a slip face that slopes downwind. As the dune migrates with time, these slip faces are commonly preserved as internal bounding surfaces. In ancient dune deposits, the orientation of such bounding surfaces can be measured and used to infer paleowind directions (Parrish and Peterson, 1988).

Despite the utility of dune slip facies for inferring paleowind directions, wind regimes are not typically unimodal but vary seasonally in their direction. The long axes of dunes deposited under such changing wind regimes are usually oriented obliquely to the average annual wind direction. Essentially, the dune is oriented in the position that is most transverse to each wind direction, weighted by wind energy. Thus, use of internal dune architecture to infer paleowind directions commonly requires three-dimensional modeling of dune morphology (e.g., Rubin, 1987) and resulting bounding surfaces. Given well-preserved three-dimensional exposures of ancient dunes and recognition of relationships among dune morphology, internal architecture, and prevalent wind direction(s), measurement of bounding surface orientations can provide paleowind information that is directly comparable with output from global atmospheric circulation models. For example, Parrish and Peterson (1988) measured the orientation of sedimentary structures produced by paleowinds as preserved in Lower Jurassic strata of the Colorado Plateau. These paleocurrent data contained convincing evidence both of summer monsoonal flow and summer subtropical high-pressure atmospheric gyres associated with the Pangean supercontinent and predicted by global circulation models.

Specific lithological indicators of climate found in continental sediments

Coal

Coal is a sedimentary rock that contains >70% organic carbon and is formed by lithification of peat, consisting of accumulations of vegetation that is adapted to saturated (waterlogged) conditions. Coal is generally described in terms of four lithotypes: vitrain, clairain, durain, and fusain (Teichmüller, 1989). Lithotypes, in turn, are composed of three types of coal macerals: vitrinite, liptinite (exinite), and inertinite. Each of these is further subdivided into a number of submacerals that typically can be recognized through petrographic analysis (Stach et al., 1982).

Peat accumulations form in raised mires or swamps under anaerobic, acidic conditions in which the local water table is at or above that of the surrounding area. This water table configuration generally inhibits the deposition of clastic sediment (clay, silt) and results in acidic conditions that inhibit bacterial decay of the peat itself. Peat accumulations also are characterized by relatively low nutrient (phosphorus and nitrogen) levels, because these elements are introduced mainly through precipitation rather than groundwater influx, particularly in the case of raised mires.

Peat, and by extension coal, is generally regarded as being associated with environments that are characterized by abundant precipitation. High precipitation not only can maintain a shallow water table, but also can promote plant growth and enhance the development of anoxic conditions within the peat accumulation. Although peat is generally associated with environments in which mean annual precipitation exceeds evaporation, Gyllenhaal (1991) demonstrated that many peats occur in environments where precipitation and evapotranspiration are roughly balanced. Ziegler

et al. (1987) and Gyllenhaal (1991) both suggested that peat accumulations are favored in environments characterized by a consistent, year-round minimum amount of monthly precipitation in the range of 20–40 mm/month. That is, peat formation is promoted more by a steady source of precipitation, rather than an annualized average net precipitation.

Despite the common association between peat formation and abundant precipitation, the interpretation of paleoclimate from coal occurrence is not straightforward. Firstly, though uncommon, a number of modern peat accumulations have been documented for areas in which the mean annual precipitation rate is less than the mean annual rate of evapotranspiration (Gyllenhaal, 1991). Second, preservation of coal in the rock records depends on a delicate balance between peat formation and subsidence of the sedimentary basin in which the peat occurs. Too rapid a rate of subsidence will drown the peat deposit. Too low a rate of subsidence will not allow sufficient peat to accumulate to produce very thick beds of coal. Thus, it is commonly difficult to formulate interpretations regarding paleoclimate based solely on the presence of coal, particularly for local basin-scale studies. On the other hand, global paleoclimate studies seeking to identify large-scale, regional trends have successfully demonstrated a link between coal occurrence and predicted distributions of high precipitation based on modeling (Parrish et al., 1982).

The petrography of coal can yield considerable information regarding the macerals that make up a coal, and many workers have attempted to link various maceral types with paleoclimatologic conditions in which the precursor peat accumulated. For example, Teichmüller (1989) proposed that abundant vitrinite in coal could be interpreted as reflecting a high rate of precipitation and a raised water table, whereas inertinite-rich coal forms under dry conditions with relatively low or seasonally fluctuating water tables. Other workers have attempted to tie the petrographic characteristics of coal to temperature (e.g., Diessel, 1992) or the taxonomic composition of the mire vegetation, which depends on both paleoclimate and geologic age (Cameron et al., 1989).

The ash and sulfur content of coal – two major considerations for determining the economic value of a coal deposit – also have been proposed as reflecting the paleoclimatologic conditions in which peat accumulates. Cecil et al. (1982) proposed three end-member conditions for the formation of peat that are related to paleoclimate and may be recognized through coal geochemistry. First, peats forming under permanently waterlogged conditions give rise to low ash, low sulfur, vitrinite-rich coals. Permanently saturated conditions inhibit the influx of detrital clays (resulting in low ash content), promote an acidic geochemical environment (pH <4.5) that inhibits the ability of sulfate-reducing bacteria to fix iron (resulting in low sulfur), and ultimately favor the preservation of abundant woody vegetation (vitrinite). Second, peats forming in planar mires under anaerobic conditions with pH >4.5 give rise to high ash, high sulfur, liptinite-rich coals, because of the introduction of significant detrital siliciclastic material, the ability of sulfate-reducing bacteria to fix iron as pyrite (FeS₂), and the accumulation of waxy cutaneous organic matter (liptinite). Third, peats forming in planar mires under conditions of lower annual rainfall or a seasonally fluctuating water table are characterized by a higher percentage of siliciclastic sediment (ash), development of aerobic conditions that inhibit sulfate reducing bacterial activity (low sulfur) and the accumulation of relatively abundant charcoal and carbonized woody debris (inertinite).

Evaporites

Most studies that use facies distributions to reconstruct global paleoclimate include evaporites. Although evaporites commonly involve the influx of marine waters as a source of dissolved ions, this is not always the case. Many modern evaporite deposits are forming in hypersaline lacustrine settings, such as the Dead Sea. The largest modern evaporite-forming environments are located in mid-latitudes (approximately 30° N and 30° S), where dry upper atmospheric air descends, heats up, and loses humidity. This humidity loss may lead to the formation of ergs (large sand seas) and associated evaporites.

As the name implies, the formation of evaporites involves concentration of dissolved ions to the point where salt precipitation occurs. Controls on evaporite mineralogy include the concentration and composition of dissolved ions. Progressive evaporation of normal marine seawater, for example, typically results first in the formation of carbonates, then sulfates, then halides. In continental environments not involving marine water as an ionic source, unusual evaporite minerals may be formed that differ from those formed at the marine-nonmarine interface. For example, economically valuable deposits of borate evaporites have formed in Death Valley, California, as a result of the weathering of surrounding hydrothermally-altered bedrock.

Environmental conditions needed for the formation of evaporite minerals typically involve low rates of precipitation, although many evaporite-forming environments involve monsoonal flow of moisture during the “wet” season. In such cases, the influx of monsoonal moisture is usually not high, and evaporation during the dry season typically exceeds precipitation during the wet season, resulting in net annual concentration of dissolved ions in surface and shallow groundwater. In many modern and ancient evaporite-forming environments, topography plays an important role in creating the aridity that leads to evaporite deposition. For example, Death Valley is located in the rain shadow of the Sierra Nevada.

Red beds

The term “red beds” is commonly applied to red-colored clastic sedimentary deposits associated with seasonally arid paleoclimate and warm temperatures. The red color is usually caused by hematite (Fe₂O₃) staining and is a function of grain size and the time elapsed since deposition, with finer grained and older deposits typically being redder. Hematite in terrestrial settings also can be formed from dehydration of hydrous iron oxides or precipitation in the presence of alkaline ground water. Terrestrial red beds associated with warm, seasonally arid climate include desert red beds (ephemeral stream, eolian, and some playa lake deposits), monsoonal “savannah” red beds in which annual wet and dry seasons are subequal in duration, and tropical red beds formed in conditions of intense chemical weathering. Tropical red beds usually contain an abundance of iron and aluminum sesquioxides (e.g., bauxite deposits) and typically form in strongly monsoonal climates. Although the term “red bed” is very common in the literature and many terrestrial clastic sedimentary deposits are likely formed in warm seasonally arid paleoclimatic conditions, red color is not diagnostic of these conditions and care should be exercised in making this interpretation.

Paleosols

Paleosols are ancient, buried weathering surfaces (soils) that are very common in the continental rock record and contain

considerable information about the nature of paleoclimatic conditions during the weathering process. Many classification schemes for paleosols have been developed (Retallack, 1988, 1990; Mack et al., 1993); in general, these classification systems are based on textural and compositional features that are quite different from the criteria that form the basis for classification of modern soils.

Physical and chemical characteristics of paleosols are determined from the duration of exposure to weathering and the composition of exposed bedrock, the availability of water, and diagenesis. Paleosols are commonly rich in carbonate, silica, organic matter, and sesquioxides such as Fe_2O_3 and Al_2O_3 and are generally more colorful than the surrounding rock. Paleosols commonly display a variety of distinctive textural features such as nodules, concretions, root traces, vertical or horizontal jointing, and hackly fracture.

Paleosols that are qualitatively associated with specific paleoclimate conditions include oxisols, vertisols, calcisols, gypsisols, histisols, and spodosols. Oxisols are characterized by low amounts of organic matter and abundant Fe or Al sesquioxides (laterites or bauxites) that typically are concentrated by poor drainage in areas of intense chemical weathering. These environments tend to be tropical with abundant rain for most of the year, followed by a several-month-long dry season. Vertisols are named so for the common presence of vertically-oriented fractures, called peds, that result from swelling and shrinkage (pedoturbation) of expandable clays (smectite or mixed layer smectite/illite). Climate regimes in which vertisols form are usually strongly seasonal with respect to rainfall (i.e., strongly monsoonal). Calcisols and gypsisols typically contain little organic matter and are named for the presence of pedogenic calcite and gypsum, respectively. Both paleosol types – gypsisols in particular – are associated with arid climates that are seasonal with respect to rainfall. Histisols are organic-rich soils that form in areas characterized by poor drainage, high rates of precipitation, and low rates of evaporation. Histosols can form in temperate or tropical areas. Spodosols can also be organic-rich and are characterized by a distinct horizon of concentrated organic matter and iron oxides formed by downward movement and accumulation (illuviation) of amorphous material during weathering. Spodosols are typically associated with cool climates in which precipitation exceeds evaporation. Lastly, argillisols, characterized by a distinct subsurface accumulation of clay, also reflect significant illuviation and commonly form in mid-latitude paleoclimates that are characterized by an excess of precipitation relative to evaporation.

Summary and conclusions

Continental sediments can provide an important basis for the interpretation of paleoclimate, including qualitative estimates of paleotemperature (hot vs. cold), annual precipitation (wet vs. dry), seasonality, and paleowind direction. However, care must be exercised in using the sedimentology or geochemistry of continental deposits to infer paleoclimate because of the wide range of influences that may control sediment composition and sedimentary architectures, the susceptibility of continental sediments to diagenetic overprinting, and the bias introduced through erosional deletion of significant portions of the sediment record.

CORALS AND CORAL REEFS

Nowhere do the sciences of biology and geology come closer together than in the study of coral reefs. Reefs can be considered as geological structures – massive ramparts of rock – that have been built by organisms in the distant past, or they can be considered as ecosystems that are as fragile as any other on Earth. Reefs, the geological structures, are the direct products of diverse living ecosystems and as such, their formation has

- Phylum Cnidaria
 Class Hydrozoa
 Order Hydroidea (hydroids)
Order Milleporina (including Genus *Millepora*)
Order Stylasterina (including Genera *Distichopora* and *Stylaster*)
 Class Scyphozoa (jellyfishes)
 Class Cubozoa (sea wasps)
 Class Anthozoa
 Subclass Octocorallia
Order Helioporacea (*Heliopora coerulea*)
Order Alcyonacea (soft corals, *Tubipora*, sea fans and relatives)
 Order Pennatulacea (sea pens)
 Subclass Hexacorallia
 Order Actiniaria (simple sea anemones)
 Order Zoanthidia (colonial anemones)
 Order Corallimorpharia (corallimorpharians)
Order Scleractinia (true stony corals)
Order Rugosa (Paleozoic corals)
Order Tabulata (Paleozoic corals)
 Subclass Ceriantipatharia
 Order Antipatharia (black corals)
 Order Ceriantharia (tube anemones)
-

Groups having some or all species with stony skeletons are indicated in bold.

always been controlled by the sorts of events that control other ecosystems, both marine and terrestrial.

The term “coral” is commonly used for both “soft” and “hard” corals and sometimes includes other colonial Cnidaria (also commonly called Coelenterata). The term “coral,” used without a qualifying term, most commonly refers to hard or skeletonized corals and it is used this way here. The taxonomic relationship between the taxa is indicated in the box below. This classification does not include many extinct orders of skeletonized Cnidaria with uncertain affinities.

Of the orders listed above, the three hexacoral orders (shown in **bold**) are, or were, dominant faunas of coral reefs as well as non-reef habitats. Scleractinia occur in the Mesozoic and Cenozoic; Rugosa and Tabulata occur in the Paleozoic. The four octocoral and hydrozoan orders (**bold**) are all primarily or entirely Cenozoic.

Of the four extant orders, all except the Stylasterina are partly or wholly zooxanthellatooxanthellatee (corals that have symbiotic blue-green algae called zooxanthellate in their tissues, see below) and are therefore restricted to sun-lit depths and warm water. Whether or not Rugosa and Tabulata were also zooxanthellate has long been debated without definite outcome.

Paleozoic corals

Many Cambrian fossils have at times been called “corals.” The most coral-like of these are small, cup-shaped, mostly solitary organisms with septa. Some have an operculum over the calice opening (Jell and Jell, 1976). In total, seven orders of Paleozoic corals may be recognized, of which the Tabulata and Rugosa are by far the most important. Unlike the Scleractinia, these two groups have left good fossil records, as their skeletons are calcitic and thus more stable than the aragonite skeletons of Scleractinia.

Order Tabulata (Early Ordovician–Permian)

Tabulata are much less variable than rugose or scleractinian corals. They are all colonial and consist of slender tube-like corallites

1–3 mm diameter, crossed internally by transverse partitions, the tabulae. Colonies are typically incrusting, flat or massive, but may be branching. Individual corallites may be in contact or widely separated. Each corallite has a theca (enveloping sheath) and groups of corallites are enclosed in a sheath-like epitheca. The corallites may be connected by fine tubules forming a three-dimensional structure. Where corallites are in close contact, internal horizontal partitions (tabulae) are usually found. Where corallites are separated, external horizontal plates (dissepiments) also occur. Radially arranged spine-like septa, sometimes forming vertical structures, may be present.

The morphology of the Tabulata does not indicate whether they were zooxanthellate or not. However, as they were colonial, had small corallites, and had growth rates comparable to those of zooxanthellate Scleractinia (up to 18 mm per year), it seems probable that they were.

The Tabulata are first seen as a distinct group in the Early Ordovician and thus pre-date the Rugosa (Figure C62). There is no evidence of common ancestry. By Middle Ordovician, there was a radiation in Tabulata diversity, with six families recognized. These are mostly associated with soft substrates rather than carbonate platforms of high-energy environments. Tabulata became significant frame builders during the Silurian but were relatively unimportant during intervals of maximum reef development in the Devonian. They appear to have not re-gained diversity during the Carboniferous or Permian, although they were periodically abundant.

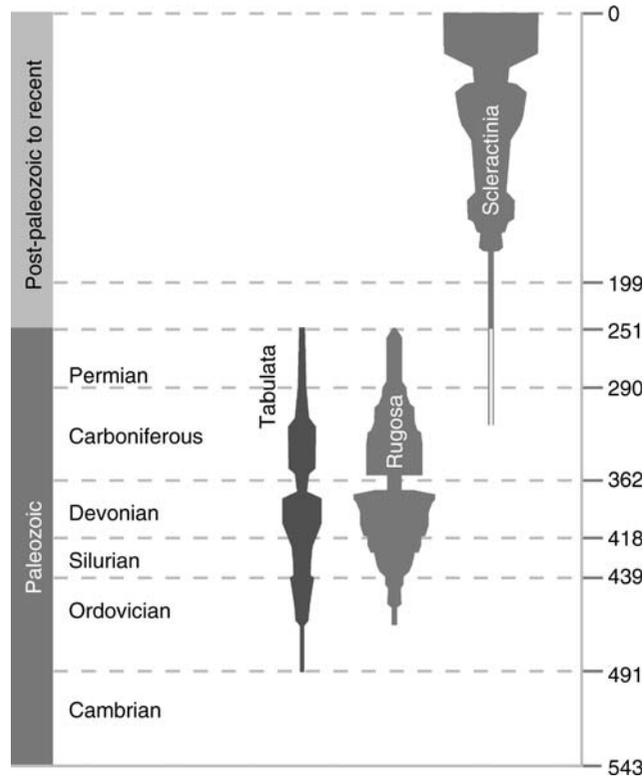

Figure C62 Approximate generic diversity of the three main orders of corals over time. Numbers to the right indicate millions of years ago. (After Stanley and Fautin, 2001.)

Order Rugosa (Mid Ordovician–Permian)

Rugosa have a much greater resemblance to Scleractinia than to Tabulata. Mature colonies have an array of growth forms comparable to Scleractinia (see below), although the majority of taxa are solitary or form colonies where individual corallites are large and dominant. Rugosa have basic structural components at least superficially similar to Scleractinia, the main difference being in the arrangement of the septa (Figure C63). Tabulae analogous to those of Tabulata are usually very abundant and so is a complex array of dissepiments that appear analogous to those of Scleractinia.

The earliest Rugosa were solitary and of simple construction. Complex colonies had evolved by Late Ordovician and thereafter the few evolutionary trends that are seen are mostly in skeletal detail and most have reversed one or more times. Differences in the pattern of insertion of septa make it unlikely that the Scleractinia arose from the Rugosa although this view is disputed.

Paleozoic coral reefs

Reef-like carbonate structures of one form or another have existed on Earth for at least 2.7 billion years (Wood, 1999). The first reef-like limestone accumulations (excluding microbial carbonates), found in Proterozoic rocks the world over, were simple structures formed by stromatolites, hemispherical mounds of what were probably blue-green algae that entrapped fine sediment much as stromatolites do today. The first reef-like structures of animal origin were built by archaeocyath sponges of the Lower Cambrian (530–520 MyBP). What reef-building there was after the extinction of the archaeocyaths was mostly due to cyanobacteria, stromatolites and some coral-like Anthozoa, all growing in shallow protected waters and containing abundant trilobites together with a wide diversity of mollusks.

Late Cambrian ecosystems persisted into the Middle Ordovician, when complex algae and invertebrate reef communities became widespread and reef biota greatly diversified. Stromatoporoïd sponges and tabulate corals radiated at this time. Rugose corals first appeared in the Middle Ordovician and rapidly increased in number and diversity (Figure C62). Thus, algal communities were largely replaced by communities of skeletonized metazoans. By Late Ordovician, colonial rugose and tabulate corals had greatly diversified in shallow water and formed coral patch reefs, along with stromatoporoids, other sponges and calcareous red algae. These reefs had little wave

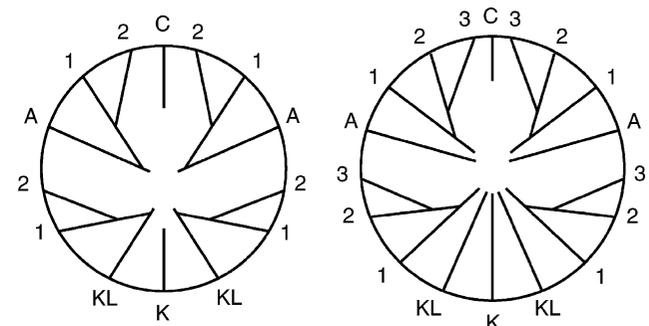

Figure C63 The basic septal pattern of Rugosa corallites. This pattern is usually unrecognizable in mature corallites. C = cardinal septum, K = counter septum, A = alar septa, KL = counter-lateral septa. (After Oliver, 1980.)

resistance and did not form solid platforms, although stromatoporoids and tabulate corals formed massive colonies several meters diameter. These are the oldest-known reef coral communities and were possibly the outcome of endo-symbiotic animal/algal associations. For at least 150 million years, different combinations of these algae, sponges, and corals built reefs around the tropical world (Wood, 1999). Silurian reefs became abundant and diverse and some reached massive proportions, the first truly wave-resistant carbonate platforms.

In the Devonian, especially the Middle to Late Devonian, reefs reached maximum development for the Paleozoic, if not the entire Phanerozoic. What remains today of these reefs are sometimes of awesome size and have the full range of zonation seen in modern reefs. They had a high diversity of frame builders including microbialites, calcifying cyanobacteria, stromatoporoid and other sponges as well as tabulate and rugose corals. They also contained a diversity of other fauna and flora perhaps comparable to modern reefs. However, before the close of the Devonian, reef building ceased abruptly and thus it remained until scleractinian-built reefs first emerged in the Late Triassic. This Late Devonian to Late Triassic interval is the longest hiatus in reef building in the geological record.

Latest Devonian reefs are relatively rare, and most reef-like constructions were relegated to relatively deep water throughout the entire Carboniferous. This was an interval of great climatic upheavals, sea-level fluctuation, and low ocean temperatures, all probably contributing to environments hostile to reef development. During the Late Carboniferous to Early Permian, phylloid (leaf-like) algae so completely dominated would-be reef substrates that most reef biota may have been displaced. Late Permian reef-like structures are characterized by frondose bryozoans, a wide range of sponges, algae, and encrusting tube-like *Tubiphytes* (of unknown taxonomic affinity), all with little cementation. Corals are uncommon everywhere.

The causes of the end-Permian extinctions are elusive, but as far as reef biota are concerned they were probably the result of a rapid drop in sea level succeeded by extensive volcanism and anoxic conditions, followed by an extensive sea-level rise. It has been estimated that 80–95% of all species became extinct. Apparently, among these were all corals.

Mesozoic and Cenozoic corals

Order Scleractinia (Middle Triassic to present)

Extant Scleractinia have similar numbers of zooxanthellate and azooxanthellate genera and species. These two groups are not taxonomically separate although they are almost all sharply eco-physiologically distinct. Zooxanthellate Scleractinia (sometimes called “reef-building corals”) are primarily colonial and are responsible for the construction of most Mesozoic to present coral reefs. Azooxanthellate Scleractinia are primarily solitary and most occupy deep water.

Structure. The simplest skeleton of an individual polyp, the corallite, is a tube-like structure, the corallite wall. Radially arranged vertical plates, the septa, are the dominant structures within the wall (Figure C64). Corallites may be solitary or joined by horizontal plates and other structures, collectively called the coenosteum. Some polyps or colonies have an epitheca, a thin film of skeleton surrounding the lower wall or colony perimeter. Complex colonies of many types are derived from this basic structure (Veron, 2000).

The sac-like body cavity of the coral polyp is the coelenteron, which serves many functions including digestion and

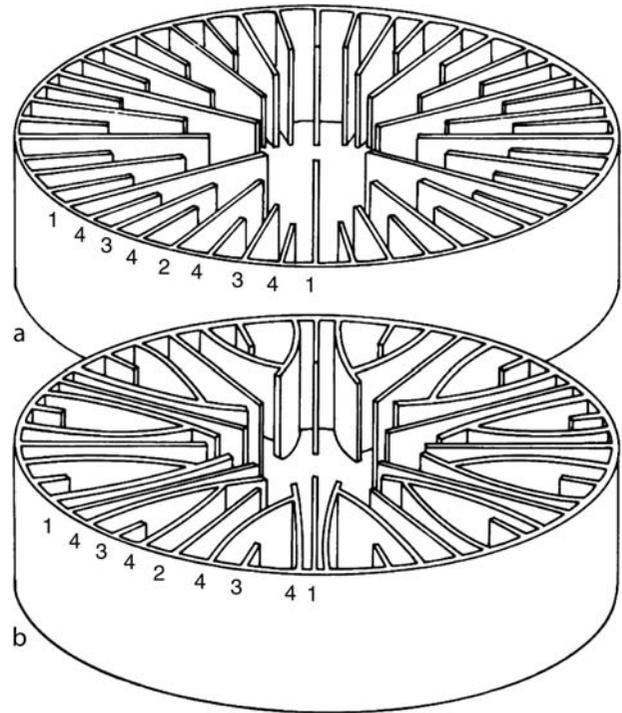

Figure C64 Septal patterns of Scleractinia showing simple radial symmetry (above) and poutales plan (below). The latter is found in several different families. *Porites* has a distinctive bi-radial symmetry of septa.

the circulation of fluids for respiration and nutrition. It is partitioned by vertical mesenteries that have coiled filaments along their inner margins.

Most Scleractinia have tentacles. These are smooth in corals that feed on detritus but most taxa have stinging cells (nematocysts) for defense and food capture. Nematocysts are commonly grouped into wart-like batteries.

Cnidaria are the simplest organisms to have discrete nervous, muscular and reproductive systems, and these are all well developed in Scleractinia. Some corals have separate male and female sexes but most are hermaphrodites.

Evolutionary history. The first organisms that might be called scleractinians are known from Paleozoic fossils from China and Scotland (Ezaki, 1998), but the earliest proliferation of organisms that were clearly ancestral Scleractinia are Middle Triassic and consisted of at least seven, but possibly nine, suborders. These corals did not build reefs; they were small solitary or phaceloid organisms of the shallow Tethys of southern Europe and Indo-China (Stanley and Fautin, 2001; Stanley, 2003).

There is current debate about whether the Scleractinia are a single lineage (monophyletic) or whether the order also includes non-skeletal taxa such as extant Corallimorpharia or other anemone-like taxa that are now extinct (Stolarski and Roniewicz, 2001; Stanley, 2003). Molecular studies (Veron et al., 1996; Romano and Cairns, 2000) are inconclusive so far, although they strongly indicate that any common ancestor would have been Paleozoic and thus were presumably Rugosa (see above) or, more likely, soft-bodied. Certainly, Scleractinia without skeletons may have existed both before and after the Middle Triassic (Oliver, 1980; Buddemeier and Fautin, 1997; see review in Stanley, 2003).

During the Middle and Late Triassic, corals became widespread throughout the Tethys region and their fossils are now found around much of the equatorial Panthalassa Ocean rim. There was an enormous time interval of 20–25 million years between the earliest Triassic corals and the earliest widespread coral reefs. Most noteworthy of Triassic corals is that they had a wide range of skeletal micro-structures, suggesting that any common ancestry would have been remote. Nevertheless, Triassic corals were not the ecological equivalents of modern corals; corallites were large and poorly integrated, such that phacelloid growth forms (where branches are composed of individual corallites) were dominant.

There was a 5–8 million year hiatus between the collapse of Triassic reef development and the onset of Jurassic reefs, a time of origin of many new scleractinian families (Beauvais, 1989). The Late Jurassic was probably the all-time global maximum of Mesozoic coral diversity with at least 150 genera recorded in the European Tethys and 51 in the Panthalassa. Paleobiogeographic provinces can be recognized that reflect continental plate movements, especially the increasing width of the Protoatlantic. By the Late Jurassic, the paleobiogeographic pattern that had developed was the precursor to the pattern that persisted into the Cenozoic. It was dominated by massive reef development throughout the Tethys, the Atlantic, and the far eastern Panthalassa. The vast expanse of the eastern Panthalassa was probably a barrier to east-west dispersion, just as the far eastern Pacific is today.

A high proportion of the families of extant Scleractinia have their origins in the Middle to Late Jurassic. For most, the fossil record is not clear and thus there are few links between the main branches of the Family Tree (Figure C65). The Jurassic was the time of proliferation if not the origin of two of the major groups of corals, the Fungiina and the Faviina. The Fungiina dominated much of the Jurassic and the Cretaceous. As a group, it was greatly diminished by the end-Cretaceous mass extinctions and the families attributed to it today have uncertain affinities. The Faviina, on the other hand, are a well-defined group and the Faviidae have remained a major family for 150 million years.

Early Cretaceous corals are broadly similar to those of the Late Jurassic (Beauvais, 1992). However, relatively little is known of the Middle Cretaceous corals. The continuity of families indicated in Figure C65 is largely due to extrapolations between Early and end-Cretaceous fauna, with poorly-known families omitted. This is because, by Middle Cretaceous, reefs worldwide had become dominated by rudist bivalves and environmental perturbations greatly affected reef development. It was not until the very late Cretaceous, following an unexplained total extinction of the rudists, that corals returned to a position of dominance. At this time reefs probably again occurred worldwide, but there are few remains of them today.

One-third of all families and over 70% of all genera became completely extinct at the end-Cretaceous boundary. The Faviidae and the Caryophylliidae are the only families that were major components of Mesozoic reefs and that also proliferated in the Cenozoic (Veron, 1995).

The evolutionary history of modern corals is divisible into three geological intervals: (a) the Paleogene, when the few survivors of the end-Cretaceous extinctions proliferated into a diverse cosmopolitan fauna; (b) the Miocene, when this fauna became subdivided into the broad biogeographic provinces we have today and pre-cursors of most extant species evolved; and (c) the Plio-Pleistocene to present, when the world went into full glacial mode and modern distribution patterns emerged.

For the 12 million years after the end-Cretaceous extinctions, only 13 new genera of corals have been recorded. It was thus a radiation of new zooxanthellate genera that populated the seas of the Eocene. By Late Oligocene, reef development became world-wide and diversity reached an all-time high in the Tethys and Caribbean (Frost, 1981).

The Miocene is the time of origin of non-Oligocene extant genera (primarily Indo-Pacific) and the immediate ancestors of extant species. It is also the time of obliteration of the Tethys, the extinction of non-zooxanthellate corals from the Mediterranean, and the start of the separate evolutionary histories of Atlantic and Indo-Pacific species.

Compared with most other major groups of animals, coral genera are long-lived in geological time and have low extinction rates: nearly half of all extant genera extend as far back as the Oligocene and nearly a quarter extend back to the Eocene.

The history of corals subsequent to the Miocene (Veron, 1995) becomes decreasingly visible in the fossil record and increasingly visible in the taxonomy and distribution of living corals. The Plio-Pleistocene fossil record of the Caribbean is better than that of the Indo-Pacific and it is in the Caribbean that the impacts of the Pleistocene glaciations were greatest. The progressive closure of the Central American Seaway was one of the most important events in the history of modern corals. Before the closure, there may have been no distinction between the corals of the far eastern Pacific and those of the Caribbean. After the closure (3.4 MyBP), the corals of the Pacific side of the Isthmus were extinguished, or nearly so.

There are no zooxanthellate scleractinian species common to the Indo-Pacific and the Caribbean today.

Order Milleporina

This order of hydrozoans is represented by several extinct genera and one common extant genus, *Millepora*, with approximately 50 species. All are zooxanthellate.

Millepora have growth forms ranging from branching to submassive and encrusting. Tiny polyps are mostly imbedded in the skeleton where they are linked by a network of minute canals (the cyclosystem). All that can be seen on the smooth surface are the pores of two types of polyps, gastropores and dactylopores. Reproductive ampullae, which produce medusae, can also be seen on the colony surface. Generations of sexual medusae alternate with generations of asexual polyps. Almost all records are Cenozoic, but as polyps are very small they are seldom distinct in fossils.

Order Stylasterina

The second group of hydrozoans is mostly found only in deep water. All are azooxanthellate. Two genera, *Distichopora* and *Stylaster*, are commonly found in caves and under overhangs in shallow reef environments.

Distichopora are ornate corals that branch in one plane. They have no cyclosystem; instead, gastropores are aligned along the edge of branches and these are flanked on each side by a row of dactylopores. Reproductive ampullae are clustered towards the ends of side branches.

Stylaster also branch in one plane but branches are fine, tapered and delicate. Gastropores are linked by individual cyclosystems and surrounded by dactylopores. These alternate on the sides of branches, giving the latter a zig-zag pattern. Wart-like reproductive ampullae occur on the sides of older branches. Almost all records are Cenozoic.

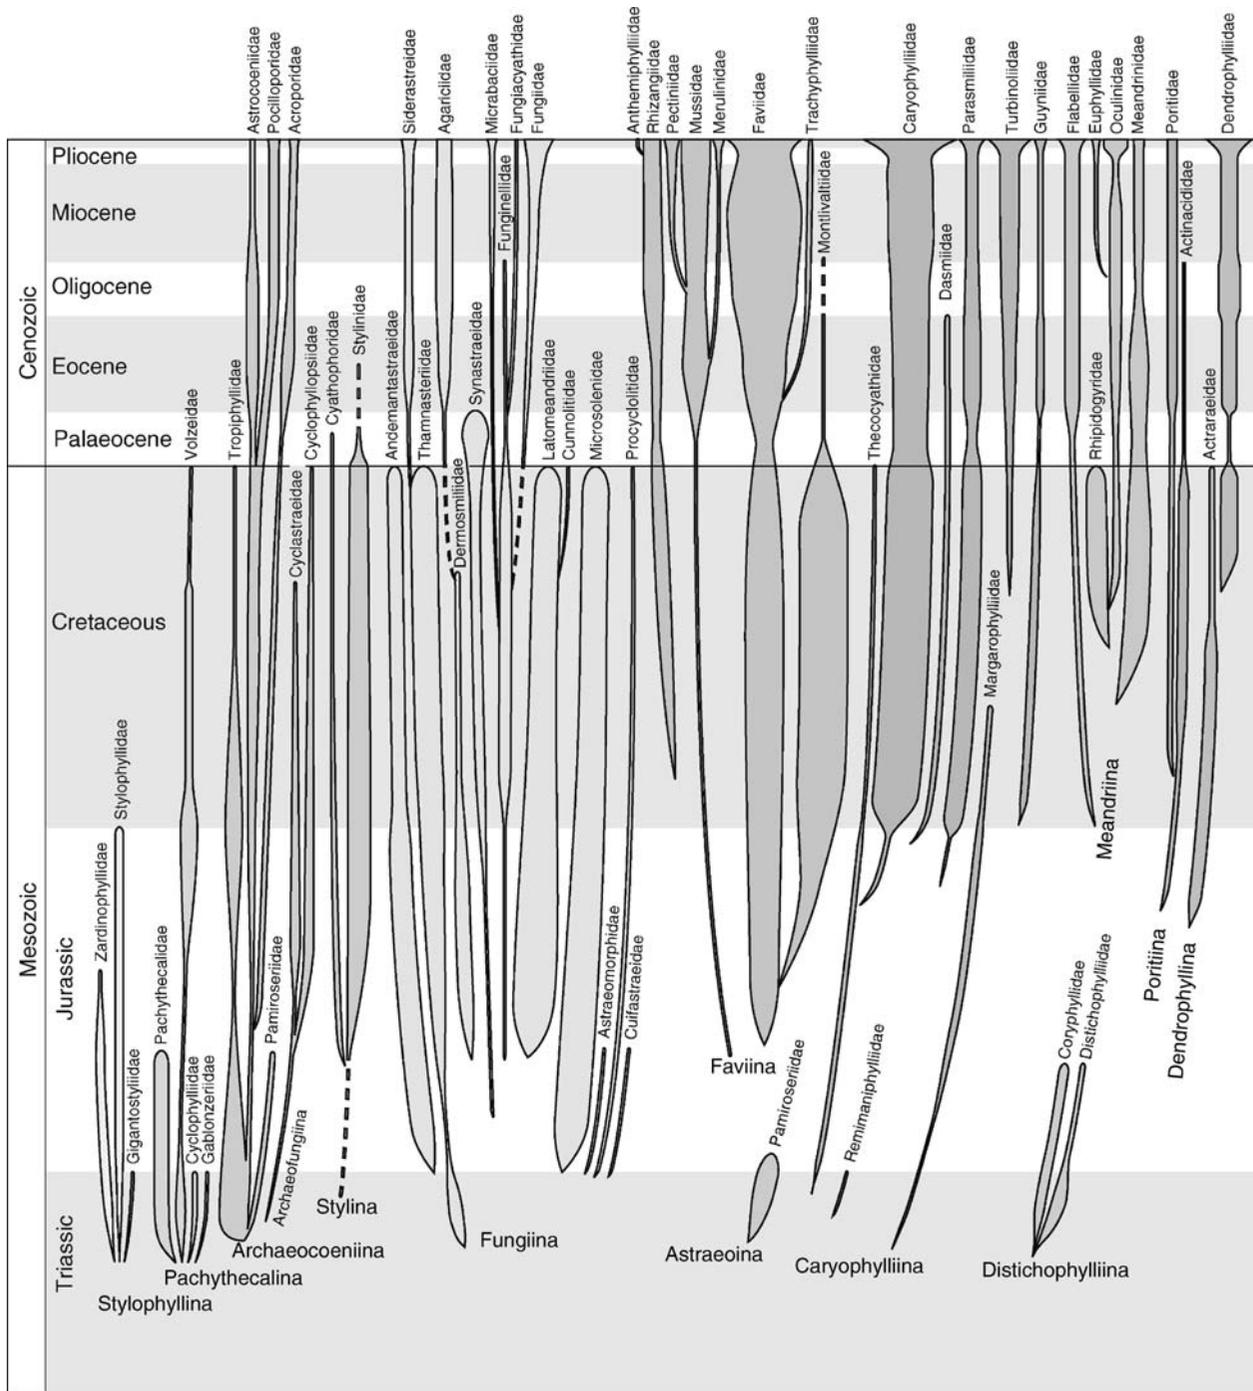

Figure C65 The “family tree” of Scleractinia. Reconstructing the evolutionary sequences of Scleractinia is a complicated process for it must encompass the fossil records over very great intervals of time, the taxonomic relationships of extant corals, and studies of coral systematics using molecular techniques. The top of the “tree” (the families of extant corals) is well established, as are the main branches through the Cenozoic, since most of these have extant representatives. However, little is known about the Mesozoic ancestors of Scleractinia, for the majority of families are extinct (simplified from Veron, 2000).

Order Helioporacea

Heliopora coerulea or “blue coral” is the sole member of Order Helioporacea. *Heliopora* is zooxanthellate and blue or greenish underwater. The skeleton, composed of fibrocrystalline

aragonite, is always permanently blue. Polyps are small and superficial and are interconnected by minute solenial tubes.

Heliopora is easily recognized in fossil outcrops by its color and therefore can be traced back to the Cretaceous. Throughout

this time, it appears to have remained a single species, in which case it would have by far the greatest geological longevity of any coral.

Order Alcyonacea

The second group of octocorals (corals which have eight tentacles) to form skeletons is part of the very large Order Alcyonacea. One genus, *Tubipora* the “organ-pipe” coral, has a skeleton. Only one species, *T. musica*, is currently named. It has an isolated taxonomic position.

Structure and evolutionary history. *Tubipora* are zooxanthellate. The skeleton is permanently colored dark red. Polyps are long and tubular and are interconnected by horizontal tabulae or stolons, which form transverse platforms. Corallites grow from the platforms, not from the branching of corallites. Living colonies have brown pinnate tentacles.

Heliopora is known only from the Plio-Pleistocene, but is widely distributed across the Indo-west Pacific.

Mesozoic and Cenozoic coral reefs

Intervals of change

Coral reef development is clearly correlated with extinction events and intervals of proliferation and diversification. The first major interval of reef development occurred after diversification of reef biota in the Middle Ordovician and lasted until the end-Devonian extinctions. The second occurred with the proliferation of Scleractinia in the Middle Triassic and ended with the end-Triassic extinctions. The third started with the proliferation of corals in the Middle to Late Jurassic and, punctuated by a 30 million year interval of rudist dominance, ended with the end-Cretaceous extinctions. The fourth started with the diversifications of the Early and Middle Eocene and, interrupted by a relatively minor end-Eocene extinction event and the Pleistocene glaciations, resulted in the reefs and the coral fauna we have today.

Although reef development is not closely linked to coral biodiversity *per se*, not surprisingly reef development clearly follows intervals of coral diversification and abundance, whilst cessation of reef development is absolutely linked to mass extinctions. The causes of mass extinctions, coral diversification, and abundance changes are not clear and may well be different in each case. However, all are underpinned by the gradual yet decisive control of the marine environment created by continental movements.

Perhaps surprisingly, the Earth’s great era-long cycles of temperature change show no dominating impact on coral or reef development, other than by controlling latitudinal spread. This is not true of shorter intervals of climate change, especially those that created sea-level changes. More rapid sea level changes have greater impact. It is very likely that these occurred at a much greater frequency, and were of greater importance, than suggested by the fossil record.

Mesozoic reefs

No reef building occurred for 12–14 million years after the end-Permian mass extinctions (Stanley, 2003). Only stromatolites remained common and it was not until the Middle Triassic that the first reef-like structures appeared; these had a fauna dominated by sponges, algae, bryozoa and *Tubiphytes*, much like those of the Late Permian. However, by Late Triassic, massive scleractinian reefs were abundant, especially in the Tethys, which remained a center of reef development throughout the Mesozoic.

The end of the Triassic was marked with a mass extinction. It was not the equal of the extinctions that marked the end of the Paleozoic 45 million years earlier, but it may have rivaled the extinctions at the end of the Mesozoic. The main impact on reefs was the collapse of the reefs of the Tethys, perhaps because of anoxic conditions correlated with sea-level and climatic changes. Whatever the cause, reef building did not recover for 6–8 million years. The inheritance of the Jurassic was a remnant of these extinctions, a depauperate although diverse suite of scleractinian genera. Early Jurassic reefs are rare everywhere in the world and all Triassic genera had become extinct by then.

The Jurassic recovery was slow, but by Middle Jurassic, reef development had again proliferated in the Tethys of Europe and in the Mediterranean. Complex ecosystems underwent a major radiation, enhanced by a warming climate and extensive flooding of shallow shelf areas. Elsewhere reefs remained poorly developed, especially in the Panthalassa and thus it may have remained throughout most of the Jurassic.

The beginning of the Cretaceous was not marked by any extinction event that had a major impact on reefs, and they continued to thrive throughout the Early Cretaceous. There was, however, an increasingly drastic change in coral communities over this time. Rudist bivalves, a previously obscure group of mollusks, progressively displaced corals as the dominant reef biota, and thus it remained for 30 million years. During this interval, zooxanthellate corals coexisted with rudists, but largely in separate, deeper habitats. The reefs of that time probably resembled the inshore fringing reefs of today, repeatedly destroyed by changing sea levels and consisting mostly of banks of entrapped sediment, with no algal cementation. Rudists were probably zooxanthellate and, as they had a lesser amount of aragonite in their shells than corals, probably survived acidic conditions better than the corals.

Repeated environmental upheavals probably had a greater influence on evolutionary change in the Cretaceous than did continental movements. The Late Cretaceous was a time of extreme sea level change, with periodic flooding of nearly 40% of the continents. Significantly for corals, this created a Super-Tethys Ocean, which covered much of present-day Europe. The consequences for reefs are unknown, but the continually decreasing sea levels of the Late Cretaceous would have had a great impact on coral communities (Kauffman and Fagerstrom, 1993).

Much of the Middle Cretaceous was characterized by release of carbon dioxide due to extensive volcanism around the continental plate margins and this, together with the accumulation of organic matter associated with sea level changes, may have increased the acidity of much of the ocean surface. Ocean and atmospheric temperatures over a range of latitude from the equator to the poles were much higher than they are now. This would have varied greatly over time, but subtropical conditions may have periodically extended to 45° N and possibly 70° S, and there were no polar ice caps. These conditions would have resulted in weaker ocean currents than we have today. Corals would have been far more widely dispersed and there would have been a much greater development of distinctive regional provinces.

Cenozoic reefs

By the close of the Mesozoic, the flooding of the continents had ceased and the warm climates that had dominated the Cretaceous had begun a long and irregular decline towards a

glacial mode (Perrin, 2002). Extensive reef development did not commence for some 12 million years after the end-Cretaceous extinctions. Eocene reefs are mostly poorly preserved, but were extensive in area. An end-Eocene extinction event, combined with progressive blockages of the Tethys Sea in the Early Oligocene created a hiatus in reef development, but did not greatly diminish coral diversity. Extensive reef development occurred throughout the Miocene. Plate tectonics remained an important aspect of reef development throughout the Cenozoic.

There were two post-Miocene events that greatly affected reef development. The first was the closure of the Central American Seaway, finally separating the coral faunas of the Indo-Pacific and Caribbean. The second was the Pleistocene glaciations, which, because of low sea temperatures, stopped reef development in the far eastern Pacific, much of the Caribbean, and high latitude locations of the western Pacific.

More importantly, low sea levels exposed all coral reefs world-wide. This clearly would have devastated all coral reefs, but the main impact was on the shallow reefs of central and western Indonesia, part of the global center of coral and coral reef biodiversity (see Figure C67).

During the Holocene, when both climate and sea levels became relatively stable, coral communities remained in constant flux as a result of changing surface currents. These create repeated changes to the distribution ranges of species and reticulate evolutionary changes resulting from repeated divergence and convergence of phylogenetic lineages.

Holocene environments are recorded in annual growth bands of massive corals like *Porites*. These bands provide proxy indicators of several environmental parameters notably temperature and rainfall, the latter where colonies grow near river mouths (Figure C66).

Types of reefs

Reefs are made of consolidated limestone and unconsolidated rubble. Consolidated reefs are usually constructed of solid limestone, made hard by the combined action of cementing (“coralline”) algae, the mechanical action of pounding waves, and the chemical action of rainwater.

There have been many attempts to classify different types of reefs. All lack general agreement because there is continual variation from one reef type to another, also because they can be classified according to their geological history, their shape, their position relative to land masses and by the material they are made of. In principle, these types of classification can be merged into three broad categories: “fringing reefs,” “barrier reefs” and “atolls” (Darwin’s original groups).

Fringing reefs are mostly close to coastlines, are usually unconsolidated wherever protected from wave action, and usually have a high component of non-carbonate sediment. Barrier reefs are off-shore and are composed of wave-resistant consolidated limestone. Atolls are usually (but not necessarily) a wall of reefs enclosing a central lagoon. As the shape of both barrier reefs and atolls is largely determined by the bathymetry of the substratum, there are all manner of intergrades between them. Likewise, “fringing reefs” gradually become “barrier reefs” with increasing distance from the shore. Reefs that do not conform to any of these descriptions are commonly called “platform” reefs.

The term “coral reef” is usually used in association with massive shallow-water limestone structures with a high coral

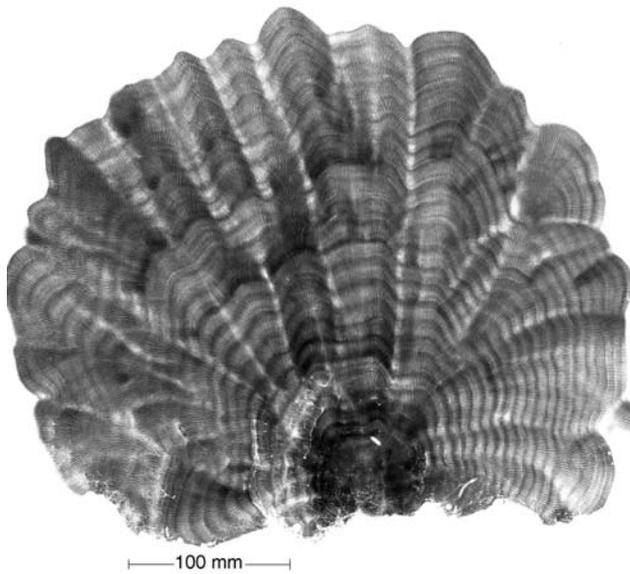

Figure C66 An X-rayed section through *Porites* showing annual growth bands. Study of these bands in fossil as well as in extant corals indicate annual growth rates and may also indicate environmental parameters, notably temperature and rainfall (image courtesy Janice Lough).

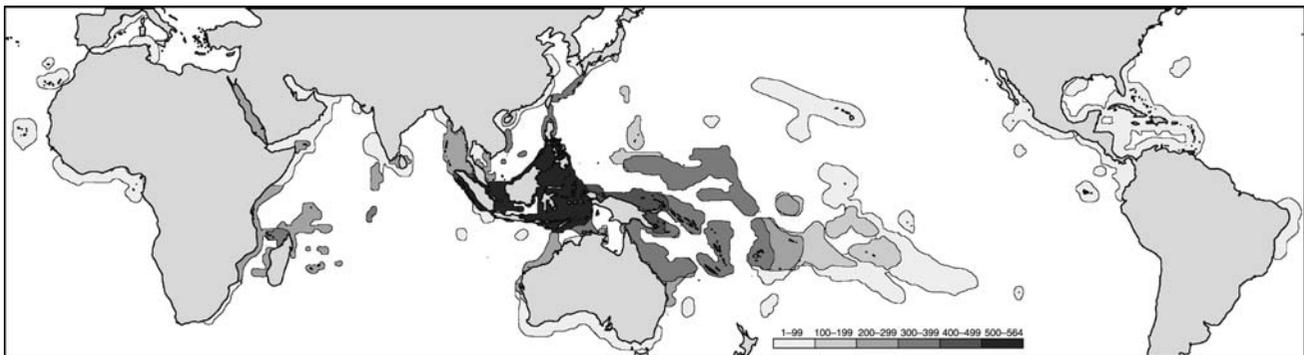

Figure C67 Species diversity contours of zooxanthellate corals. (After Veron, 1995, 2000.)

diversity, but other types of coral accumulations found in deep water are also of great size. These structures, sometimes called “bioherms,” are commonly formed of skeletal debris accumulated from one or a few species of azooxanthellate corals.

Zonation

Most accounts of coral reefs draw attention to the coral zones that they invariably display. These zones have been likened to zones of vegetation found on mountain slopes but on coral reefs they are mostly created by decreasing light and turbulence with increasing depth and, even in very clear water, this occurs within a depth range of less than 50 meters. Contrary to popular belief, species diversity is not at its highest on the scenically attractive reefs found in clear oceanic water. It reaches a peak for any given region on fringing reefs protected from strong wave action, where the water is slightly turbid. This is probably because *Acropora*, by far the most common Indo-Pacific coral, does not dominate these habitats, allowing for a higher diversity of other groups of coral.

Distribution patterns

The global distribution of reefs and the global pattern of coral diversity are linked, but not strongly (Figure C67). The Indonesian/Philippines archipelago has the world’s greatest concentration of reefs and the greatest coral diversity. Other areas of reef concentration are the Great Barrier Reef of Australia, the Red Sea and the Caribbean, the latter having a much lower diversity than all major Indo-Pacific regions. The reefs and coral faunas of each geological period are a combination of inheritance from the past and the outcome of more contemporary events. The distribution of modern reefs are an inheritance of the Tethys-dominated world of the Eocene (Figure C68), subsequently modified by the obliteration of both the Tethys Seaway (Miocene) and the Central American Seaway (Pliocene).

Reef environments

Calcareous algae thrive, but corals are uncommon on parts of reefs exposed to extreme wave action. Where there is some protection and where the water is clear, Indo-Pacific reef flats are usually dominated by *Acropora*. Unconsolidated rubble accumulations occur primarily where conditions for coralline

algae growth are poor: where wave action is weak, the water turbid, or the temperature frequently falls below 18 °C. Conditions for coral growth, however, may be good in such places.

Environmental factors. Substrate availability, sedimentary regimes, bathymetry, tidal regimes, turbulence, water quality, nutrients and biotic factors all affect reef development by controlling coral growth. These operate on local scales in shallow tropical seas primarily by affecting substrate conditions and light availability. On larger scales of space and time, sea levels and temperature are the most important limiting environmental parameters.

Sea level. Because coral reefs built by zooxanthellate corals can exist only in very shallow water, they are continually at the mercy of sea-level changes due to the land or sea rising or falling. Darwin recognized this long before the phenomenon of changing sea levels per se was actually discovered, yet even now it is not generally appreciated that coral reefs have not always looked like they do today. In times past, sea-level changes have been so rapid and so frequent that what are reefs today would have alternated between being exposed limestone islands and submerged limestone pinnacles. The reefs of today are artifacts of an unusually long period of relatively stable sea level.

Temperature. Reef-building corals and the reefs that they build have similar, tropical, distributions. This creates an interesting dilemma: which comes first, the coral or the reef? There have been many theories, all assuming some effect of ocean temperature. There is no correlation between coral diversity and reef formation: only a small number of coral species are needed to build the most massive reefs. There is, however, a clear correlation between ocean temperature and zooxanthellate coral distribution, and between the former and formation of highly consolidated reefs. The latter only occur where sea temperature does not fall below 18 °C for extended periods of time, a restriction that does not apply to those corals where approximately half of all species occur where temperatures regularly fall to 14 °C (Veron, 1995). The likely solution to the dilemma is that temperature controls the formation of reefs through ecological processes. Reef building requires carbonate production and that requires coral-dominated ecosystems. In the tropics, coral ecosystems exist because they are able to out-compete algae-dominated ecosystems, but this is not the case in higher

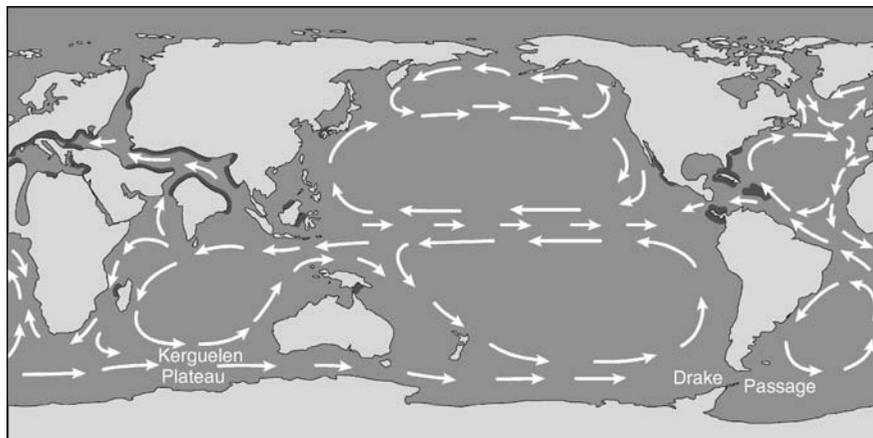

Figure C68 The distribution of coral reefs of the Eocene. (After Veron, 2000.)

latitudes. Thus, the highest latitude coral reefs in the world all have mixtures of coral and algal communities, which compete, and the corals struggle to get enough light and space to survive.

Symbiosis

Reefs of today are an ancient phenomenon without parallel in nature – a specific example of a symbiotic relationship between plants and animals. The sort of plants and animals is not critical, but the relationship between them is. Symbiosis allows the limitless resources of sunlight and carbon dioxide to be harnessed and used to construct a place to live. In effect, symbiosis allows reefs to be built by animals because it gives them the energy-generating capacity of plants. What the animal gives the plant is a medium in which to live that is stable yet exposed to sunlight. What the plant gives the animal is an enhanced capacity to remove metabolic waste, an enhanced capacity to calcify, a direct nutrient source and a capacity to concentrate and re-cycle limited nutrients, including nitrogen and phosphate. Symbiosis allows corals to exist in an almost nutrient-free environment, including the nutrient deserts of the emptiest oceans.

Clearly, the evolutionary advantage of symbiosis is very great, but the evolutionary cost is great also. Zooxanthellate corals are constrained to live near the ocean surface, the most hostile of marine environments both physically and biologically. Most importantly, symbiosis constrains corals to live in places where they must compete with macroalgae. Coral-algae symbiosis is therefore ultimately responsible for the geographic constraints of reefs as well as their construction.

When did symbiosis evolve? This question has been debated almost since coral/algal symbiosis was first discovered, and the debate continues. It is tempting to conclude that the building and maintenance of wave-resistant carbonate platforms requires sunlight as the primary energy source. If so, such platforms, found as reefs worldwide, especially in the Silurian, Devonian, Jurassic and Cenozoic, could only have been built by calcifying plants or by plant-animal symbioses. This is not true for the reefs of most other periods or those which were not wave resistant or which were not exposed to high-energy conditions. Nor can it be supposed that symbioses or capacity for skeletonization are irreversible conditions. Indeed, it is quite possible that corals are anemone-like organisms of many unrelated groups that can, over geological time intervals of environmental change, develop or lose the capacity for symbiosis concurrently or separately from the capacity for skeletonization.

CORDILLERAN ICE SHEET

The Cordillera of western Canada was repeatedly enveloped by a continental ice sheet, known as the Cordilleran Ice Sheet, during the Pleistocene and latest Pliocene (Flint, 1971; Clague, 1989; Jackson and Clague, 1991). At its maximum extent, the Cordilleran Ice Sheet and its satellite glaciers covered almost all of British Columbia, southern Yukon Territory, and southern Alaska, and extended south into the northwestern conterminous United States (Figure C69 and C70). The ice sheet, to a considerable extent, was confined between the high mountain ranges bordering the Canadian Cordillera on the west and east, but large areas on the east flank of the Rocky Mountains and west of the Coast Mountains were also covered by ice. Glaciers in several mountain ranges, such as the Olympic, Cascade, and Mackenzie Mountains, were more or less independent of the ice sheet, even at times of maximum ice cover.

The Cordilleran Ice Sheet attained its maximum size in British Columbia where it was up to 900 km wide and reached to 2,000–3,000 m elevation over the plateaus of the interior (Wilson et al., 1958). When fully formed, the ice sheet probably had the shape of an elongate dish, with gentle slopes in the interior region and steeper slopes at the periphery. It closely resembled the present-day Greenland Ice Sheet at such times. More commonly, the interior of the ice sheet had an irregular,

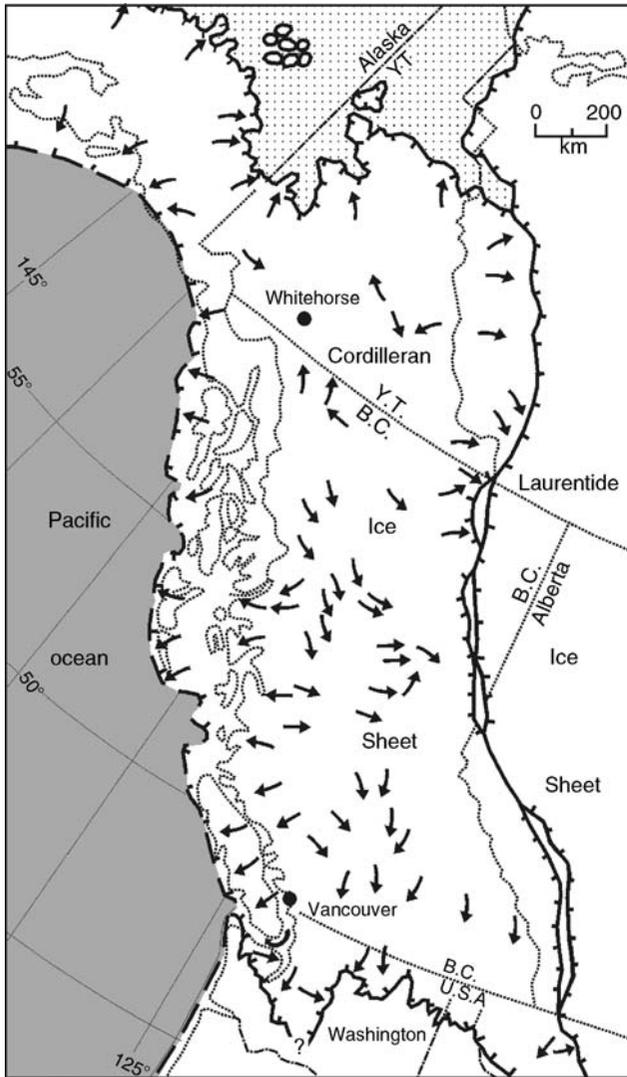

Figure C69 The Cordilleran Ice Sheet about 17,000 years ago at the maximum of the last glaciation. The upper surface of the ice sheet reached up to 2,000–3,000 m a.s.l. Arrows indicate directions of ice flow.

undulating surface, with several ice divides that shifted through time. These ice divides were subordinate to the main divide along the axis of the Coast Mountains.

In western British Columbia, ice streamed down fjords and valleys in the coastal mountains and covered large areas of the Pacific continental shelf. Some lobes extended to the shelf edge where they calved into deep water. Glaciers issuing from the southern Coast Mountains and Vancouver Island Ranges coalesced over the Strait of Georgia to produce a great outlet glacier that flowed far into Puget Lowland in Washington State (Waitt and Thorson, 1983). Glaciers streaming down valleys farther to the east likewise terminated as large lobes in eastern Washington, Idaho, and Montana (Waitt and Thorson, 1983).

Glaciers in southern Alaska were connected to the Cordilleran Ice Sheet and are considered by most researchers to be part of that ice sheet (Hamilton and Thorson, 1983). They flowed from

Figure C70 The Homathko Icefield in the southern Coast Mountains of British Columbia. Most of the Cordillera of western Canada looked something like this 16,000 years ago (photo by J. J. Clague).

mountain source areas across the continental shelf to the south and into the broad low country drained by the Yukon River to the north. Most of interior Alaska and northern Yukon Territory (Beringia) were extremely dry throughout the Pleistocene and consequently remained unglaciated. The Cordilleran Ice Sheet in southern Yukon was fed principally from the Selwyn and Cassiar Mountains, although some ice was supplied from the St. Elias Mountains (Jackson et al., 1991).

To the east, ice flowed out of the Rocky Mountains and locally coalesced with ice originating in the Keewatin sector of the Laurentide Ice Sheet (Clague, 1989). Some valley glaciers in the eastern Mackenzie Mountains also came into contact with Laurentide ice (Duk-Rodkin and Hughes, 1991). These ice masses coalesced only rarely, at times of maximum glaciation, most recently about 20,000 years ago. At other times, an ice-free zone (the “ice-free corridor”) existed between the Cordilleran and Laurentide Ice Sheets.

Growth and decay of Cordilleran Ice Sheet

The Cordilleran Ice Sheet nucleated in the high mountains of British Columbia, Yukon, and Alaska (Figure C71a and C72a). Small mountain ice fields grew and valley glaciers advanced when climate deteriorated early during each glaciation (Figure C71b; Kerr, 1934; Davis and Mathews, 1944). With continued cooling and an increase in precipitation, glaciers expanded and coalesced to form a more extensive cover of ice in mountains (Figure C72). The glaciers advanced out of the mountains and across plateaus and lowlands (Figure C72c), eventually coalescing to form an ice sheet that covered most of British Columbia and adjacent areas (Figure C71c and C72d). During this period, which spanned thousands of years, the major mountain ranges remained the principal sources of ice, and ice flow was controlled by topography. Ice thickened to such an extent during the final phase of glaciation that one or more domes became established over the interior of British Columbia, with surface flow radially away from their centers. This full continental ice sheet phase of glaciation was rarely achieved. The transition into this final phase was accompanied by a local reversal of ice flow in the

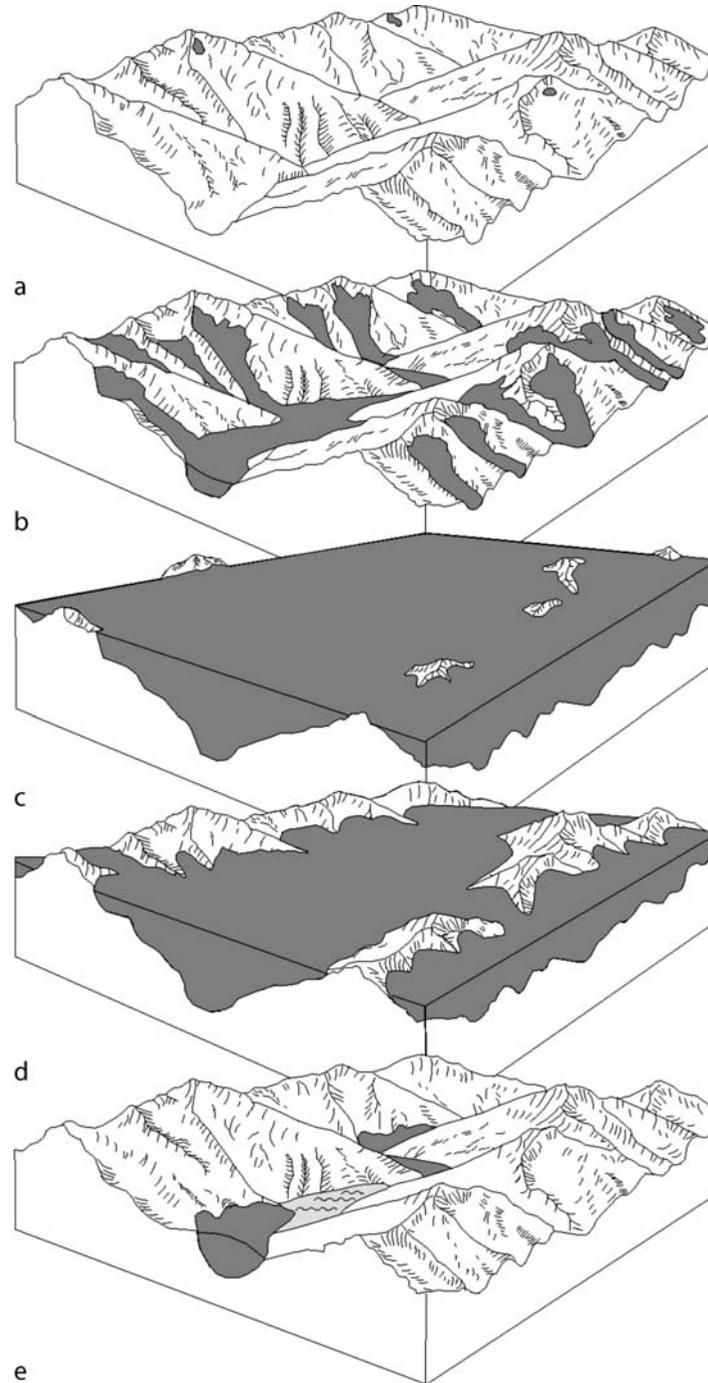

Figure C71 Schematic diagram showing growth and decay of the Cordilleran Ice Sheet. (a) Mountain area at the beginning of a glaciation. (b) Development of a network of valley glaciers. (c) Coalescence of valley and piedmont lobes to form an ice sheet. (d) Decay of ice sheet by downwasting; upland areas are deglaciated before adjacent valleys. Coast Mountains as the ice divide shifted eastward, from the mountain crest to a position over the British Columbia interior. A comparable westward shift and reversal of flow may also have occurred locally in the Rocky Mountains. The flow reversals resulted from the buildup of ice in the interior to

levels higher than the main accumulation areas in the flanking mountains.

The model outlined in the preceding paragraph provides a framework for conceptualizing the growth of the Cordilleran Ice Sheet, but the actual history of the ice sheet is more

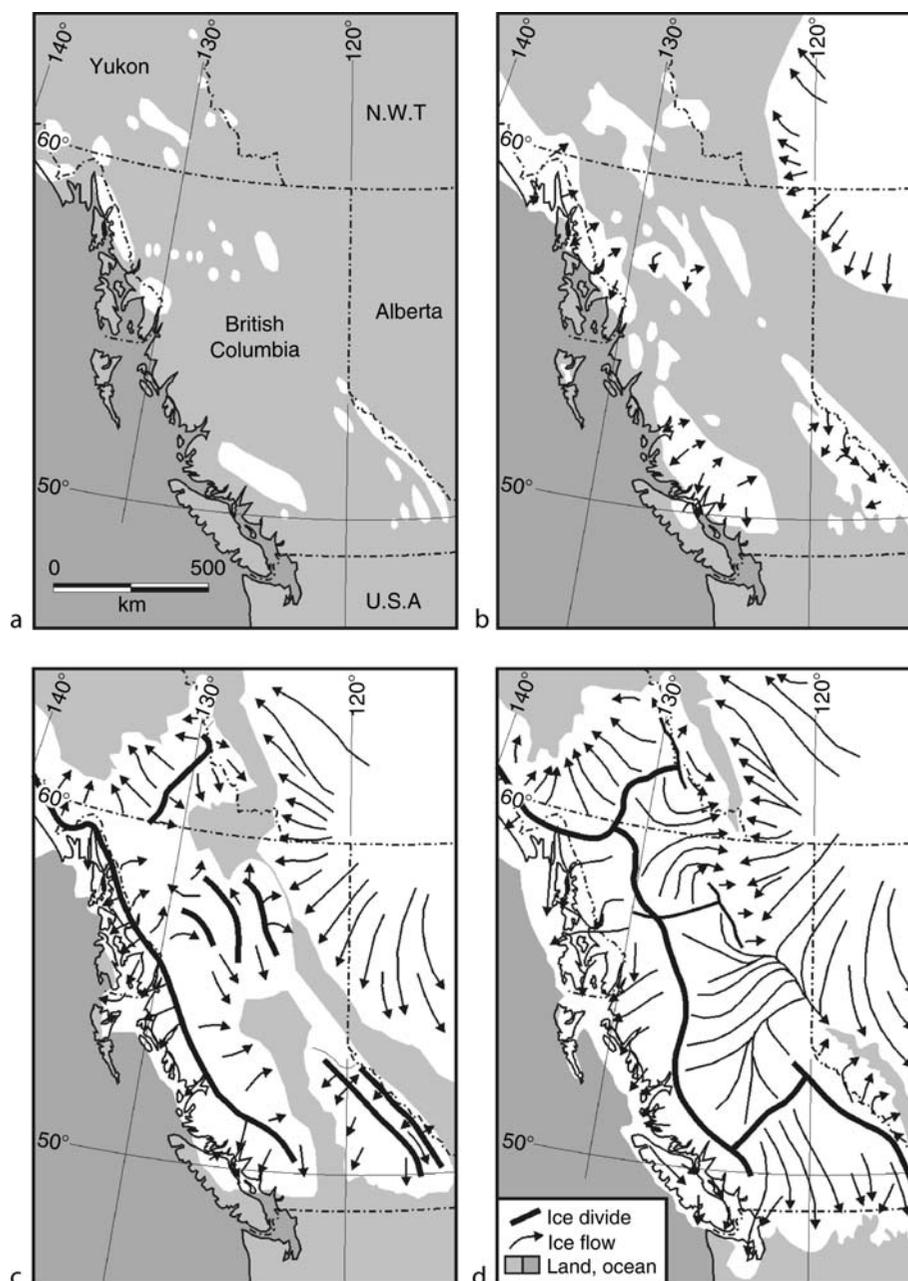

Figure C72 Schematic maps of ice cover in British Columbia during the growth phase of the last glaciation, about (a) 35,000, (b) 30,000, (c) 25,000, and (d) 18,000 years ago. Ice distributions are inferred from limited data and should only be considered approximations. (Modified from Clague et al., 2004, figure 4).

complicated (Clague, 1989). Ice did not build up in a uniform, monotonic fashion; rather, periods of growth were interrupted by intervals during which glaciers stabilized or receded.

Most glacial cycles terminated with rapid climate warming. Deglaciation was characterized by complex frontal retreat in peripheral glaciated areas and by downwasting accompanied by widespread stagnation throughout the Cordilleran interior. The western periphery of the ice sheet became unstable due,

in part, to the global rise in sea level that occurred at such times. The British Columbia continental shelf was rapidly freed of ice as glaciers calved back to fjord heads and valleys. Frontal retreat also occurred elsewhere along the periphery of the ice sheet, for example in northern Washington and southern Yukon.

A different style of deglaciation has been documented for areas of low and moderate relief nearer the center of the ice

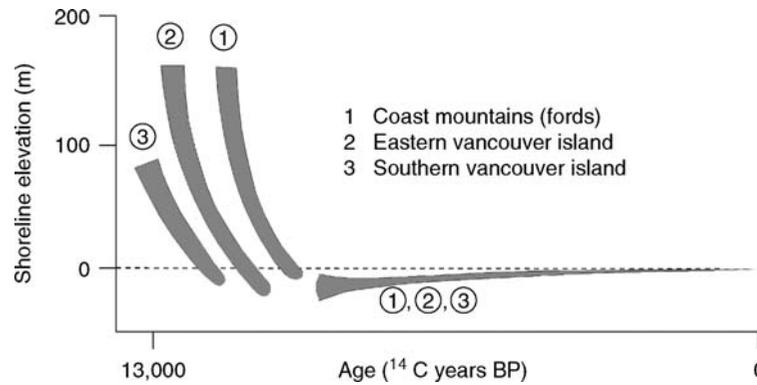

Figure C73 Generalized patterns of sea-level change on the British Columbia coast since the end of the last glaciation. Deglaciation and isostatic rebound occurred later in the Coast Mountains than on Vancouver Island. (Modified from Muhs et al., 1987, figure 10).

sheet. Deglaciation in these areas occurred mainly by downwasting and stagnation and proceeded through four stages (Fulton, 1967): (a) active ice phase – regional flow continued but diminished as ice thinned (Figure C71d); (b) transitional upland phase – the highest uplands became ice free, but regional flow continued in valleys; (c) stagnant ice phase – ice was confined to valleys but was still thick enough to flow; and (d) dead ice phase – ice tongues in valleys thinned to the point that they no longer flowed (Figure C71e).

The first areas to become ice-free were those near the periphery of the ice sheet, for example British Columbia's continental shelf and the plateaus of the northwestern United States (Clague, 1989). Active glaciers probably persisted longest in high mountain valleys, but they may have coexisted with large masses of dead ice on the plateaus of the Cordilleran interior. In general, retreat in the interior proceeded from both southern and northern peripheral areas towards the center of the ice sheet. In detail, however, the pattern of retreat was complex, with uplands in each region becoming ice-free before adjacent valleys.

Decay of the Cordilleran Ice Sheet at the close of each glaciation was interrupted repeatedly by glacier readvances (Clague, 1989). Most readvances affected relatively small areas and may not have been synchronous from one region to another.

Glacial erosion and deposition

The ice sheet and the alpine glaciers from which it formed modified the late Tertiary landscape of British Columbia and Yukon Territory. Mountain areas are dominated by erosional glacial landforms, whereas plateaus, coastal lowlands, and intermontane valleys record both the erosional and depositional effects of glaciers. In high mountains, classic alpine forms were created, including cirques and overdeepened valley heads, horns, and comb ridges. Most mountain valleys are typical glacial troughs. Some valleys in the westernmost Cordillera extend into fjords, which attain water depths of up to 750 m. Much of the sediment produced by glacial erosion was transported beyond the periphery of the ice sheet. Considerable sediment, however, was deposited in valleys, on coastal lowlands, and on the plateaus of the Cordilleran interior as proglacial and ice-contact sediments, mainly during the advance and recessional phases of the last glaciation. Deposits of older glaciations are less common, because they have been extensively eroded by the last Cordilleran Ice Sheet. Even in areas

where these older deposits are present, they are covered by younger sediments and, consequently, are poorly exposed.

Ice sheet glaciation and sea-level change

Growth and decay of the Cordilleran Ice Sheet triggered crustal movements that were dominantly isostatic in origin (Clague, 1983; Clague and James, 2002). The crust was displaced downward during periods of ice-sheet growth. Initially, the depression was localized beneath the mountain ranges that were loci of glacier growth. The area of crustal subsidence grew larger as glaciers advanced out of mountains and into lowlands. At times of maximum ice cover, the entire area of the ice sheet was displaced downward.

The amount of isostatic depression during times of maximum ice cover depended primarily on the thickness and extent of the ice sheet, the length of time over which it formed, and the structure and composition of the crust and mantle (James et al., 2000). Isostatic depression was greatest beneath the center of the ice sheet and decreased west of the Coast Mountains and Strait of Georgia toward the continental margin, and south into Washington State.

Elevated glaciomarine sediments and shoreline features along the British Columbia and northern Washington coasts provide evidence for isostatic depression at the end of the last glaciation (Clague et al., 1982a; Thorson, 1989). The elevation of the late-glacial marine limit differs in relation to distance from former centers of ice accumulation and time of deglaciation. In general, the marine limit is highest (ca. 200 m a.s.l.) on the British Columbia mainland coast and drops towards the west, southwest, and south. Many mainland fjords, however, were deglaciated after much of the local isostatic rebound had occurred; consequently, the marine limit in those areas is relatively low. Late-glacial shorelines on Haida Gwaii (Queen Charlotte Islands) were lower than at present, indicating that glacio-isostatic depression was less than the coeval global (eustatic) lowering of sea level (Clague et al., 1982b; Clague, 1983; Josenhans et al., 1997; Barrie and Conway, 2002).

Rapid deglaciation at the end of each glaciation triggered isostatic adjustments that were opposite in direction to those that occurred during ice-sheet growth (Figure C73; Clague, 1983; Clague and James, 2002). Material moved laterally in the mantle, from extraglacial regions towards the center of the decaying ice sheet. Areas at the periphery of the ice sheet, which

were deglaciated earliest, rebounded first. The total amount of uplift in these areas, however, was less than at the center of the ice sheet where ice thicknesses generally were greater. As deglaciation progressed, the zone of rapid isostatic uplift migrated in step with receding glacier margins (Figure C73; Clague, 1983). The rate of uplift in each region decreased exponentially with time, and rebound was largely complete within several thousand years of deglaciation (Clague et al., 1982a; James et al., 2000).

COSMOGENIC RADIONUCLIDES

In contrast to stable isotopes, cosmogenic isotopes or radionuclides are continuously produced and destroyed by nuclear reactions. The fact that their sources and sinks (the radioactive decay) are well known makes them extremely useful tools in environmental sciences.

Sources and sinks

The main source of cosmogenic radionuclides is nuclear interactions caused by galactic cosmic rays. Solar cosmic rays are too low in energy to contribute significantly to the total production rate. Production induced by decay or fission of uranium or thorium, for instance, is only important under special circumstances (for example, underground).

The galactic cosmic rays are composed of protons (91%), helium nuclei (8%), and heavier nuclei (1%). Coming from space, cosmic rays first interact with the atmosphere. When they collide with nitrogen, oxygen or argon, a cascade of secondary particles is produced. Among them are mainly neutrons and protons, which interact with atmospheric nuclei producing a variety of cosmogenic nuclides with masses equal to or smaller than the target nucleus. The majority of these nuclides is unstable and they decay within a very short time into stable nuclides. Only few cosmogenic nuclides live long enough to be detected and useful for applications (Table C8).

Cosmogenic nuclides are detected using decay counting for short-lived nuclides or accelerator mass spectrometry (AMS) techniques for long-lived nuclides. The detection limits are on the order of a million atoms.

Before reaching the atmosphere, the cosmic rays have to cross the heliosphere, which expands to about 100 astronomical units (1.5×10^{10} km) and is filled with solar plasma of a very low density. This plasma streams out from the Sun (so-called solar wind) and carries solar magnetic fields, which deflect especially low-energy galactic cosmic ray particles and therefore reduce the production rate of cosmogenic nuclides depending on the solar activity. In addition, the geomagnetic dipole field prevents cosmic ray particles with too low a magnetic rigidity (momentum per charge) from penetrating into the atmosphere. This geomagnetic shielding effect is largest at low latitudes, where the field lines are parallel to the Earth's surface, and negligible at high latitudes, where the charged particles are guided into the atmosphere by the field lines. The dependence of the production rate on atmospheric depth (expressed in g cm^{-2}) and latitude is shown in Figure C74a using ^{10}Be as an example. As a result of these interactions, the intensity of the galactic cosmic rays is reduced within the atmosphere by almost three orders of magnitude. Therefore, the production of cosmogenic nuclides within the lithosphere is much smaller. However, due to a large number of heavier target nuclei, a variety of additional cosmogenic nuclides is produced in the lithosphere that cannot be produced in the atmosphere.

Some of the nuclides also have anthropogenic sources. During the nuclear bomb tests from the 1940s to 1970s, the atmospheric amount of several nuclides was considerably increased: ^{14}C by a factor of 2 and ^3H and ^{36}Cl by almost three orders of magnitude. Additional sources are nuclear power and reprocessing plants.

Table C8 List of some of the main cosmogenic nuclides with half-lives longer than 1 month that are produced by cosmic rays in the atmosphere (after Masarik and Beer, 1999)

Nuclide	Half-life	Target	Reaction	Production rate [$\text{cm}^{-2} \text{s}^{-1}$]	Decay (keV)	Detection
^3H	12.34 yr	N, O	Spallation	0.28	β^- (0.02)	Decay
^7Be	53.4 d	N, O	Spallation	0.035	ε (487)	Decay
^{10}Be	1.5 706 yr	N, O	Spallation	0.018	β^- (0.6)	AMS
^{14}C	5,730 yr	N	$^{14}\text{N}(n, p) ^{14}\text{C}$	2.0	β^- (0.2)	AMS/Decay
^{26}Al	740,000 yr	Ar	Spallation	7×10^{-5} *	β^- (5.1)	AMS
^{32}Si	150* yr	Ar	Spallation		β^- (0.2)	Decay/AMS
^{36}Cl	301,000 yr	Ar	Spallation	8.8×10^{-4} *	β^- (0.7)	AMS

*Indicate values with a large uncertainty.

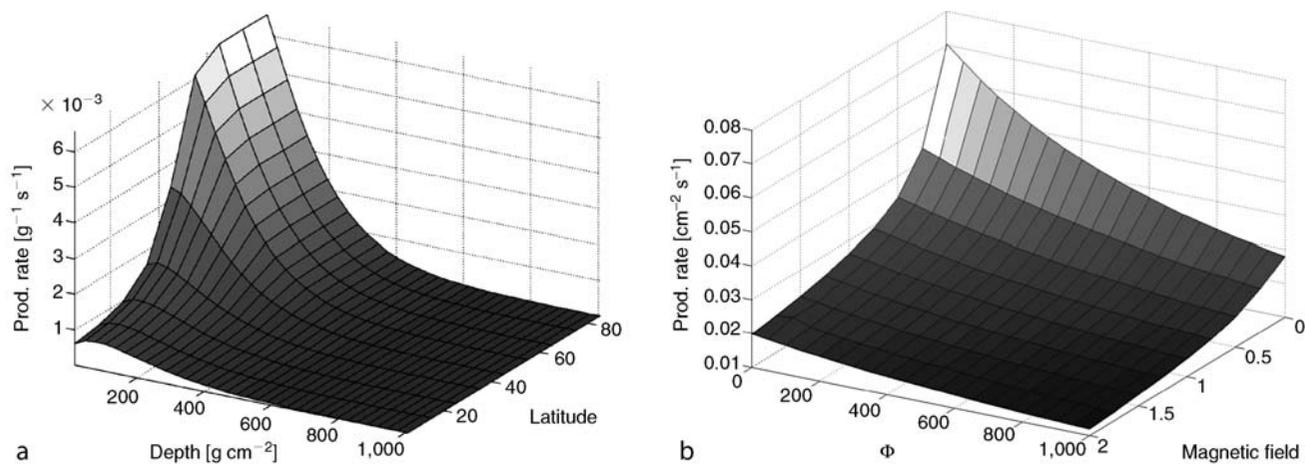

Figure C74 (a) Dependence of the ^{10}Be production rate on the atmospheric depth (0 g cm^{-2} : top of the atmosphere; $1,033 \text{ g cm}^{-2}$: sea level) and the latitude (Masarik and Beer, 1999). (b) Dependence of the mean global ^{10}Be production rate on the solar activity ($\phi = 0$, quiet sun; $\phi = 1000$, very active sun) and the geomagnetic field intensity (relative units, 1 = present field) (Masarik and Beer, 1999). The dynamic range between high solar activity/large magnetic field and quiet sun/no field is about an order of magnitude.

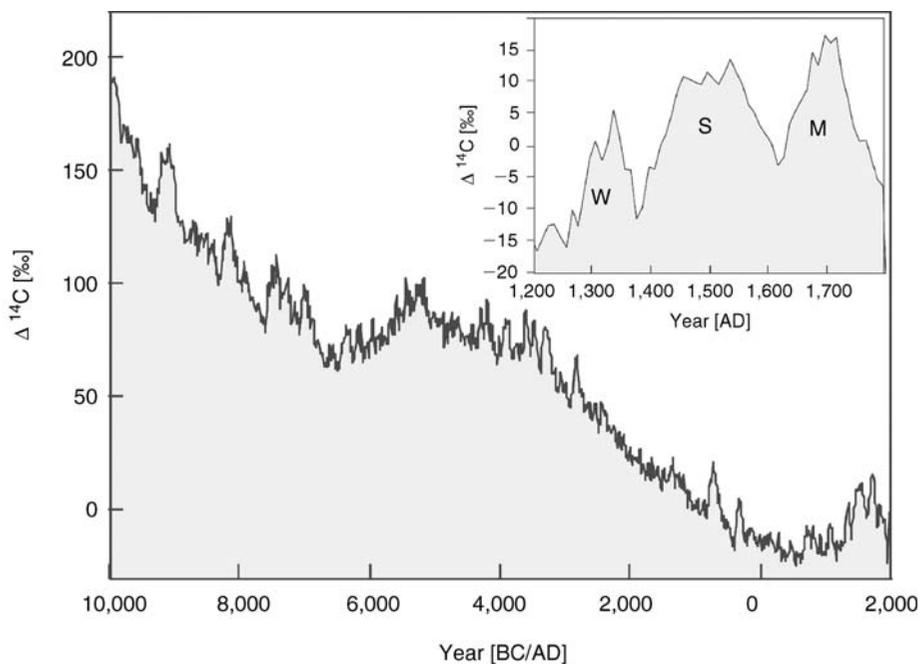

Figure C75 Deviations of the atmospheric $^{14}\text{C}/^{12}\text{C}$ ratio from the value of 1950 as a result of changes in the production rate caused by geomagnetic (long-term trend) and solar (short-term fluctuations) modulation of cosmic rays. (Modified from Stuiver et al., 1998; Stuiver and Braziunas, 1993.)

Applications

The two main fields of application of cosmogenic radionuclides are dating and tracing. In the case of dating, decay dating and exposure dating can be distinguished.

Dating

Decay dating makes use of the law of radioactive decay:

$$A(t) = A_0 \cdot \exp\left(-\frac{\ln 2}{T_{1/2}} \cdot t\right), \text{ with}$$

$A(t)$ = number of radioactive atoms, their concentration or their isotopic ratio at time t

$A_0 = A$ at the time zero

$T_{1/2}$ = half-life

If A_0 is constant or known and $A(t)$ is measured, the time t can be calculated. The crucial point is A_0 . By radiocarbon dating of tree-rings with known ages, the deviation of A_0 ($^{14}\text{C}/^{12}\text{C}$ ratio) from A_0 of 1950 could be determined for the past 12,000 years. These deviations in ‰, called $\Delta^{14}\text{C}$, are plotted in [Figure C75](#). The curve shows a long-term trend related to changes in geomagnetic field intensity and superimposed short-term fluctuations caused by changes in solar activity [Figure C74b](#), such as the well known Maunder, Spoerer and Wolf minima (see insert in [Figure C75](#)). The curve of [Figure C75](#) provides the basis to convert radiocarbon ages into calendar ages.

In contrast to decay dating, the exposure dating technique is based on the increasing number of cosmogenic nuclides that are produced in matter (e.g., rocks) previously shielded, for example, by a glacier. If the production rate is known, the exposure time can be calculated from the measured total number of produced atoms (Lal, 1988).

Tracing

In the case of tracer applications, cosmogenic nuclides can be used according to their specific properties to study a large variety of different physical, chemical and biological processes. They are particularly useful in investigating the behavior of their stable counterparts, such as, for example, the carbon cycle. Examples of ^{10}Be applications are given in the article on ^{10}Be .

CRETACEOUS WARM CLIMATES

Introduction

The Cretaceous period spans approximately 70 million years of Earth's history, from 135 to 65.4 million years ago. Warm intervals of the Cretaceous account for almost half the duration of the period. A cool temperate climate in the Early Cretaceous was followed by a warm to extremely warm Middle and Late Cretaceous, and the warmth persisted into the Paleogene. The Cretaceous and Paleogene greenhouse interval was longer in duration than the ensuing icehouse intervals of the Neogene. The termination of the Cretaceous is coincident with a major mass extinction event in Earth's history and a meteorite or bolide impact at the Cretaceous-Tertiary (K/T) boundary.

In describing the world during the Cretaceous period, geochemical model results indicate that atmospheric CO_2 levels were at least 2–10 times higher than present day values (Berner, 1994). The lack of permanent ice in the polar regions resulted in a low equator to pole thermal gradient. Processes that distributed the warmth from the low to high latitudes were the oceans and the atmosphere, but the amount of heat apportioned to each process is debated for these warm intervals (Barron et al., 1993). The driver of circulation lies in the tropical world, at least for atmospheric and surface ocean currents. Subsurface circulation of the Late Cretaceous Campanian oceans was probably initiated from high latitudes (DeConto et al., 2000a).

The warm intervals of the Cretaceous are known for the abundance of unique marine bivalve groups such as the ubiquitous inoceramids and the reef-building rudists. Major terrestrial floral groups such as the gymnosperms persisted during the warm climates, and angiosperms flourished during the Late Cretaceous. Dinosaurs of various groups, such as ceratopsians hadrosaurs, tyrannosaurs, and ornithomids, roamed the land.

The techniques used to infer Cretaceous climates have evolved over the decades. Traditional tools applied the distribution, abundance, and ecological associations of biota toward climatic interpretations. In particular, the geographic dispersion patterns of bivalves, gastropods, and foraminifera allowed for the original establishment of Cretaceous climate zones across the globe, as biotas were designated the most sensitive indicators of paleoclimatic conditions. Research directions then shifted to include stable isotopes to infer temperatures for the marine realm. Analyses focused on isotopes of carbon and oxygen, first for whole rock, later for ecological associations of foraminifers and inoceramid bivalves, and eventually for individuals from a specific species group. Single crystals of unaltered calcite, as preserved in the inoceramid bivalves, or original shell material containing calcite or aragonite provided the most reliable database from which thermal interpretations were developed. Currently, organic geochemical techniques such as TEX_{86} (see below) are applied toward the investigation of Cretaceous warmth in the marine realm (see also: *Geochemical proxies (non-isotopic)*; *Organic geochemical proxies*). Research on the terrestrial domain has not kept pace with that of the oceanic world, but land-ocean correlations and interpretations of interactions have accelerated in recent years.

Concurrent with the utilization of empirical and analytical data toward climate sensors was the development of the numerical climate model, three-dimensional General Circulation Models (GCMs) simulating atmospheric and/or oceanic conditions. Models contributed to understanding mechanisms of the atmosphere

and oceans by providing sensitivity experiments encompassing the entire globe. Advances in paleoclimate modeling, and limits to the models as applied to paleoclimate studies, are summarized in DeConto et al. (2000b). Valdes (2000) provides a comprehensive review of factors included in models for warm climates, and feedback mechanisms. One of the greatest challenges for modeling warm Cretaceous climates is in keeping the polar regions free of ice while not overheating the tropics. Ocean heat transport, high atmospheric CO₂ levels, and forest vegetation at high latitudes are the proposed mechanisms for modifying polar climates during Cretaceous warm intervals (Rind and Chandler, 1991; Barron et al., 1993; Otto-Bliesner and Upchurch, 1997).

Atmosphere

Extra-terrestrial and terrestrial sources influenced Cretaceous climate. Extra-terrestrial climatic forcing is expressed in Cretaceous rocks across the globe (Fischer, 1993; Park et al., 1993; Herbert et al., 1999). Cycles of precession, obliquity, and eccentricity, indicating a Milankovitch-style expression of climatic conditions, modulated the distribution of energy and the surface temperature of the Earth. Cool-wet and warm-dry climatic conditions controlled deposition of sediments during these cycles. Siliclastic input was higher than carbonate production during the cool-wet phase, resulting in deposition of calcareous shale and marlstone, and carbonate deposition dominated during the warm-dry phase of the cycle, resulting in the deposition of limestone and chalk.

Terrestrial forcing of climate occurred through sea floor spreading and volcanism that released CO₂ into the atmosphere. Although the warmth of the Cretaceous is attributed primarily to atmospheric CO₂ levels higher than those of today, the exact levels of CO₂ contributing to the warmth are under investigation. Model

experiments center on 2–4 times present-day values to match the distribution of temperatures inferred from macrofaunal and floral paleobiogeographic ranges. Continued production of CO₂ over millions of years, and retention of this greenhouse gas in the atmosphere, set up the conditions for warmth that extended from the middle through the Late Cretaceous stages.

Across the Cretaceous globe, the effects of global warmth resulted in the disappearance of the North and South Polar to Subpolar climatic zones, and their replacement by North and South Cold-Temperate zones (Figure C76). No permanent ice existed at the poles (Frakes, 1979), although slush caps and the periodic development of ice on the South Pole have been suggested. Cold Temperate, Mild Temperate, and Warm Temperate zones extended from the polar region through southern Canada. Episodically during highstands, subtropical conditions extended from approximately the Canadian-US border southward to the tropics. The tropical zone existed in the southern parts of the Gulf Coast states and north-central Mexico. A supertropical or Supertethyan zone, characterized by unusually high temperatures and salinities, emerged episodically within the tropics and included the islands of Puerto Rico, Cuba, and Hispaniola, as well as southern Mexico, northern Venezuela, and northern Columbia. These global climate zones were originally determined through the geographic mapping of bivalve genera and subgenera (Kauffman, 1973; Johnson and Kauffman, 1996).

In North America, atmospheric conditions were influenced by the presence of the Western Interior Basin, a fully marine seaway that extended from Arctic Canada and Alaska to the Gulf of Mexico during peak sea level highstand. This large seaway serves as a model for equivalent bodies of water across the globe. A relatively flat landmass bordered the eastern coastal plain, and a mountain belt developed to the west. A westerly

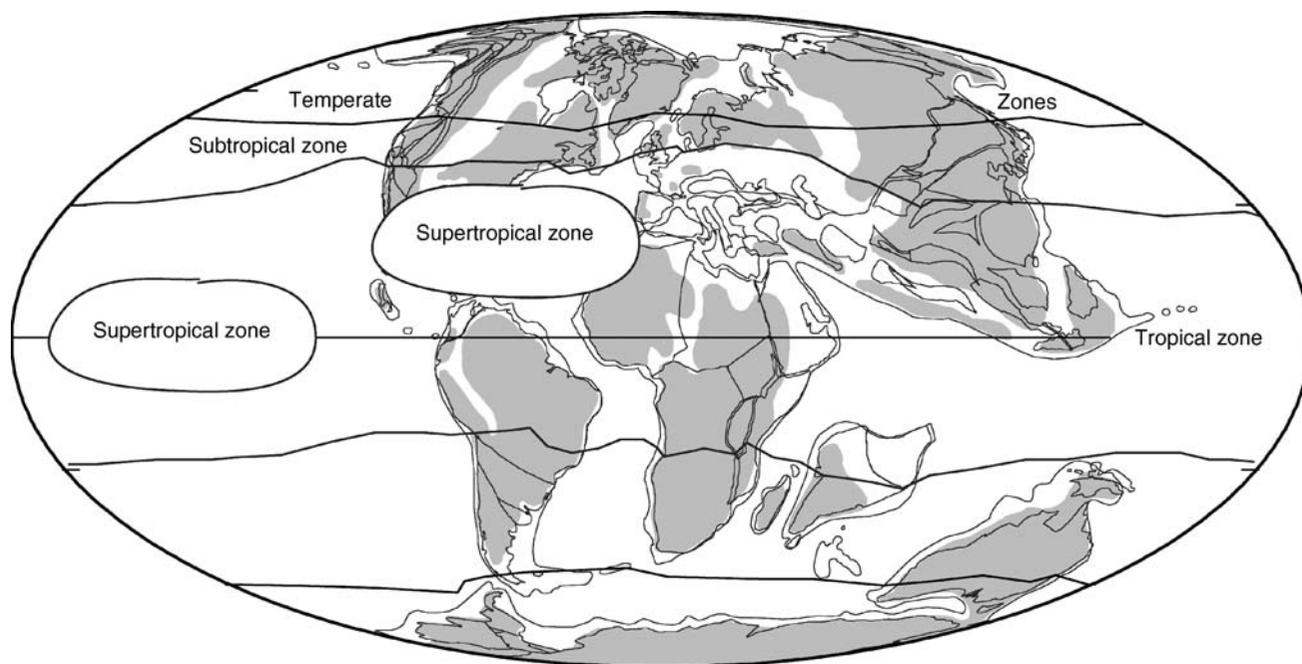

Figure C76 Cretaceous climate zones for paleolatitudes across the globe. Cold, Mild, and Warm Temperate Zones replaced the Polar Zones in the highest latitudes. Subtropical, Tropical, and Supertropical Zones expanded during the warmest stages of the Cretaceous, as indicated in text (base map for 80 Myr from C. R. Scotese).

wind system, as today, was prevalent. As the mountains rose progressively through the Late Cretaceous and especially the Paleogene, a more variable wind system developed. Updrafts carried moisture to heights where they produced rain. Progressive runoff into river systems formed a freshwater cap at the riverine mouths. On the western side of the Seaway, large deltas formed from Coniacian-Maastrichtian time and into the Paleogene, reflecting the rising Rocky Mountains. Paleoenvironments became marginal marine during deltaic deposition, and fully marine offshore. Along the eastern shoreline, deltaic deposition was restricted both spatially and temporally.

In essence, the presence of the Western Interior Seaway brought an abundance of tropical moisture from the Gulf of Mexico northward, and cool-temperate waters from Arctic Canada and Alaska southward across a large portion of North America. This conduit, 3,000 km long by 1,000 km wide, and 500 m to 1,000 m at its deepest during maximum transgression, provided a region for mixing of atmospheric and oceanic air masses and ocean currents, with potential for CO₂ exchange across the atmosphere-oceanic boundary.

During the past several decades, the Cretaceous world was viewed as one in which global atmospheric circulation was sluggish due to a low thermal gradient from the equator to the poles. In this scenario, meridional heat transport from the low to high paleolatitudes was apportioned more to the oceans than to the atmosphere (Barron et al., 1993). Newer interpretations from the oceanic realm, however, indicate that the tropics superheated, probably several times, between the middle and latest Cretaceous interval. In this revised scenario, a thermal gradient strong enough to induce atmospheric circulation may have been established between the superheated tropics and the cool polar regions (Norris et al., 2002).

Oceans

Sea level

Progressively through the Lower Cretaceous, sea level rose and advanced with each pulse, and the climate warmed across the globe. In North America, the Upper Albian marked the first north-south connection of the Western Interior Seaway. In South America and Africa, vast warm seas were connected in the Late Albian. In Europe, northern cold-temperate and subtropical seas linked up in at least two broad areas, one in western Europe during the Albian and later, and the other in western Russia, Poland, Czechoslovakia, Hungary, and Bulgaria.

Sea level reached a peak near the Cenomanian-Turonian boundary, fell in the Upper Turonian, and rose again at the Turonian-Coniacian boundary. Sea level remained high through the Coniacian and Santonian and until the Lower Campanian, as expressed in the Niobrara Formation and its equivalents where limestones and/or chalks, chalky shales, and calcareous shales were deposited continuously through the interval. Sea level fell in the Lower Campanian, rose moderately in the Middle Campanian, fell in the Upper Campanian, transgressed even more moderately in the Lower Maastrichtian, underwent a mild regression in the Middle Maastrichtian, and after a relative rise in the early Late Maastrichtian, fell at the end of the latest Maastrichtian. The extent of sea level fall in the Maastrichtian is much debated, although a small Antarctic ice sheet has been proposed (Miller et al., 1999; see also *Sea level change, last 250 million years*).

In the absence of ice during the Cretaceous, variations in sea level are attributed to variable rates of sea floor spreading

and volumetric changes in the ocean basins. The net effect of high sea level on climate in epicontinental seaways is in the production of maritime climatic conditions within and adjacent to the seaways, especially in the direction of the prevailing winds.

Pulses of elevated seas brought tropical surface waters from the Gulf Coast through the Western Interior Seaway to Canada. Most important in this migration of surface currents was the northward transport of tropical larvae, humidity, and relatively high temperatures. Likewise, in the western European region of the Northern Hemisphere, conduits for surface currents developed during high stands of the sea and carried heat northward. These simplified scenarios of heat export from the tropics by surface currents were complicated by regional and local tectonic episodes.

Elevated sea levels that flooded continents and tectonic subsidence that occurred in active basins combined to create silled basins with restricted circulation (Hay, 1988). Large portions of the temperate water columns became oxygen-restricted and had limited faunas. The higher the anoxic conditions, the more depauperate the fauna was in calcareous shales, limestones, and chalks. Ultimately, during the most anoxic of conditions, there was little or no macrofauna or burrowing, and organic carbon was preserved in the rock record as oceanic anoxic events.

The rise and fall of sea level affected climatic conditions in the atmosphere, which in turn affected hydrologic conditions on the land and deposition in the sea. The atmosphere contained latent moisture; rainy and dry seasons alternated. During the rainy season, the land was flooded and streams and rivers rose, with the runoff resulting in deltaic construction, downcutting, and an increase in sediment load and the rate of sedimentation for quite a distance offshore. Increased rainfall resulted in a reduction in the salinity of the sea and lack of clarity of the water. Marine chemistry, sediment types, and biotic compositions were affected. Likewise, during dry seasons, evaporative conditions prevailed and moisture returned to the atmosphere. The strength of the hydrologic cycle during the Cretaceous was reported as being more vigorous than that of today (White et al., 2001).

Marine temperatures

Cautions exist regarding our ability to predict pre-Pleistocene mean annual temperatures because of salinity uncertainties and potential problems with alkalinity/diagenesis (Crowley and Zachos, 2000). Yet, new fossil discoveries and excellent preservation of fossils, precision in analytical equipment, and further understanding of diagenetic effects allow for continued refinement of interpretations regarding temperatures from the marine realm. For example, based on oxygen isotopes derived from well-preserved planktic foraminifers, estimated sea surface temperatures (SSTs) for the Late Albian and Early Cenomanian were 30–31 °C (Norris and Wilson, 1998). From calculations, the authors determined that SSTs of 35–37 °C would be necessary to support hypersaline conditions. A few years later, isotopic determinations from planktic foraminifers yielded SST interpretations of 33–34 ± 2 °C (Norris et al., 2002), thus moving into the range of hypersaline conditions.

A SST proxy that is free from diagenetic effects and salinity corrections has emerged recently from organic chemical analyses (Schouten et al., 2003). TEX₈₆ (tetraether index of 86 carbon atoms) is based on membrane lipids of marine crenarchaeota. Crenarchaeota comprise 20–30% of the picoplankton component

in today's ocean; they adjust the composition of their tetraether membranes lipids in response to SST. This response, quantified as TEX₈₆, shows a strong linear relationship to today's SST and was used to evaluate middle Cretaceous sea surface temperatures. Results yielded high SSTs (e.g., Early Aptian equatorial Pacific 27–32°C, Late Albian 30° N Atlantic 35°C, Cenomanian/Turonian equatorial Pacific 34–36°C, Cenomanian/Turonian 30° N Atlantic 34–36°C), indicating extreme warmth from the low latitudes for the middle Cretaceous and giving support to the concept of a more vigorous atmospheric circulation than that envisioned 10 years ago.

Subsurface circulation from hypersaline waters in low latitudes was a prediction of Chamberlin (1906), with support from Brass et al. (1982). Newest model results from the Campanian indicate that deep water formation likely occurred at high southern latitudes (Deconto et al., 2000a), rather than in saline pools at low latitudes, and the process of subsurface circulation was more like today's thermohaline circulatory process during this stage.

The land

Investigations into the role of vegetation and its effect on the distribution of warmth across the Cretaceous globe are evolving rapidly, especially with numerical models. Otto-Bliesner and Upchurch (1997) examined the interrelationships between high- and middle-latitude forests and surface temperature regulation. Model results for the K/T indicated that forest vegetation warmed the global climate by 2.2°C. Forests caused warming in the high-latitude land areas, heat was transferred to the oceans, sea-ice formation was delayed, and winter temperatures over coastal land increased. DeConto et al. (2000a) used an OGCM that was forced by the Campanian climate simulated by the climate-vegetation model. The inclusion of plant community information into numerical models thus appears to assist with determinations of meridional thermal gradients and ocean heat-transport mechanisms, long-standing endeavors in the Cretaceous research community.

Correlation of events from terrestrial to marine sequences was difficult in the past due to the relatively poor temporal precision extracted from terrestrial rocks and fossils. Recently, however, analyses of co-equal events occurring between the two realms have been accomplished through correlation of the isotopic excursions of terrestrial and marine organic carbon, and marine carbonate carbon (Hasegawa, 2003). For example, based on a comparison of these species of carbon, it was proposed that the climatic optimum of warm and humid conditions occurred during the latest Cenomanian in northeastern Asia. This is significant in that data from the large continental landmass can now be integrated into the global database and used not only for climatic interpretations, but also for purposes of model-data comparisons.

Pulses of warming associated with Deccan volcanism and release of CO₂ are among the most current avenues of marine-terrestrial investigation, and these are achieved by analysis of the ¹⁸⁷Os/¹⁸⁸Os record. The seawater osmium ratio was declining during the Maastrichtian and prior to the K/T boundary. The drop in this ratio was identified from several Deep Sea Drilling Project (DSDP) sites and shows an abrupt decline more than 100,000 years before the boundary. The decline is coincident with Deccan volcanism from continental flood basalts (leading to release of CO₂), and the Late Maastrichtian warming of 3–5°C that is separate from that of the K/T

boundary extinction (Ravizza and Peucker-Ehrenbrink, 2003). In a similar manner, terrestrial evidence for a warming is also derived from carbon and oxygen isotopes from paleosol carbonates. Through this method, it was determined that atmospheric warming events occurred between 70 and 69 Myr, and also 65.5 and 65 Myr ago (Nordt et al., 2003), indicating that dramatic climatic fluctuations occurred several million years before as well as during the K/T boundary extinction interval. Although a wealth of empirical data has been accumulated from the K/T boundary extinction interval, definitive processes causal to the mass extinction continue to be debated vigorously.

Summary and conclusions

Empirical, analytical, and experimental techniques have been applied toward understanding the development and persistence of processes that produced Cretaceous warm climates. Used in combination, biotic distributions, isotopic and/or geochemical analyses, and numerical climate models yield the most comprehensive results and the most robust interpretations on Cretaceous climates.

The role of the atmosphere, and of the oceans, in distributing the warmth across the globe is as yet unresolved. The process of atmospheric circulation transporting heat across the latitudes may have been the same for icehouse and greenhouse intervals, but the actual temperatures for each steady state system were quite distinct. Cretaceous oceans distributed warmth across latitudes *via* surface currents, but subsurface circulation commenced in high latitudes, at least during the Campanian. Determination of sea surface temperatures and the interaction of the sea surface with atmospheric CO₂ exchange remain active research areas.

Thermal changes in the Cretaceous tropics dispute the theory of time-stable biotic evolution within equable tropical environments, and suggest an important role for large-scale disturbance in the evolution of tropical, and perhaps temperate, ecosystems (Johnson et al., 1996).

CRETACEOUS/TERTIARY (K-T) BOUNDARY IMPACT, CLIMATE EFFECTS

Introduction

Collisions of asteroids and comets with the Earth's surface are rare events that punctuate the geologic record. The collision of a large asteroid or comet with a planetary surface produces a tremendous explosion, equivalent to thousands of times the explosive energy of the world's combined nuclear arsenal. The end result is a crater tens to hundreds of kilometers in size. Although the existence of large impact structures on Earth is undisputed, the possible climatic effects of an impact were not seriously considered until 1980, when a team led by the famous physicist Luis Alvarez and his son, the geologist Walter Alvarez, suggested that the profound end-Cretaceous mass extinction might have been caused by the impact of a 10-km diameter asteroid or comet (Alvarez et al., 1980). Dated to 65 million years ago, this extinction is the last of the large, known mass extinctions on Earth and defines a major geologic boundary between the Cretaceous and Tertiary (or Paleogene, as it is often referred to in the recent literature) periods, the K/T boundary. The discovery by the Alvarez team of an anomalous enrichment of extraterrestrial iridium at the K/T boundary in the sections at Gubbio, Italy and Stevns Klint, Denmark opened a whole new era of reanalysis of the geologic record in search of more clues that could confirm the impact hypothesis. Since 1980, the list of "clues" has become long and overwhelming, culminating with the discovery of the K/T boundary crater, the Chicxulub structure, in the Yucatán Peninsula, Mexico (Figure C77). That region is a partially submerged continental platform consisting of a thick sedimentary sequence of carbonates and evaporites overlying continental crust. At the time of impact, a shallow sea a few tens to several hundreds of meters deep covered the impact region. The crater is roughly 180–200 km in diameter and currently buried under about 1 km of Tertiary sediments. Such a large impact event would affect the environment and climate worldwide. However, while several impact structures larger than 100 km in diameter have been identified on the Earth's surface, to this date Chicxulub is the only large, known crater that closely coincides in time with a mass extinction event.

Several short-term and long-term environmental effects result from a large impact event (e.g., see Toon et al., 1997). Short-term effects extend up to few weeks after the impact and are generally believed to have little influence on the long-term evolution of the climate. They include the localized direct effects of shock waves generated by the impact in the atmosphere, like blast waves (high pressure pulses traveling through the atmosphere at high velocity), and at the Earth's surface, such as earthquakes and tsunamis. Effects that are more widespread include the production of toxic gases like nitrogen oxides (NO, NO₂) and nitric acid (HNO₃) by shock heating of the atmosphere from the entering projectile as well as the atmospheric re-entry of material initially ejected well beyond the stratosphere by the impact. These gases also caused massive destruction of stratospheric ozone. The re-entering ejecta also produced intense friction heating of the atmosphere, leading to major wildfires that, in turn, filled the lower atmosphere with smoke, dust and pyrotoxins in a scenario reminiscent of a nuclear winter. Indication that much of the end-Cretaceous land biomass was consumed by fire is provided by widespread evidence of soot at the K/T boundary,

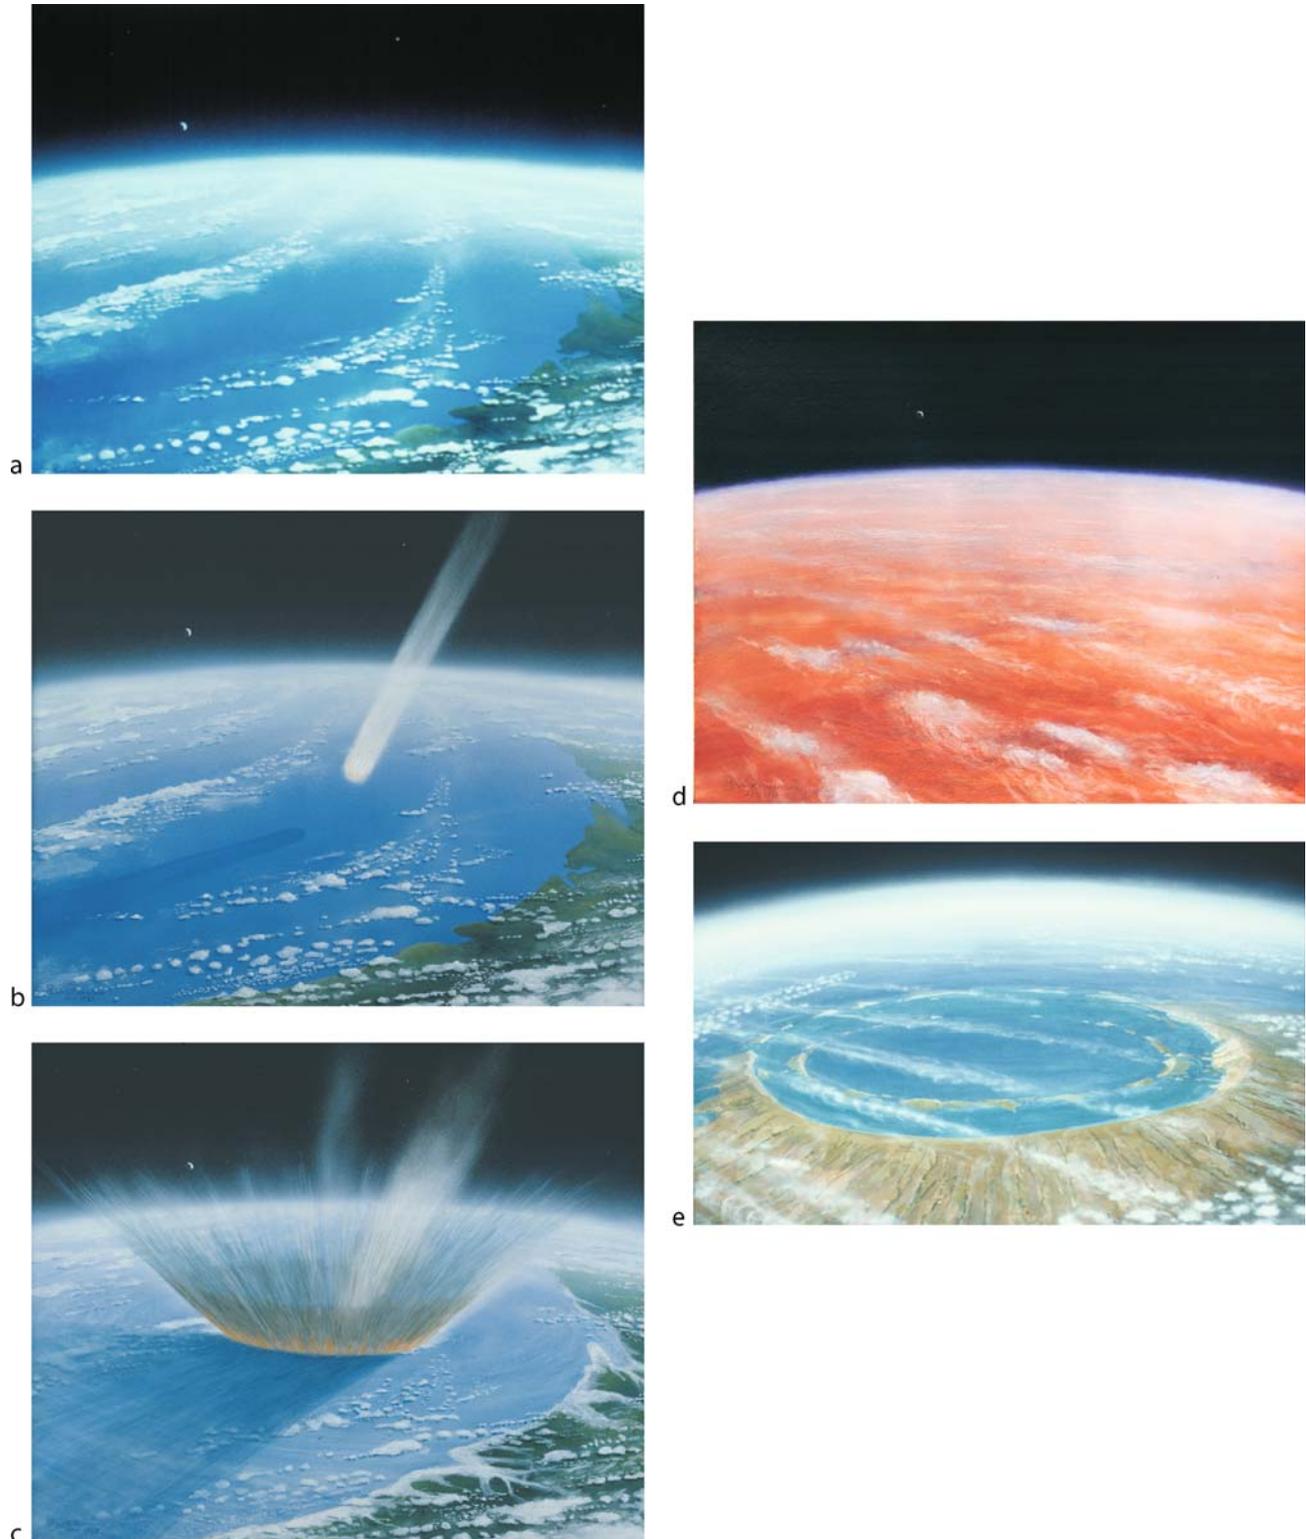

Figure C77 Artistic view of the Chicxulub impact event: (a) end-Cretaceous, 5 s before impact (Yucatan peninsula, Mexico); (b) end-Cretaceous, 1 s before impact (approaching asteroid or comet); (c) end-Cretaceous, the impact event; (d) beginning of Tertiary, about 1 month after impact (dust and sulfate clouds blocking sunlight); (e) Early Tertiary, 1,000 years after impact (final multiring Chicxulub structure) (paintings by William K. Hartmann).

consisting of up to 2% of the carbon content of the end-Cretaceous biosphere. Soot is a strong absorber of solar radiation, thus preventing it from reaching the surface.

Long-term effects extend over months to decades after the impact, and can have profound effects on the environment both directly and indirectly by perturbing the overall climate. They include the radiative effects due to the stratospheric loading of small size dust (e.g., Alvarez et al., 1980; Covey et al., 1994; Luder et al., 2003), and greenhouse gases such as carbon dioxide (CO₂) and water vapor (H₂O). Unique to the Chicxulub impact is the climatic effect of sulfur-bearing gases (Ivanov et al., 1996; Pierazzo et al., 1998), whose importance has been inferred from the climatic effects associated with major volcanic eruptions (see below).

The geologic record of the end-cretaceous climate and its perturbation

The end-Cretaceous geologic record can provide some constraints on the climatic effects of the Chicxulub impact event. The Cretaceous Period is characterized by one of the warmest climates documented in Earth's history (Barron et al., 1995). No evidence of extensive glaciation has yet been found for any time during this geologic period (although late-Cretaceous eustatic sea level fluctuations have been interpreted as being caused by the growth and shrinkage of minor ice sheets on Antarctica (see *Sea level change, last 250 million years*, ed.). The late-Cretaceous climate was slightly cooler than the mid-Cretaceous (up to 8–10°C), but its estimated mean global surface temperatures were still several degrees (°C) higher than present. Oceanic and continental data suggest equatorial paleotemperatures similar to the present-day, but a much lower latitudinal temperature gradient and thus warmer high-latitude temperatures.

Moving across the K/T boundary, the plant records of the Northern Hemisphere (mainly North America) indicate a major ecological disruption and quick recovery, which has been attributed to a brief low temperature excursion and change in the hydrologic cycle. This excursion, however, may not have affected the Southern Hemisphere as much, since only minor palynological changes have been found at the few investigated Southern Hemisphere locations. The marine isotopic record, on the other hand, shows little convincing evidence for either warming or cooling across the K/T boundary (see *Bolide impacts and climate*). This suggests that if any climate change occurred as a result of the impact event, it must have been of very short duration. The mean early Paleocene climate (~64 Ma) was very similar to that of the latest Maastrichtian (~67 Ma). It must be kept in mind, however, that the pre-Paleogene geologic record is characterized by rather low resolution, at best of the order of a few thousands years; time-averaging effects (like bioturbation) may further hide short-lasting shifts in the signal. Consequently, if evidence from a climate change spanning a few hundred years is averaged within a 10,000-year record, it may be very difficult to resolve in the geologic record.

Impact-related climatic effects

The most widely discussed climatic effect of a large impact is caused by dust loading of the upper atmosphere. Alvarez et al. (1980) suggested that dust raised by the impact would have spread worldwide in clouds thick enough to cause an endless night and block photosynthesis for periods longer than a year, with catastrophic consequences for the terrestrial biota. Today, the original Alvarez's scenario has been scaled down to a much

less catastrophic view where only the stratospheric portion of the fine (sub-micron) dust from the impact can affect the climate on a global scale (Toon et al., 1997). It is well known (and well-illustrated by the aftermath of the impact of comet Shoemaker-Levy 9 on Jupiter, in July 1994), both from observations and computer modeling, that large impacts can inject hot, melted or vaporized debris from the projectile and target well above the tropopause and beyond the stratosphere, and ballistically distribute it globally over the Earth.

The "darkness-at-noon" scenario (which incidentally led to the "nuclear winter" idea) was first explored using simple numeric models of the atmosphere's radiative balance. The results initially indicated that even a rapidly coagulating dust layer caused sub-freezing temperatures in continental interiors for at least 2 months after the impact and a global loss of photosynthesis for about half that time. Subsequently it was realized that most of the impact-generated dust (large particles) would have a very short residence time in the atmosphere. Furthermore, only the stratospheric portion of the fine (sub-micron) dust, which corresponds to a very small fraction of the impact-produced dust (Toon et al., 1997), would affect climate globally and over a significant period of time. Therefore, the initial "darkness-at-noon" hypothesis was scaled down to a less catastrophic view. There is still much uncertainty on the amount and size distribution of dust injected into the atmosphere by the impact, thus causing equal uncertainty on the extent of the climatic change. An early three-dimensional (3D) atmospheric general circulation model was used to investigate the effect of a uniform, thick stratospheric dust-layer that would decay in about a year (Covey et al., 1994). The results indicate a strong and "patchy" cooling on land, with temperature declining by up to ~12°C, and a mild cooling (few degrees) over the oceans, accompanied by a collapse of the hydrologic cycle. Although the climate model was extended to only one year after the impact, it suggested that the climate would probably recover in about a decade. Recently, the role of the oceans in the long-term response of the radiative perturbation following a Chicxulub-type dust loading of the atmosphere was explored using a two-dimensional (2D), zonally-averaged dynamic ocean circulation model (Luder et al., 2003). The model results indicate that in the first year after the impact the sea surface temperature dropped by several degrees, with the strongest effects in the equatorial regions, but this change remained confined to the upper 200 m of the oceans. Deep-sea temperatures started to change only after ~100 years, but never exceeded few tenths of °C. Overall, the dust-related climatic change did not affect the structure of the ocean circulation. These studies confirm the deep ocean's crucial role as moderator of the Earth's climate.

The presence of a thick sequence of carbonates and evaporites at the impact location brings into the discussion the atmospheric release of large amounts of carbon dioxide (CO₂), sulfur-bearing gases, and water vapor from the sedimentary layer (e.g., Ivanov et al., 1996; Pierazzo et al., 1998). Large amounts of greenhouse gases could be responsible for an abrupt and long lasting climate shift. Various computer simulations have been carried out to assess the influence of the sedimentary layer in the climatic effects of the Chicxulub impact. Early models suggested the release of CO₂ amounts large enough to affect the global climate significantly. However, more detailed modeling studies (Ivanov et al., 1996; Pierazzo et al., 1998) strongly revised the amount of CO₂ released in the impact, and consequently its climatic effects (even these lower estimates may have to be further downsized in light of new laboratory and field studies on the behavior of carbonates in impacts). Considering that the estimated atmospheric inventory

of CO₂ toward the end of the Cretaceous was about 2–10 times pre-industrial values, it is doubtful that the CO₂ directly released by the Chicxulub impact event would have increased the end-Cretaceous atmospheric inventory of CO₂ by more than ~50%. The radiative forcing associated with the impact-released CO₂ is in the range of 1.2–3.4 W m⁻², comparable to the estimated forcing from greenhouse gases due to industrialization (Pierazzo et al., 2003). This forcing is not considered to be large enough to cause a climate change capable of a major mass extinction. A bigger contribution to the atmospheric CO₂ inventory may come from the impact-related wildfires. Estimates from the identified soot layer at the K/T boundary suggest at most a doubling of the preimpact CO₂ inventory (Toon et al., 1997).

The release of sulfur-bearing gases and water vapor in the stratosphere results in the production of sulfate aerosols, as documented by volcanic eruptions. Sulfate aerosols are strong absorbers of long-wave (LW) radiation, while they mainly scatter short-wave (SW) radiation, resulting in a net cooling of the Earth's surface. The effect of injecting sulfur-bearing gases and water vapor into the stratosphere has been investigated with simple atmospheric models. Using a general planetary radiative transfer model, Pope et al. (1997) modeled the solar flux through a sulfate aerosol cloud. Sulfate formation from over 2×10^{17} g of sulfur dioxide (SO₂) and of water vapor (average K/T boundary impact scenario) was modeled with a simple coagulation model. Their results indicate that solar transmission would be significantly reduced (below 50% of normal) for about 8–13 years after the impact and cause a negative forcing (300 W m⁻²) about two orders of magnitude larger than the estimated forcing from CO₂. The presence of dust and soot grains could speed up the coagulation process, significantly decreasing the overall duration of the effect, but increasing its magnitude by further decreasing the solar transmission. Pope et al. (1997) estimated that forcing from the sulfates would cause the continental surface temperature to drop by several degrees, approaching freezing for several years. Using a similar approach but assuming that S would be released as a mixture of SO₂ and SO₃ Pierazzo et al. (2003) suggest a slightly shorter duration of the sulfate effect, with a 50% reduction in solar transmission for 4–5 years after the impact, but a stronger overall forcing (over 500 W m⁻²). They also found no significant change in the maximum forcing for sulfur loadings above about 3×10^{16} g of S (or 6×10^{16} g of SO₂; minimum K/T boundary impact scenario), suggesting a saturation of the sulfur-related forcing. In particular, in investigating the immediate (few days) post-impact climate responses using a single column version of an atmospheric general circulation model, Pierazzo and colleagues found strong temperature drops over the summer hemisphere continents, with milder effects over winter hemisphere continents and oceans. Adding impact-loads of CO₂ to the sulfate effects mitigates the overall cooling only slightly (0.5 °C at most). More comprehensive and detailed 3D climate system models of the impact-related climate change at the end-Cretaceous are still not available.

Study of the responses of terrestrial biota to impact-related climatic effects is still in its infancy. Lomax et al. (2000, 2001) used a dynamic global vegetation-biogeochimistry model to investigate the potential global-scale response of terrestrial ecosystems to an increase in atmospheric CO₂, and to a combined initial cooling plus greenhouse warming resulting from a Chicxulub-type impact. They found that a four to tenfold increase of the atmospheric end-Cretaceous CO₂ inventory produces spatially heterogeneous increases in the distribution of canopy structure, net primary

productivity, and soil carbon concentrations, possibly causing a biotic feedback mechanism that would ultimately help long-term climate stabilization (Lomax et al., 2000). They then investigated the overall combined effect of dust/sulfates and CO₂ loading on the terrestrial ecosystem by artificially reducing the mean annual temperature in the model by 6 °C and the solar irradiance by 30% for 100 years, and simulating the effects of wildfires by burning 25% of the vegetation carbon and setting the CO₂ concentration to ten times pre-impact levels (Lomax et al., 2001). The model results indicate a collapse of the terrestrial net primary productivity that recovered to pre-impact values within a decade. In particular, they found that the overall change in productivity and vegetation biomass is stronger at low latitudes than at high latitudes, and is consistent with ecological extinction gradients derived from terrestrial paleobotanical data.

Conclusions

The Chicxulub structure, 65 million years in age, is the youngest of the known terrestrial impact structures larger than 100 km in diameter. Structures of this size are associated with impact events that are capable of perturbing the environment and climate worldwide. Likely global scale effects include depletion of stratospheric ozone, ignition of global wildfires, release of climatically active gases, production of toxic oxides and acid rain, and atmospheric loading of dust and smoke. When looking at the geologic record, it appears that any climatic change introduced by the Chicxulub impact event did not destabilize the paleoclimate, which was able to recover to the pre-impact state over a geologically short timescale (<10,000 years). On the other hand, a sudden, large climate change lasting a few hundred years would still have enormous repercussions on the evolution of the biosphere.

Various investigations on the climatic effects associated with the K/T boundary impact indicate that an abrupt cooling episode occurred immediately after the impact and could have extended for a few years. The atmospheric loading of impact-produced CO₂ could then have caused a mild warming that may have helped climate recovery. The impact apparently did not affect the deep ocean. The slow response of the deep ocean and the quick reaction of the terrestrial ecosystem contribute to a fast recovery of the climate system.

To this day, the magnitude of the end-Cretaceous climate change is still an open question; answering it may shed new light on our understanding of the end-Cretaceous mass extinction.

CRYOSPHERE

Introduction

The cryosphere (derived from the Greek *kryos* for “cold”) comprises all of the frozen water and soil on the surface of the Earth. While this term is often used by climatologists, a more accurate name for the study of all aspects of ice and snow is *glaciology*. Ice in clouds is also an important element of climate but is not considered part of the cryosphere. Because the freezing point of water lies in the center of the range of terrestrially achieved temperatures, the cryosphere is a very changeable feature of the Earth’s surface. Its six main elements, in diminishing order of area for today’s climate, are: (a) seasonal snow cover, (b) sea ice, (c) permafrost, (d) ice sheets, (e) river and lake ice, and (f) mountain glaciers and small ice caps.

Seasonal snow cover is the most dynamic element of the cryosphere. It responds rapidly to atmospheric conditions on timescales of days to weeks and, in fact, exhibits the greatest seasonal variation of any geophysical element on the Earth’s surface. Although it has a small seasonal heat storage capacity, its main effect on climate comes from its high albedo (fraction of incident solar radiation reflected back to space). Fresh snow has an albedo of 0.9. *Sea ice* forms when sea water is cooled below its freezing point. This freezing is a complex process because the freezing point of water depends on the salt concentration of the ocean. A sea ice field usually consists of numerous individual floes, typically 0.5–4 m thick, with diameters between 1 meter and many kilometers. Sea ice has a high albedo and therefore the effect its seasonal cycle exerts on the surface heat balance of the Earth is similar to, though smaller than, that exerted by seasonal snow cover. Sea ice also acts as a barrier to the exchange of heat, moisture, and momentum between the atmosphere and the ocean, and furthermore plays a role in the formation of deep water masses in some oceanic areas. Sea ice is covered by snow for much of its lifetime. *River and lake ice* form in a similar manner to sea ice but without

the complications of high salt concentrations. Their climatic behavior resembles that of sea ice. *Ice sheets* are quasi-permanent features, responding to environmental changes on time scales of millennia. Today, only the two polar ice sheets on Antarctica and Greenland remain. Together, they contain by far the greatest proportion of mass of the cryosphere but are least sensitive to climate change on the shorter timescales. Ice sheets have a high elevation and high albedo, and so act as elevated cooling surfaces for atmospheric heat balance. They also play an important role in the freshwater balance of the oceans. Changes in their volume, though slow, are the main cause for sea-level changes on geological timescales. *Mountain glaciers* and small ice caps are a small component of the cryosphere. They are distinguished from the large ice sheets by their size and by the fact that they are topographically controlled. They are too small to have a direct influence on climate; however, their high rates of mass turnover allow rapid changes in response to climatic change (timescales of the order of decades to centuries). *Permafrost* is ground material that remains below freezing for at least two consecutive years, whether or not it contains ice. It may be continuous, underlying the whole of a region, or discontinuous, occurring in patches. In many regions the uppermost, so-called active layer, thaws annually to a depth of 1 to a few meters. Permafrost is a product of heat exchange between the land surface and the atmosphere, changing on timescales of centuries. It affects surface ecosystems and river discharge, and changes in its extent can control rates of trace gas emissions, especially of methane. Permafrost records temperature changes, hence its role as geo-indicator for monitoring and assessing environmental change.

Current distribution of ice in the cryosphere

Today, nearly 80% of the Earth’s freshwater is stored on the continents in the form of ice, almost all of it in the polar regions and in high mountain areas, cf. [Table C9](#) and [Figure C78](#). Perennial ice covers 10% of the Earth’s land surface and 4% of the oceans. The seasonal distribution of snow, lake and river ice, and to a lesser extent, sea ice, is closely linked with atmospheric conditions, in particular with temperature.

Seasonal snow

Seasonal snow reaches its maximum extent in late winter, when it covers almost 50% of the land surface of the Northern Hemisphere. It is almost absent in the Southern Hemisphere, where it is limited to the mountainous areas of New Zealand, southeastern Australia, and South Africa; it is more widespread only in Patagonia and ice-free regions of Antarctica and on sub-Antarctic islands.

Sea ice

The seasonal variation of sea ice is much smaller in the Arctic than in the Antarctic owing to the different geography of the two polar regions. The Arctic Ocean is a truly polar ocean surrounded by land, with only a limited range of longitudes within which sea ice can expand seasonally into lower latitudes. By contrast, in the Southern Hemisphere the central polar region is covered by the continent of Antarctica, preventing sea ice from extending to the highest latitudes in summer but at the same time allowing winter sea ice to extend in a roughly concentric zone around Antarctica at almost all longitudes. A second contrast between the two hemispheres is the larger upward oceanic heat flux in the Antarctic, as less fresh water enters the ocean to cause a low-salinity layer of polar surface water

Table C9 Size of the present-day cryosphere and average mass turnover times of its main components as given by the ice flux and average residence time (adapted from Fitzharris et al., 1996; Vaughan et al., 1999; Zhang et al., 1999; Huybrechts et al., 2000; Church et al., 2001; Lythe et al., 2001)

Cryospheric element	Area (10 ⁶ km ²)	Ice volume (10 ⁶ km ³)	Ice flux (km ³ yr ⁻¹)	Residence time ^a (yr)
Seasonal snow cover	47.2	~0.01	~25,000	~0.4
Northern Hemisphere (max)	46.3			
Southern Hemisphere (max)	0.9			
Sea ice				
Northern Hemisphere (max/min)	16.0/9.0	0.05/0.03	~40,000	~1
Southern Hemisphere (max/min)	22.0/4.0	0.03/ <0.01	~20,000	~1
Permafrost	25.4	~0.02	~40	~500
Ice sheets				
Antarctic Ice Sheet (grounded ice)	12.37	25.71	2,100	~12,500
Antarctic ice shelves	1.49	0.66	540	~1,200
East Antarctic Ice Sheet	10.09	22.59	1,350	~17,000
West Antarctic Ice Sheet	2.28	3.12	750	~4,000
Greenland Ice Sheet	1.71	2.85	570	~5,000
River and lake ice	<1.0			~0.3
Mountain glaciers and small ice caps	0.68	0.18	~750	~250

^aThe residence time is defined as the ice volume divided by the ice flux.

hampering vertical heat exchange from below. For these reasons, the Arctic features a thicker permanent sea ice cover of multiyear ice, augmented in winter by a seasonal ice cover of first-year ice extending into the surrounding subpolar seas. Around Antarctica, however, almost all of the winter ice melts in summer, leaving multiyear ice confined only to the western Weddell Sea, the Bellingshausen and Amundsen Seas, and coastal embayments. Arctic sea ice generally reaches its maximum extent in March and minimum extent in September. By contrast, Antarctic autumnal ice growth is slower and spring decay about one month faster.

Polar ice sheets

Present-day continental ice cover is entirely dominated by the Antarctic Ice Sheet, which is responsible for 90% of the volume and 85% of the area of all land ice. Most of this ice is in the East Antarctic Ice Sheet, which constitutes a vast, relatively flat dome with a maximum elevation of 4,030 m and a maximum known thickness of 4,776 m. The Transantarctic Mountains divide the East Antarctic Ice Sheet from the West Antarctic Ice Sheet and the Antarctic Peninsula. The West Antarctic Ice Sheet rests on bedrock below sea level and largely drains into two big ice shelves in the Ross and Weddell Seas. These ice shelves are up to 1,000 m thick and float in equilibrium with the ocean water. Smaller ice shelves fringe the Antarctic coastline elsewhere. Ice flow towards the margin results mainly from internal ice deformation under the action of gravity. At the margin, the flow is often channeled in outlet glaciers and in ice streams, in which the dominant flow mechanism is basal sliding, and that are responsible for the bulk of the ice discharge across the grounding line into the ice shelves.

Mass is lost from the ice shelves by bottom melting and by calving of icebergs from their ice fronts. Current Antarctic surface temperatures are so low that there is virtually no surface melting. These low temperatures also limit the amount of water vapor that can be advected inland. Accumulation rates over the vast interior of the continent are only a few cm per year and this makes the central Antarctic Plateau one of the driest places on Earth.

The only Arctic ice mass of significance is the Greenland Ice Sheet. It is a relict from the ice ages that overlies a bowl-shaped continent and has a maximum surface elevation of 3,230 m. In contrast to Antarctica, summer temperatures on Greenland are high enough to cause widespread summer melting, resulting in a negative mass balance below elevations of about 500 m in the north and 1,800 m in the south. Greenland has no major ice shelves apart from a few small ones along the north and northeast coast. Ice not lost by ablation is discharged into the ocean by iceberg calving from glaciers, in roughly the same amount as runoff. Complete melting of both polar ice sheets would raise global sea level by about 70 m.

Glaciers and ice caps

The water currently contained in glaciers and ice caps (excluding Antarctica and Greenland) is equivalent to about 0.5 m of global sea level. Half of it is in small ice caps, mostly in the Arctic, and the other half is stored in mountain glaciers elsewhere. Most mountain glacier ice is in Alaska, followed by Central Asia and Patagonia. Ice volume contained in the Alps is less than 1% of total glacier volume, but its glaciers have been studied the most. There are more than 160,000 glaciers worldwide. Glaciers enlarge when the accumulation of snow and ice exceed the loss by melting, and sometimes calving. Net accumulation occurs at higher altitude, net ablation at lower altitude. To compensate for net accumulation and ablation, the ice flows downhill by internal deformation and basal sliding. The primary controls on glacier mass balance are temperature, especially in summer, and accumulation, especially in winter. The nature of the response varies from glacier to glacier depending on mass-balance gradient, hypsometry, and glacier length.

Permafrost

About 24% of the exposed land area of the Northern Hemisphere is currently underlain by permafrost, most of it in the tundra of Canada, Alaska, and Russia (Zhang et al., 1999). It is also present under shallow polar sea beds, in ice-free areas in Antarctica, on some sub-Antarctic islands, and in many mountain areas and high plateaus of the world. Its distribution roughly follows the pattern of air temperature, though some of it is relict, having formed during colder glacial periods and having melted only very slowly since then. Sizeable areas below the polar ice sheets and small ice caps are also below freezing. This thermal condition of the ground extends to maximum depths of about 1,500 m in Siberia, 1,000 m in the Canadian Arctic, and 680 m in Alaska, but often it is also less than 20 m thick. Generally, permafrost with high ice content (>20% by volume) is found at high latitudes, and permafrost with low ice content (<10% by volume) mainly in mountainous regions and high plateaus. Almost half of the total permafrost area is continuous permafrost. The remaining part is made up of discontinuous and sporadic permafrost or occurs in isolated patches.

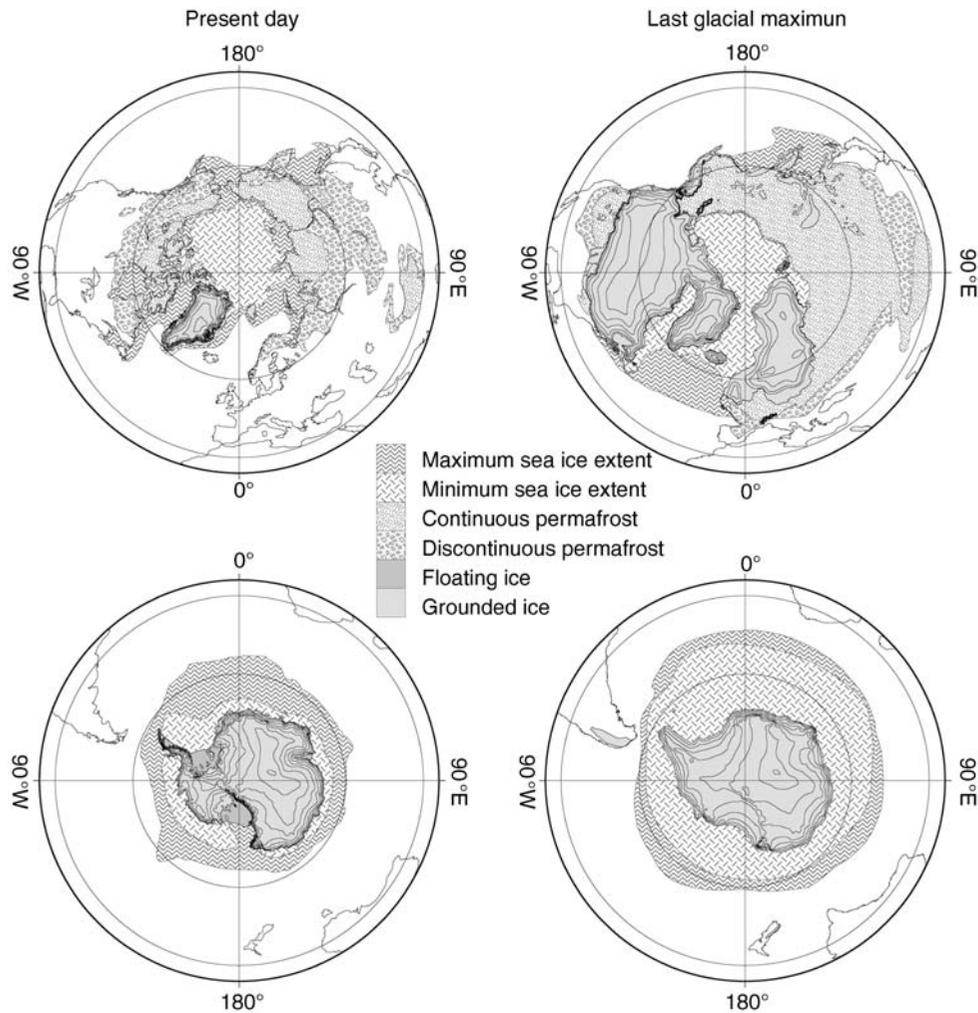

Figure C78 Geographic extent of main components of the cryosphere in both hemispheres. The *left panels* are for the present distribution, the *right panels* depict the situation during the Last Glacial Maximum between 23,000 and 19,000 years ago (adapted from maps presented in Cooke and Hays, 1982; Untersteiner, 1984; Frenzel et al., 1992; Fitzharris et al., 1996; Van Vliet-Lanoë and Lisitsyna, 2001, and the author's own ice sheet model results).

Current evolution of the cryosphere

The current evolution of many elements of the cryosphere, especially of those with the shorter response times, appears well correlated with the recent global warming trend of about 0.6°C since the late nineteenth century.

Snow covers in temperate regions are usually thin and often close to their melting point, hence they are sensitive indicators of climate change. Monitoring of seasonal snow is practical only with satellites, so there are no reliable records prior to 1971. Visible-band and passive microwave data since then show considerable variability from year to year, but also reveal a decline in the extent of snow cover in the Northern Hemisphere by about 10% since the mid-1980s, largely due to a decrease in spring extent (Robinson et al., 1993). This reduction in snow cover is highly correlated with increasing air temperature. Snow-cover observations at ground stations have been recorded for many decades and suggest that Northern Hemisphere spring extents are currently at their lowest values in the past 100 years. Numerous small perennial snow patches have

disappeared over the twentieth century, commensurate with the general warming trend.

Like seasonal snow, *sea ice* is also thought to be sensitive to climate change but the mechanisms are less well understood as additional processes such as ice transport, ocean circulation, and convection depths come into play. Warming is nevertheless thought to cause a reduction in both area and thickness of sea ice, which sets in motion a positive feedback, as more solar radiation is absorbed and more oceanic heat is transferred to the atmosphere. Satellite passive microwave data show a marked decrease of perennial Arctic sea ice extent for the period 1978–2000 of 9% per decade consistent with a summer warming of 1.2°C per decade over the same period (Comiso, 2002). Antarctic records of sea-ice extent, on the other hand, show large variability but a negligible, albeit slightly positive, overall trend. Knowledge of sea-ice thickness largely comes from upward sonar profiling from submarines in the Arctic and more recently, from buoys moored to the sea floor. Observations of sea ice thickness have also been derived from satellite altimetry of the freeboard height, but

geographical coverage and/or record length do not yet allow for strong conclusions. Summer Arctic sea ice cover and thickness have decreased in recent years (e.g., Lindsay and Zhang, 2005; Serreze et al., 2007).

Observations of *lake and river ice* exist primarily in the form of freeze-up and break-up dates. Records for the Northern Hemisphere since 1850 show significant evidence of later autumn freeze-up and earlier spring break-up of on average 5.8 days and 6.5 days per 100 years, respectively, consistent with the warming trend from the beginning of the twentieth century (Magnuson et al., 2000).

The present evolution of the *polar ice sheets* is still not known with confidence but a picture is starting to emerge from a combination of mass budget studies, satellite altimetry, and modeling (Rignot and Thomas, 2002). Current evidence indicates that the Antarctic Ice Sheet has probably lagged behind in the last glacial cycle of retreat. Most of the ongoing shrinking probably occurs in West Antarctica as a delayed response to post-glacial sea-level rise, whereas the East Antarctic Ice Sheet may be close to a stationary state, or growing slightly in response to increased accumulation rates. Superimposed on this long-term trend is a likely thickening effect of modern accumulation increases. Larger imbalances have recently been detected in West Antarctica, positive for the Siple Coast ice stream area and negative for the Pine Island/Thwaites catchment area. These probably represent local ice-dynamic effects that are unrelated to climate. The Greenland Ice Sheet is believed to be close to an overall neutral equilibrium. Current data show a consistent picture of a small thickening of the accumulation zone offset by larger thinning rates at lower altitudes. According to the Intergovernmental Panel on Climate Change (IPCC), both ice sheets together may have contributed between -2 cm and $+6$ cm to the observed twentieth century sea-level rise (Church et al., 2001).

A wealth of data exists on the geometry of valley *glaciers*. A large amount of information is available from sketches, etchings, paintings, and old photographs. In many cases, information from terminal moraines and trimlines is available to construct the history of a glacier over the last few centuries. An overwhelming characteristic of global glacier length records is the almost uniform recession of glaciers, which started about 1850 at the end of the Little Ice Age and is still continuing today. Rising global temperature is the most likely explanation and so the worldwide glacier retreat is probably one of the strongest measures of global warming. The only exceptions today are Norwegian and New Zealand glaciers, which are currently advancing, due to local increases in precipitation. However, this is an exceptional state that can probably not be sustained in the long term. Global glacier melt assessments indicate that since the late nineteenth century, glaciers and ice caps have lost between 5 and 10% of their volume and a little less than that in area. The IPCC reports a glacier contribution to global sea-level rise of between 2 and 4 cm over the last 100 years, less than the contribution from thermal expansion but similar to the combined contribution from the Antarctic and Greenland Ice Sheets. Findings of ancient remains in the European Alps (e.g., the 5,000-year old Oetztal “ice man”) indicate that current glacier recession is reaching levels not seen for probably several millennia. Recent studies suggest that the twentieth century rate of glacier wastage in Alaska and the Patagonian Andes doubled after the mid-1990s (Arendt et al., 2002; Rignot et al., 2003).

Deep *permafrost* temperatures change by conduction and therefore are a manifestation of past climatic conditions over long spans of time. Permafrost is also very sensitive to changes in its surface energy balance. Very small changes in surface climate can produce robust changes in permafrost temperatures. Long-term measurements in deep boreholes in Alaska, Canada, and elsewhere demonstrate a distinct but spatially heterogeneous warming trend in low-land permafrost (Romanovsky and Osterkamp, 2001). Temperature measurements in northern Alaska have demonstrated a warming of the permafrost of $2-4^{\circ}\text{C}$ over the last century. In North America, the southern extent of the discontinuous permafrost zone has migrated northward in response to warming after the Little Ice Age, and continues to do so today. In China, both an increase in the lower altitudinal limit of mountain permafrost and a decrease in areal extent have been observed. Increases of the thickness of the active layer in response to climate warming have also been reported.

The cryosphere during the last glacial cycle

During the last ice age, which was most severe from about 23,000 to 19,000 years ago, an extensive ice complex stretched across North America, Greenland, the polar seas, and parts of northern Eurasia. It consisted of huge land-based glaciers, marine-based ice sheets, and either permanent pack-ice or shelf ice. Ice increased synchronously over Antarctica and the Southern Ocean. Sea levels were 125 m lower than today because water was bound up in continental ice sheets that increased their total mass by about a factor of three (Clark and Mix, 2002; Figure C78 and Table C10).

The surface of the Earth during the Last Glacial Maximum (LGM) was comprehensively mapped by the CLIMAP (Climate: Long-range Investigation, Mapping, and Prediction) project in the 1970s from a combination of biological and lithological evidence from deep-sea cores and from the land (CLIMAP, 1976). Best documented is the chronology of Northern Hemisphere ice-sheet extent. The largest glacier complex was situated over North America. It is inferred to have consisted of several domes centered over the high plateaus of eastern Canada and the Rocky Mountains. An ice-free corridor separated the Cordilleran Ice Sheet from the Laurentide Ice Sheet until late in the glacial

Table C10 Size of main cryospheric elements during the Last Glacial Maximum (adapted from Denton and Hughes, 1981; Cooke and Hays, 1982; Van Vliet-Lanoë and Lisitsyna, 2001; Huybrechts, 2002; Clark and Mix, 2002)

Cryospheric element	Area (10^6 km ²)	Ice volume (10^6 km ³)	Excess ice-equivalent sea level (m)
All land ice	41.8	75–88	110–135
Laurentide Ice Sheet	14.6	31–38	75–88
Fennoscandian Ice Sheet	6.2	5.8–7.5	14–18
Greenland Ice Sheet	2.6	4.0–4.5	2–3
Antarctic Ice Sheet (grounded)	15.1	33–36	15–20
Other ice caps and glaciers	3.3	1.4–2.2	4–6
Northern Hemisphere sea ice (max/min)	18/11	–	–
Southern Hemisphere sea ice (max/min)	35/25	–	–
Exposed permafrost (continuous and discontinuous)	30	–	–

period. The glaciation of Eurasia had an ice sheet centered over the British Isles in the west and that extended beyond the present day shoreline onto the then emerged shelf of the North Sea. The Fennoscandian Ice Sheet spread into the same area from the east but did not coalesce into the British Isles at the LGM. To the east, the Fennoscandian Ice Sheet extended into the northern part of the Russian plain and the Barents Sea, which in the northwest was also covered by ice from Novaya Zemlya. The Kara Sea, except at its western margin, was not glaciated at the LGM, but likely at an earlier stage of the last glacial cycle. The thickness of the ice sheets cannot be reconstructed from glacial-geological observations but it has been inferred to have been up to 4 km from indirect evidence such as uplift rates of the land, and from modeling.

By comparison, the Antarctic and Greenland Ice Sheets underwent only small changes in volume and extent during the last glacial cycle. Volume changes of the Antarctic Ice Sheet were largely concentrated in West Antarctica and the Antarctic Peninsula. At the LGM, grounding lines advanced close to the continental shelf break almost everywhere as global sea level dropped. It is unclear whether extensive ice streams continued to exist in the Ross basin and elsewhere. Ice over interior East Antarctica was generally thinner than today because of lower accumulation rates. The Greenland Ice Sheet also extended beyond the present coastline to cover at least the inner continental shelf. Summer melting ceased and mass was lost by calving only. The Greenland Ice Sheet extended northwest to join the Laurentide Ice Sheet flowing out of Canada. Ice retreat of the Antarctic and Greenland Ice Sheets was in full progress between 13,000 and 8,000 years ago, several thousand years later than for the North American and European Ice Sheets (Huybrechts, 2002).

To date, no criteria have been developed to recognize paleo-ice shelves. It has been speculated that the Antarctic continent was entirely encircled by a vast ice shelf that merged imperceptibly with the permanent pack ice and possibly extended as far as 800 km beyond the continental shelf (Denton and Hughes, 1981). Russian scientists have hypothesized a 1 km thick Arctic ice shelf from glacial scouring of ridges at the sea floor, but its dating is uncertain (Polyak et al., 2001).

Small ice caps and glaciers merged to larger glacier complexes in Patagonia, the Alps, and many presently glaciated areas elsewhere (Pyrenees, Caucasus, eastern Siberia, New Zealand Alps, and other mountain areas). There is no convincing evidence for the occurrence of a Tibetan Ice Sheet, but glacier fronts in the Himalayas descended by about 1,000 m elevation.

In the Southern Hemisphere, the most striking difference was the winter extent of sea ice, which was significantly greater than it is today (Cooke and Hays, 1982). Summer extent was probably similar to today's winter extent. Permanent sea-ice cover also existed in the Norwegian, Greenland, and Labrador Seas coincident with a large shift in the path of the Gulf Stream, which flowed due east at 40°N during the glacial maximum. A striking and unexplained difference was the comparably small amount of cooling in the North Pacific and the associated southward extension of sea ice at LGM compared with equivalent latitudes in the North Atlantic.

There are no proxy data to infer the seasonal variation of snow cover and river and lake ice. Nevertheless, winter cover must have been greatly expanded, commensurate with Northern Hemisphere continental coolings of up to -20°C (CLIMAP Project members, 1981; Frenzel et al., 1992). There are also many fossil periglacial features at the surface that show that permafrost at the LGM was more extensive than today. In North America,

discontinuous permafrost extended up to 1,000 km south of the southern margin of the Laurentide Ice Sheet. Permafrost was also present on most of Europe, the Atlas Mountains, Turkey, Iran, the whole of Siberia, the Tibetan Plateau, northern China, and Hokkaido. In the Southern Hemisphere, widespread permafrost extended at mid altitude in southern America, as far north as 40°S, and was present in Patagonia, the southern island of New Zealand, and on all sub-Antarctic islands. It occurred isolated in mountainous areas of Tasmania and southeast Australia, and even in the highest mountains of East Africa and the high Andes. It never existed in South Africa, with the exception of a small spot of mountain permafrost in the Drakensberg (Van Vliet-Lanoë and Lisitsyna, 2001).

The last glacial cycle was enclosed by two periods when the cryosphere was smaller than today. During the Last Interglacial, which culminated 125,000 years ago, Northern Hemisphere temperatures at mid-latitudes were 2–3°C warmer than today, increasing towards the pole to more than 4°C. The Greenland Ice Sheet may have retracted to a small central ice dome, thus providing most of the melt to explain the inferred sea-level stand of approximately 6 m higher than today (Letréguilly et al., 1991; Cuffey and Marshall, 2000). The Holocene Climatic Optimum occurred around 6,000 years ago. The warming was of a similar magnitude as that of the Eemian warming, but it was shorter-lived. At that time, the Greenland Ice Sheet margin receded inland from its present position. The other components of the cryosphere, except the Antarctic Ice Sheet, were also smaller.

The cryosphere before the last glacial cycle

In geological terms, the last ice age ended a short time ago. It was the last episode of a period of climate oscillations between glacial and relatively ice-free environments that began about 2.3 million years ago. Over the last 800,000 years, such ice ages had a period of about 100,000 years; before that, 41,000-year cycles dominated. The penultimate glacial cycle, which ended 130,000 years ago, was probably the most severe. Periods of extensive glaciation also existed prior to those of the Pleistocene epoch. Though the record of early climates is dominated by evidence of global warmth and likely almost total absence of land and sea ice, there were intervals of widespread ice cover during Paleoproterozoic times, at around 2.3 billion years ago and perhaps also between 3.1 and 2.9 billion years ago.

The most extreme glacial climate in the Earth's history probably occurred during the Late Precambrian between 900 and 600 million years ago, and is known as the *Proterozoic ice house*. In its extreme version, ice sheets extended to the equator and the world's ocean was virtually entirely frozen over (Hoffman et al., 1998). At that time, the Earth experienced anomalously low atmospheric carbon dioxide concentrations, possibly as a result of mountain building and continental weathering, in addition to the Sun being 6% fainter than it is today. Recovery from such a *snowball Earth* could have resulted from volcanic outgassing of greenhouse gases. Glaciation of the Earth also occurred in the Late Ordovician at 450 million years ago, and during Carboniferous-Permian times between 320 and 250 million years ago. At this time, a single supercontinent, Gondwanaland, lay over the South Pole, which suggests that the presence of a large land mass at high latitude is a critical element for glaciation.

Glaciation on Earth started again during the Cenozoic Era, from 65 million years ago to the present. It started first in the

Southern Hemisphere and was punctuated by two periods of significant ice growth. The first ice increase occurred near the Eocene-Oligocene boundary 36 million years ago and saw frequent ice sheets growing and decaying on East Antarctica, reaching the margin of the continent in a few places (Barker et al., 1999). Global ice sheet volume increased again in the middle Miocene around 15 million years ago with the formation of a quasi-permanent East Antarctic Ice Sheet that may have reached its maximum extent. The first period of ice increase was probably driven by declining levels of atmospheric carbon dioxide, while the second period has been linked to the thermal isolation of Antarctica, as newly formed continents moved to the north and the Antarctic Circumpolar Current developed. The West Antarctic Ice Sheet likely formed later, during the Late Miocene. By 2 million years ago, the Antarctic glacial regime was much as at present and ice ages started to occur on the Northern Hemisphere, as did mountain glaciers in midlatitude highlands.

CYCLIC SEDIMENTATION (CYCLOTHEM)

The term “cyclic sedimentation” is generic and can be applied to any type or scale of repetitive sedimentation (Einsele et al., 1991). Conversely, the term “cyclothem” has a much more specific application. The concept has mostly been applied to stratigraphic successions of middle to late Pennsylvanian (upper Carboniferous) rocks that were deposited in cratonic basins of the eastern and mid-continental USA. Well-developed

cyclic sedimentation was first noted in Illinois Basin (Eastern Interior Coal Basin), within late Paleozoic rocks in the state of Illinois. These lithological cycles exhibited vertical oscillations between coal bearing, siliciclastic-rich facies and carbonate-rich facies (Udden, 1912; Weller, 1930, 1931). The term “cyclothem” was subsequently applied to this style of cyclic sedimentation (Wanless and Weller, 1932).

The siliciclastic-rich facies were traditionally viewed as terrestrial or continental facies, however, tidal influences are now widely recognized (Archer and Kvale, 1993; Archer et al., 1994a,b). The carbonate-rich facies commonly contain marine fossils. Thus, cyclothem were commonly interpreted as resulting from changes in base level brought about by sea level fluctuations. These changes could be related to basinal tectonics, or most commonly, to global glacioeustatic changes that are related to Gondwanaland paleoglaciations. More recently, climatic oscillations and the resultant changes in rates of clastic flux into subsiding basins have been advocated as a potential driving mechanism (Cecil, 1990).

A recurring problem that haunts the application of cyclothem models is that there are a great number of different models at different scales. Reger (1931) employed an unusual and extreme application of the cyclothem paradigm for cycles in the Appalachian Basin. In sections that did not conform to his idealized model, he insisted that any missing units would be given stratigraphic names, but referred to as “phantoms” since they did not occur at that specific locality.

Commonly, a cyclothem model, which was derived from a specific basin and from a specific stratigraphic interval, has subsequently been applied far from its original areas of suitability. On the other hand, some general models, which do have a wide-ranging applicability, are named such that they imply occurrence only within a specific basin. For example, a common model is the “Illinois-Basin cyclothem,” which was applied originally by Wanless and Weller (1932) to coal-bearing sequences in middle Pennsylvanian rocks of southern Illinois (see also Wanless and Wright, 1978). Initially, the concept was thought to be a mapable entity and was applied as a formation-level stratigraphic entity. Another popular model is the “Kansas cyclothem,” which was described from non-coal bearing, more marine cycles in upper Pennsylvanian rocks of eastern Kansas (Moore, 1936, 1949, 1964). Similar to the application within the Illinois Basin, the cyclothem was used commonly as a mapable, lithostratigraphic entity.

The use of geographic descriptors for the names of these different types of cyclothem has continued to create confusion. For example, the “Illinois-Basin cyclothem” not only occurs in the middle Pennsylvanian of Illinois, but is also the typical sequence seen in age-equivalent rocks of Kansas. Similar, the “Kansas cyclothem” is the typical sequence observed in upper Pennsylvanian in eastern Kansas but also in age-equivalent strata of the Illinois Basin. Thus, there is a far greater similarity of the Pennsylvanian system in Illinois and Kansas than is commonly supposed. Largely, these misunderstandings have been perpetuated by the superficial application of the standard cyclothem models.

Although the cyclothem concept was originally conceived in the 1930s for sequences in Illinois, it was subsequently discarded as a meaningful stratigraphic entity in the land of its origin. However, the concept was developed in far greater detail for strata within the U.S. mid-continent (particularly within Kansas and adjacent states). Over a period of decades, ranging from the 1930s to the 1960s, increasingly more complex

models of cyclothem were discussed by Moore (1931, 1936, 1949, 1964). It is perhaps Moore’s near obsession and his dominating role in mid-continent geology that did much to entrench the concept of a “cyclothem” into the field of sedimentary geology. At its most complex, Moore’s models included cycles of cyclothem, which he termed a “megacyclothem.”

Later, Moore’s megacyclothem concept was modified and simplified by Heckel (1977, 1986). This adapted model was itself termed a “cyclothem”; thus, Moore’s earlier definition and Heckel’s subsequent modification of the term referred to different scales of stratigraphic sequences. This also increased the confusion over the historical use of the term. The reinterpretation of Moore’s cyclothem concepts included a reinterpretation of organic-rich facies as deep-water deposits and an inferred and hypothetical depth zonation based upon conodont distributions (Heckel and Baesemann, 1975). West et al. (1997) presented a summary of the various cyclothem models and discussions on their potential eustatic and climatic controls.

Attempts have made to quantify cyclothem and to develop a mathematical or statistical model. Such attempts have never been successful (see Pearn, 1964; West et al., 1997). Arguments have been proposed that a search for cyclicity in lithological successions is an inherent human bias (Zeller, 1964).

There are many drawbacks that exist with the traditional usage of the cyclothem concept. The biggest limitation is that most of the work has focused on the more regular and recurring parts of the cycle, which consist of the more-marine, carbonate-dominated portions of the sedimentary cycle. These units, which also include organic-rich laminated black shales, are the easiest to correlate, particularly when using subsurface, geophysical logs. The more clastic components, which have been referred to as clastic wedges (Wanless, 1964; Archer and Kvale, 1993) of the cycle, are far more variable and are much harder to adapt to simple cyclothem models. Subsequent work on the clastic wedges suggests that these facies were formed by deltaic and tidal-estuarine depositional systems (Archer et al., 1994a). From a sequence stratigraphic perspective, these clastic wedges include incised valley-fill (IVF) facies (Archer et al., 1994b).

Ongoing appreciation and application of sequence-stratigraphic models (see Van Wagoner et al., 1990), particularly to the clastic components of cyclothem, suggest that the cyclothem concept is largely obsolete. However, because of the extensive historical literature that has applied the various permutations of cyclothem models, the concept still creates considerable confusion in studies of cyclic sedimentation. Postdating the influence of Moore, the subsequent compendia of formal stratigraphic units of Kansas no longer attempted to apply the cyclothem concept (Zeller, 1968).

D

DANSGAARD-OESCHGER CYCLES

Dansgaard-Oeschger (D-O) cycles are oscillations of the climate system during the Wisconsinan glacial, where the climate switched between a cold glacial climate and a “warm” glacial climate. The glacial climate, which ended around 11,500 years ago, was colder than the present warm period (the Holocene) and variations were of much greater amplitude than those recorded during the Holocene.

D-O cycles are not regular sinusoidal cycles, but are characterized by rapid warming events. Such events occurred 24 times during the Wisconsinan glacial ($\sim 115\text{--}10\text{ kyBP}$) ($\text{ky} = 10^3$ years). The magnitude of the warming over Greenland is estimated to be approximately $10\text{--}15^\circ\text{C}$ based on data from Greenland ice cores. However, these temperatures did not reach the warm temperatures of the Holocene. A cycle is characterized by a rapid transition from the cold glacial climate to a warmer phase (which is also called a D-O event) within only 20–50 years. After this rapid warming, the warmer climate persists for hundreds to thousands of years. A slow decline in temperatures (recorded in the $\delta^{18}\text{O}$ values) occurs during D-O events, until the climate finally “jumps” back to the colder glacial climate (see [Figures D1](#) and [D2](#)). The cold phase does not show any characteristic behavior; it may be described as stable with a noisy signal. This cyclical behavior is what gives the D-O events their characteristic sawtooth shape.

Ocean sediment records show an oscillation of $\sim 1,500$ years (Bond and Lotti, 1995) during the Wisconsinan glacial period. These cycles are considered to originate from the D-O cycles (Bond and Lotti, 1995; Alley et al., 1999).

Occurrence and labeling of D-O cycles

The record of D-O cycles has been labeled by dividing each cycle into a warm and a cold phase, where the warm phases are named Greenland interstadials (GI) and the cold phases are named Greenland stadials (GS) (Björck et al., 1998; [Table D1](#) and [Figure D1](#)). Each GI/GS is associated with a number (1, 2, 3...) and each numbered GI/GS is then subdivided by

alphabetic letters (a, b, c...), which can be divided further by numbers associated with warm and cold phases. This numbering system allows the incorporation of data from new sites if additional variations or oscillations are found within a specific GI/GS. For example, GI-1 contains three warm periods, where the two oldest are the well-known Allerød and Bølling. GS-1 is also called Younger Dryas. Older Dryas (GI-1d), however, is the cold spell between the before-mentioned Allerød (GI-1c) and Bølling (GI-1e) in GI-1. This shows that the naming has been confusing in the past. The INTIMATE name convention (see Björck et al., 1998) has been used for the D-O cycles presented in [Table D1](#), which shows the dating of each GI and GS and its duration for the GRIP ice core.

History

D-O cycles are named after the two scientists who led the work on the phenomena, namely the Danish scientist Willy Dansgaard and the Swiss scientist Hans Oeschger. They were the first to relate the changes in the $\delta^{18}\text{O}$ record from the Greenland ice cores to a possible climate change over the North Atlantic region, and to changes in the thermohaline circulation (THC) (Dansgaard et al., 1983).

D-O cycles were first seen in the $\delta^{18}\text{O}$ record from the Camp Century ice core (Hansen and Langway, 1966) that was drilled in northwestern Greenland (see *Oxygen isotopes and Paleotemperatures, proxy reconstructions* to understand how $\delta^{18}\text{O}$ is used as a proxy for temperature). However, the climatic significance was not realized until the same behavior was seen in the $\delta^{18}\text{O}$ record of the Dye 3 ice core (from southern Greenland). Finally, the climatic relevance of the D-O cycles in Greenland ice cores was confirmed when the two Summit drillings, GRIP (Dansgaard et al., 1993) and GISP2 (Groote et al., 1993), were finished. At Summit, where horizontal movement is slow, the changes in the oxygen isotope record cannot originate from internal folding of the ice layers due to ice movement over rough bedrock. Therefore, they must be a signal of actual climate changes occurring over most of Greenland. At first, the signal was circumspectly attributed to climatic changes in the Greenland/North Atlantic region. Later, the area was enlarged to include Europe when evidence of D-O cycles was found in

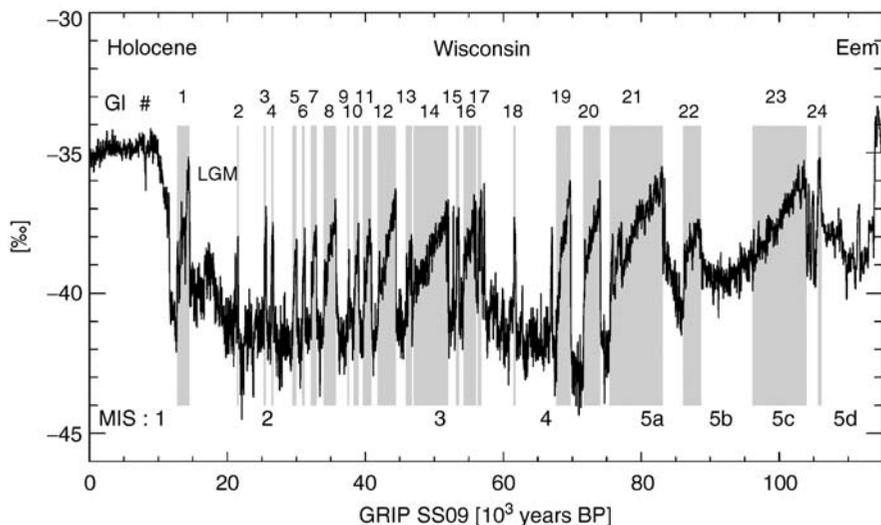

Figure D1 The GRIP $\delta^{18}\text{O}$ record is shown for the last 115,000 years. The Dansgaard-Oeschger events (GI/warm phase of the D-O cycle) are shaded and numbered accordingly (Björck et al., 1998). Note the sawtooth shape. During MIS 3, the two Bond cycles, consisting of GI:12-11-10-9 and GI:8-7-6-5, LGM denotes last glacial maximum. Only the last ~4,000 years of the last warm period (Eemian) is shown to the right. The time scale is the GRIP time scale SS09 (after Johnsen et al., 1995).

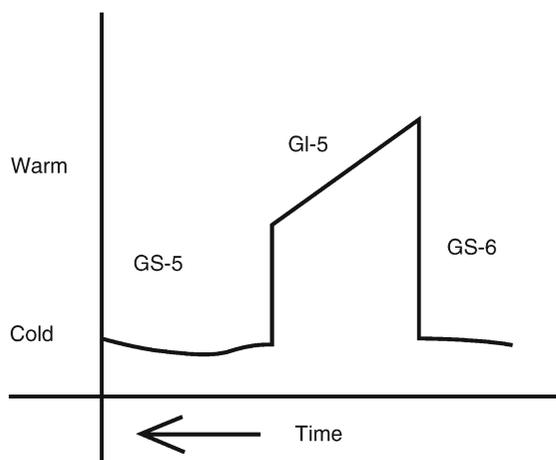

Figure D2 The figure shows schematically the name convention of the INTIMATE group for the Greenland stadials (GS) and Greenland interstadials (GI). It should be clear from the figure that each Dansgaard-Oeschger cycle consists of a GS and a GI. For the whole glacial record see Figure D1.

Europe (Thouveny et al., 1994; Allen and Huntley, 2000). The area influenced by the D-O cycles was once again enlarged to encompass most of the Northern Hemisphere and even across the Equator. Evidence of D-O cycles has been found in paleo-data from different regions of the world, for an up-to-date overview see Voelker et al. (2002) and Figure D3.

Dansgaard-Oeschger cycles in ocean sediment cores

Ocean sediment cores, particularly from the North Atlantic and Nordic seas, have also shown evidence of D-O cycles (Rasmussen et al., 1996; Elliot et al., 1998; Dokken and Jansen, 1999; van Kreveld et al., 2000). In ocean sediment cores, D-O cycles can be identified in many of the different climate proxy records, a few of which will be mentioned below.

Table D1 The transitions from stadials to interstadials and vice versa use the GRIP SS09 time scale; the names for the Dansgaard-Oeschger cycles are based on Björck et al. (1998). The ages correspond to the GIs and GSs shown in Figure D1. Stadial numbers that have a "H" and a number are stadials in which Heinrich events took place, and the number of the Heinrich event. This is not part of the INTIMATE naming convention, but is added for illustrative reasons

Events	GRIP age (years bp)	Duration	Events	GRIP age (years bp)	Duration
Holocene	11,551		GS-1	12,711	1,160
GI-1	14,491	1,780	GS-2 _{H1}	21,391	6,900
GI-2	21,631	240	GS-3 _{H2}	25,271	3,640
GI-3	25,571	300	GS-4	28,111	2,540
GI-4	28,311	300	GS-5 _{H3}	29,451	1,140

GI-22	88,700	2,609	GS-23	96,100	7,400
GI-23	103,946	7,846	GS-24	105,601	1,655
GI-24	106,180				

Layers of ice-rafted debris (IRD) are observed just before D-O events. Hence, it is thought that the warming is preceded by large amounts of icebergs carrying the IRD, which is then deposited in the North Atlantic region. The IRD signal is

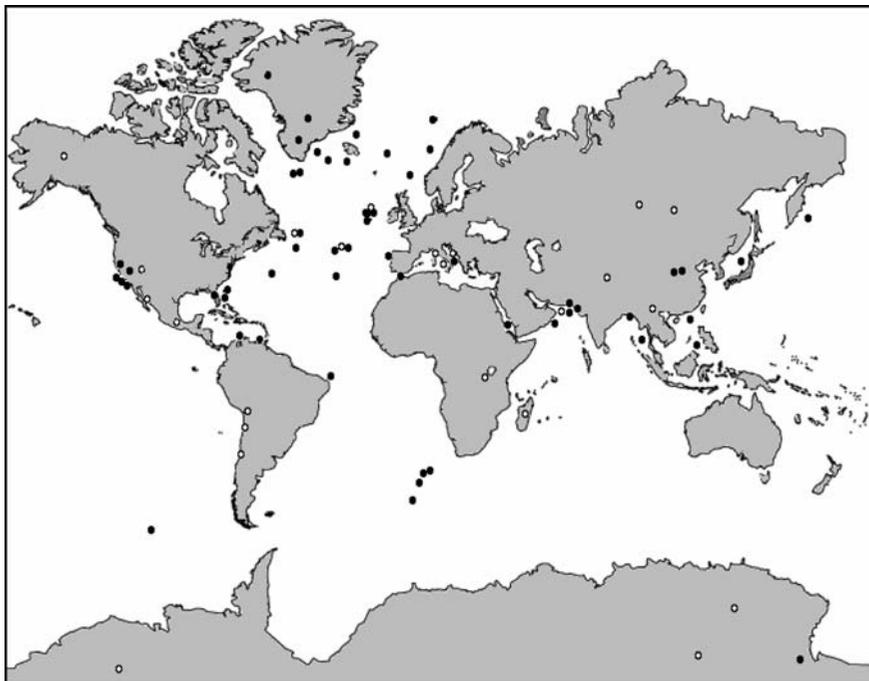

Figure D3 Global spatial distribution of sites where impacts of Dansgaard-Oeschger cycles have been recorded in paleorecords. *Black dots* indicate sites with a clear D-O type oscillation, *open circles* show sites where no or unclear D-O cycles have been found (after Voelker et al., 2002).

mostly of local character; the IRD has been shown to originate from the Fennoscandian (also known as the Scandinavian Ice Sheet), Greenland and Icelandic Ice Sheets. A few of these IRD events are also called Heinrich events; in these cases, the IRD mostly originates from the Laurentide Ice Sheet. Heinrich events are very large outbreaks of IRD/icebergs and only occurred six times during the Wisconsinan glacial (see Table D1). IRD events associated with outbreaks of icebergs are considered to imply a freshwater input into the North Atlantic, with a succeeding cooling of the region. After each cooling, the region warms very rapidly, this is seen for example in the abundance of the planktonic species (near surface) *Neogloboquadrina pachyderma* (sin). *N. pachyderma* is a cold water species and therefore it almost disappears during the warm phases. Another indicator of these climate changes is the $\delta^{18}\text{O}$ record in benthic (bottom) species, where the fluctuations in marine sediments mirror the $\delta^{18}\text{O}$ fluctuations in ice cores. For the benthic $\delta^{18}\text{O}$, low isotopic values indicate stadials (cold phases) and high values indicate interstadials (warm phases). A climate change that can be detected in the fauna at 1,000 meter depth indicates that the climate change must have affected not only the atmosphere, but also the ocean circulation (Rasmussen et al., 1996) and deep water convection in the North Atlantic in particular, which is important for the THC.

The changes in the ocean sediment cores indicate that the THC was weaker during stadials, and became enhanced to almost Holocene strength during interstadials. There are also indications of changes in the geographical occurrence of deep water convection. It can be seen that convection only occurred south of Iceland during the stadials, and both south and north of Iceland (in the Nordic seas) during the interstadials (Ganopolski and Rahmstorf, 2001).

Dansgaard-Oeschger cycles – a global phenomenon?

As mentioned above and shown in Figure D3, evidence of D-O cycles has been found over large parts of the globe. Therefore, it is particularly puzzling why there is no clear signal of D-O cycles in Antarctic ice cores (e.g., compare Figure D4, profiles A and E).

Antarctic ice cores show a different signal in the $\delta^{18}\text{O}$ record, looking completely different to the Greenland $\delta^{18}\text{O}$ record (see Figure D4). In Antarctica, the sawtooth shape is not present at all. The cycles look more like a triangle during the warm phase, with a slow warming, which, after peaking, immediately starts to slowly decline back to its cold period values. Due to uncertainty in the time scales of the Greenland and Antarctic ice cores, it was long discussed which came first – the Greenland or the Antarctic warming, or whether they were synchronous. This controversy was finally resolved when Blunier et al. (1998) measured atmospheric methane in microscopic air bubbles in the ice cores. The methane is well mixed globally within a year, and is therefore an inter-hemispheric marker that can be used to link the records from Greenland and Antarctica, respectively. It was shown that Antarctica was warming while Greenland was in the cold phase, and when the Greenland $\delta^{18}\text{O}$ record jumped into a warm phase of a D-O cycle, Antarctica started to cool. This asynchronous see-saw mechanism between the two hemispheres still lacks a full explanation. However, it is believed to arise from changes in the oceanic heat transport from the Southern Hemisphere to the Northern Hemisphere, which is believed to have differed during the different phases of the D-O cycles.

The trigger of Dansgaard-Oeschger events/cycles

D-O cycles have become a large research field within paleoclimatology. Evidence of D-O cycles in many different

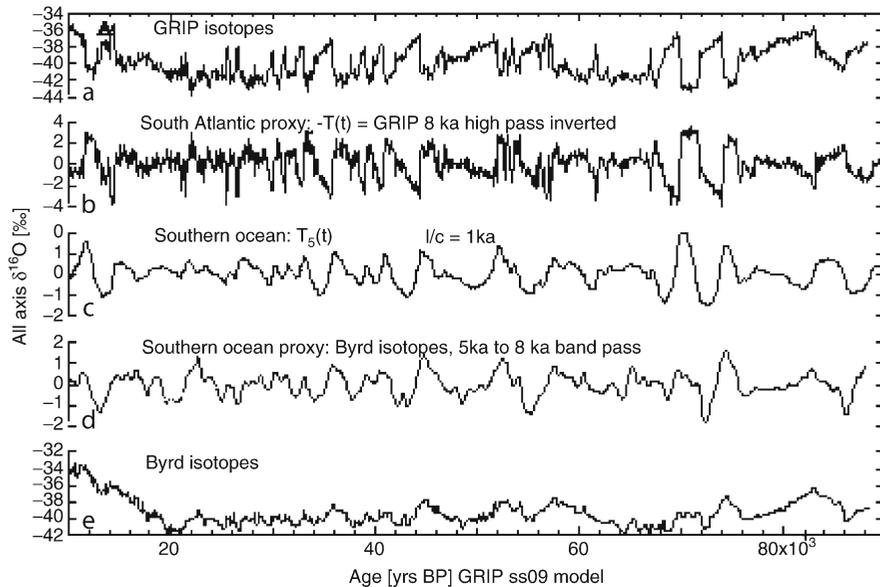

Figure D4 The GRIP isotope profile is shown in (a). (b) shows a 8 ky high pass filtering of *a* after inversion, which is considered the S-Atlantic temperature proxy. Folding *b* with $e^{-t/\tau}$, where $1/\tau = 1,000$ years, results in the profile shown in *c*; this profile depends on the time constant (τ) used. The 0.5 to 8 ky band pass filtering of the Byrd isotope profile (e) is shown in (d). The profiles in *c* and *d* are quite similar in shape and give a very high correlation coefficient of 0.87 for $\tau = 1$ ky in MIS 3 (22 to 58 kyrBP) (after Johnsen and Stocker, 2003).

paleorecords from around the world have made the understanding of these rapid and abrupt climate changes an intriguing challenge.

Retrieval of ocean sediment cores has shed some light on the magnitude of the impact of the D-O cycles. However, looking to the ocean for a possible mechanism for the triggering of D-O events is problematic, as the natural time scale of the THC is much longer than the 20–50 years it takes to switch into a D-O event. Furthermore, the ice sheets react on much longer time scales, and there is no astronomical forcing with a period of $\sim 1,500$ years. Sea ice has been mentioned as a possible trigger mechanism that would influence the deep water convection, and hence the THC. Another possibility that has been proposed is surging glaciers from the surrounding ice sheets, but simultaneously surging glaciers also lack an explanation or a trigger. Therefore, the triggering mechanism is still being debated.

Data analysis (Alley et al., 2001) and model studies (Ganopolski and Rahmstorf, 2002) have shown that a possible trigger of the D-O events could be stochastic resonance in the climate system under glacial conditions. A stochastic resonance implies that small changes, i.e., in the freshwater flux into the northern North Atlantic, could cause large rapid changes of the ocean circulation during the glacial period and hence large climate changes such as the D-O cycles (Ganopolski and Rahmstorf, 2002).

DATING, AMINO ACID GEOCHRONOLOGY

Dating Earth history using the racemization of amino acids preserved in biominerals belongs to the chemical family of dating methods. Chemical methods differ from radioactive dating techniques in that their reaction rates depend on one or more environmental parameters, whereas radioactive decay remains constant regardless of most environmental conditions. Amino acids, derived from indigenous protein residues protected by the skeletal hardparts of organisms, survive in most environments for thousands to millions of years. The extent of racemization (defined below) of these amino acids is dependent primarily on the time elapsed since death of the organism and the integrated thermal history experienced by the biominerals, and to a lesser extent on vital effects unique to each taxon.

Amino acids are simple organic molecules that are the fundamental building blocks of proteins. They are exceptionally stable, with lifetimes for most of the more stable forms exceeding a million years at ambient temperatures. Although there are a large number of possible amino acids, only about 20 are common constituents of proteins. Amino acid geochronology (often

referred to as simply Amino Acid Racemization, or AAR) relies on the chiral nature of most amino acids. Chiral (derived from the Greek word for “hand”) molecules are asymmetric, or exhibit “handedness.” Chiral molecules are not superimposable on their mirror image. All but the simplest protein amino acid can exist in either a “left-” or “right-” handed configuration (enantiomers). The designation of the handedness for chemical compounds is determined by the direction they rotate plane-polarized light when in solution. Molecules that rotate polarized light are said to be optically active, whereas an equilibrium mixture of left- and right-handed amino acids (a racemic mixture) is “achiral,” or optically inactive, and will not rotate polarized light. The interaction of chiral molecules with other chiral molecules can be different to interactions with achiral molecules. A simple analog for a chiral compound is a glove, where the left and right hand gloves are mirror images of each other but they are not superimposable, whereas a ski pole is achiral. Bare hands (also chiral) inserted into a box containing only right-hand gloves, will only emerge with a gloved right hand, never with a gloved left hand, whereas bare hands inserted into a box of ski poles would always emerge with a ski pole, regardless of which hand was inserted. These principles are exploited by analytical procedures to separate chiral forms of amino acids.

It is a quirk of nature that the proteins of almost all living organisms utilize exclusively amino acids of the “left hand” configuration. Left-handed forms are given the abbreviation “L,” for levorotatory (they rotate polarized light in the left-hand direction), whereas right-hand forms are dextrorotatory, or D-amino acids. All amino acids have a three-letter abbreviation. Thus the common amino acid alanine, is abbreviated Ala, and its left- and right-handed forms are then D-Ala and L-Ala, respectively. The extent of amino acid racemization is expressed as the proportion of D- relative to L-amino acids, or D/L.

Amino acid geochronology capitalizes on the original uniquely left-handed character of amino acids preserved in skeletal hard parts or biominerals. Once the biological constraints that created optically active assemblages of amino acids are removed, usually at death of the organism, amino acids begin to spontaneously invert to their right-handed, or D-configuration. The process by which amino acids of one configuration convert into their opposite handedness is known as racemization. The rate at which this inversion occurs is strongly dependent on ambient temperature and, to a lesser extent, vital effects and environmental pH. At room temperature (22 °C), conversion from an optically pure amino acid (protein from a living organism has a D/L = 0) to a racemic mixture lacking optical activity (D/L = 1.0 for most amino acids) requires several thousands to several tens of thousands of years for most amino acids. The racemization reaction rate is exponentially related to temperature; at 160 °C, a racemic mixture is reached in 10–20 h, whereas in Arctic regions (–10 °C) equilibrium requires 1–2 million years. As a rule of thumb, at normal ambient temperatures (0–25 °C), the rate of racemization doubles for every 4 °C increase in temperature. [Figure D5](#) illustrates the useful time range for AAR dating under different mean annual temperatures for isoleucine; aspartic acid racemizes about an order of magnitude faster and is widely used for very young materials, or extremely cold sites (e.g., Goodfriend, 1992; Goodfriend et al., 1996; [Figure D6](#)). The effect of temperature on reaction rate is readily apparent in a plot of racemization levels for last interglacial “moderate” racemization-rate mollusks from the European Arctic to the Mediterranean ([Figure D7](#)).

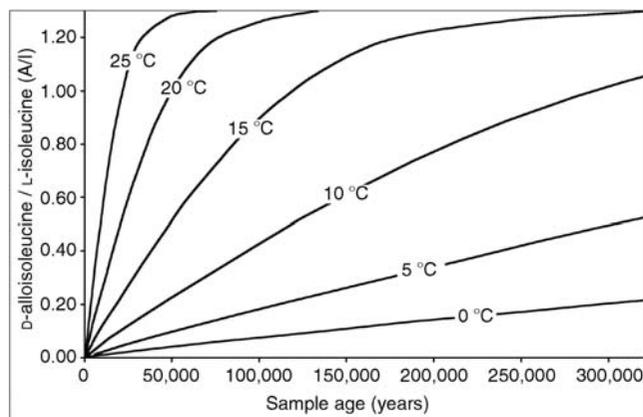

Figure D5 Relation between the extent of isoleucine epimerization (A/I) and sample age for effective diagenetic temperatures between 0 and +25 °C showing the strong dependence of epimerization rate on temperature. Lines derived from kinetics in eggshells of the Australian emu (*Dromaius*) shown in Miller et al. (2000).

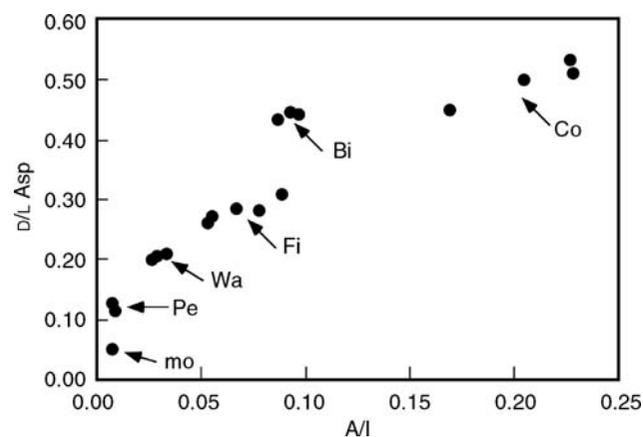

Figure D6 Fast-racemizing amino acids provide superior resolution for cold or very young samples. In this figure, D/L aspartic acid and D-alloisoleucine/L-isoleucine (A/I) were measured in the marine bivalve *Hiatella arctica*, collected from raised marine terraces along the north coast of Alaska (mean annual temperature ca. -12 °C). For the younger shorelines, D/L Asp provides a clearer separation of the sites, but this difference decreases for the older shorelines. (mo = modern; Pe = Pelukian shoreline (last interglacial); Wa = Wainwrightian shoreline; Fi = Fishcreekian shoreline; Bi = Bigbendian shoreline; Co = Colvillian shoreline (probably late Pliocene)). Modified from Goodfriend et al. (1996).

Racemization of amino acids in fossils

Fifty years ago, Abelson (1954) first showed that amino acids could be preserved in biominerals for hundreds of millions of years, and in a series of papers a few years later with P.E. Hare, outlined the potential of amino acid racemization as a geological dating method (Hare and Abelson, 1968). They showed that mollusks of known age exhibited increasing levels of racemization with increasing age, and the dating method of Amino Acid Geochronology was launched. Recent summaries of the methods are given by Miller and Brigham-Grette (1989), Wehmiller (1993), Wehmiller and Miller (2000).

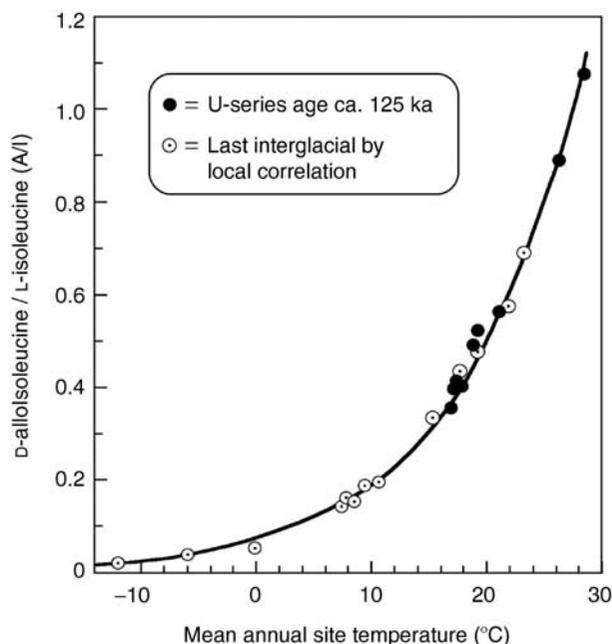

Figure D7 D-alloisoleucine/L-isoleucine (A/I) in moderate-racemization-rate mollusks from last interglacial (ca. 125 ka) sites across western Europe, ranging from Svalbard and Arctic Russia to the Mediterranean Basin, plotted against current mean annual site temperature. Last interglacial sites are dated by U/Th on corals or correlated to the last interglacial on the basis of diagnostic marine faunal elements. The data document the exponential dependency of racemization rate on site temperature. Unpublished data from G.H. Miller and P.J. Hearty.

Not all amino acids are suitable for geochronology. Glycine, the simplest and one of the most common amino acids, is not a chiral molecule. Other simple amino acids, such as alanine, are created in fossils by the decomposition of other more complex amino acids. Thermodynamically unstable amino acids, like serine and threonine, have half-lives too short for most geological applications. The most widely used slow-racemizing amino acids are isoleucine, leucine, valine and glutamic acid, whereas aspartic acid racemizes much more rapidly (Figure D6). All of these amino acids except isoleucine have a single chiral carbon atom, and can exist in either their D- or L-forms, which have identical physical and chemical properties except in their interaction with other chiral substances. Isoleucine, in contrast, has two chiral carbon atoms and can racemize about either carbon, or both. In nature, isoleucine racemizes almost exclusively about the alpha carbon, producing a new molecule, D-alloisoleucine, which has different chemical and physical characteristics, making it easier to separate in the laboratory. This reaction is known as epimerization, and the extent of isoleucine epimerization is abbreviated A/I or alle/Ile.

The separation, detection and quantification of the D- and L-amino acids are accomplished by either gas or liquid chromatography. L-isoleucine can be separated from its D-alloisoleucine pair by conventional ion-exchange high-pressure liquid chromatography (HPLC), whereas most other amino acids are separated by gas chromatography (GC) or reverse-phase liquid chromatography (RPLC) using a chiral stationary or mobile phase to separate the enantiomers.

Prerequisites of racemization dating

To utilize amino acid racemization as a dating tool requires a medium that not only preserves indigenous protein amino acids from bacterial attack, but that also excludes contamination by other amino acids. The more tightly the amino acids are integrated into the biominerals, the closer the medium will be to a closed system. The most common media that meet this prerequisite are carbonate biominerals, including the carbonate exoskeletons of bivalve and gastropod mollusks, foraminifera, and ostracods, bird eggshells and fish otoliths. Extensive studies on bone and wood have produced mixed results, largely due to the relatively porous nature of these media. Carbonate minerals also have the advantage that they provide a buffered system (pH = 8), eliminating pH as an environmental variable. Carbonate media in ideal preservation settings have been shown to preserve indigenous amino acids from mollusks more than 100 million years old.

Protein residues that occupy intracrystalline positions are less susceptible to diffusional loss than those that occur between mineral crystals. For example, almost all of the amino acids in bird eggshell are intracrystalline, and fossils show virtually no loss of amino acids over hundreds of thousands of years, whereas most of the amino acids in bivalve mollusks are situated between mineral layers, and exhibit slow diffusional loss over tens of thousands of years (Miller et al., 2000). A small amount of mollusk protein occupies intracrystalline positions, and targeting these residues may avoid uncertainties related to the slow diffusional loss of bulk analyses (Collins and Riles, 2000).

Each species that secretes a skeletal hard part containing amino acids incorporates different suites of proteins, so that the relative proportion of each amino acid in protein differs between taxa. A consequence of this variability is that the rates of racemization exhibit subtle but frequently significant differences between taxa (Figure D8); this vital effect is almost always significant at the genus level, occasionally at the species level. Racemization rates for isoleucine in different mollusk genera may be twice as fast for “fast” racemizers as for “slow” racemizers. Furthermore, some broad groups of mollusks, such

as the cockles, are less suitable for racemization studies. For these reasons, each species used must be rigorously evaluated. The activation energy for racemization appears to exhibit little variation across all carbonate biominerals, with most reported activation energies falling within $29 \pm 1 \text{ kcal mol}^{-1}$. But the entropy factor shows strong variability so that some amino acids racemize as much as 10 times more rapidly than others (Figure D6).

Once a suitable medium has been evaluated, certain site-selection criteria must be met. Because of the exponential sensitivity of reaction rate to temperature, near-surface samples that experience high seasonal temperature fluctuations will racemize more rapidly than deeply buried samples with the same arithmetic mean temperature but without seasonal fluctuations. Samples must have been buried deeply enough to avoid seasonal temperature oscillations with amplitudes more than 6°C . In most settings, this translates to a burial depth of at least 1 and preferably 2 meters. A short time in a near-surface setting has negligible influence,

Aminostratigraphy

Amino acid racemization can be applied as a geological dating tool in both a relative and absolute sense. As a relative dating tool, the technique is known as Aminostratigraphy. The premise is that over a limited geographic range and elevation, all sites can be expected to have experienced a similar thermal history ($\pm 1^\circ\text{C}$). Over this limited region, samples with similar D/L ratios are of the same age, those sites with higher D/L ratios are older, and those with lower ratios are younger. Samples with similar D/L ratios are typically grouped into aminozones (Figure D9). Aminostratigraphy does not require an assessment of racemization kinetics or estimates of past thermal histories. It is the least ambiguous application of Amino Acid Geochronology.

Aminostratigraphy has been commonly applied to mollusks excavated from raised marine terraces in coastal regions throughout the world. One example is a series of uplifted interglacial terraces along the Peruvian coast from which bivalve mollusks exhibit a regular increase in D/L leucine in higher (older) terraces, with corresponding absolute ages derived from electron-spin resonance (ESR) dating (Figure D9).

Absolute age and paleothermometry

Once the kinetics of racemization in a particular biomineral have been derived, the equation describing racemization contains only three unknowns: D/L (the extent of the reaction, which can be measured in the laboratory); t, the time since death; and T, the integrated thermal history. Theoretically, if either t or T is known, the other can be predicted. In an evaluation of uncertainties, McCoy (1987) showed that predicting paleotemperatures is inherently more precise than predicting ages. Unlike most biological proxies that record the temperature at which an organism lived, racemization-derived paleotemperatures reflect the integrated thermal history since the organism died. In the case of deeply buried samples, this equates to the mean annual temperature. If samples with independently derived ages are available from a limited region, then the evolution of temperature across the region can be calculated.

Comparing the extent of racemization in a series of radiocarbon-dated samples provides a powerful tool to derive quantitative estimates of the glacial-age temperature depression during the last glacial maximum. The glacial/Holocene temperature change in semi-arid Australia was quantified from A/I in emu

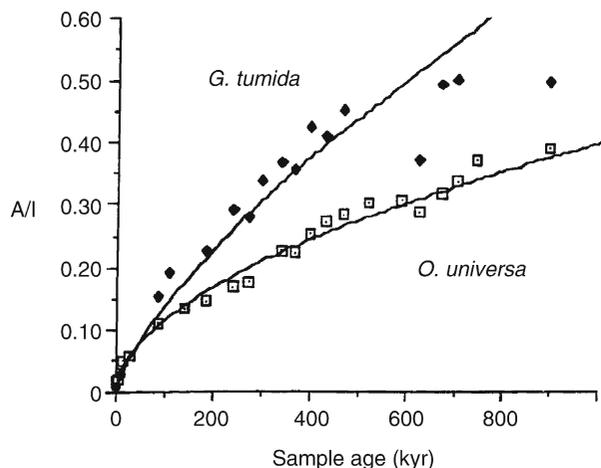

Figure D8 Comparison of the extent of isoleucine epimerization against sample age for two foraminifera taxa from deep-sea sediment cores. Both the vital effect (*Globobulimina tumida* epimerizes almost twice as fast as *Orbulina universa*), and non-linear kinetics are apparent. Modified from Müller (1984).

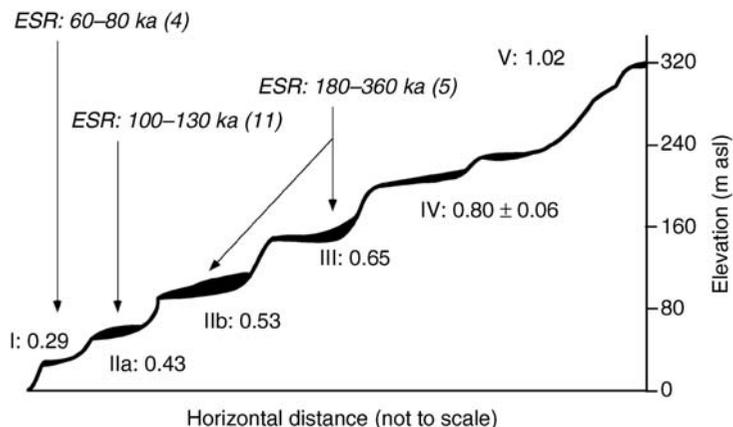

Figure D9 Schematic cross-section through a flight of raised marine terraces on the coast of Peru with aminozones (in roman numerals) defined by the extent of leucine racemization. ESR dates provide additional chronological control. The highest terraces are of early Quaternary age. Modified from Wehmiller (1993).

eggshells, each of which had also been dated by ^{14}C . The dataset spanned the last 40,000 years. Not all samples were deeply buried, hence some samples exhibited more advanced levels of racemization than expected. However, the change in slope between samples younger than about 16,000 years ago and those older than 16,000 years was unambiguous, and reflected at least 7°C warming from the cold last glacial maximum to the warmth of the present interglacial (Miller et al., 1997).

In theory, deriving absolute ages from the extent of amino acid racemization requires only a reasonable estimate ($\pm 1^\circ\text{C}$) of the average diagenetic temperature. For samples of Holocene age, this can be reasonably estimated from the instrumental record, but secure estimates for the time-dependent changes in mean annual temperatures across glacial/interglacial cycles are rarely possible. Age estimates are further complicated by kinetic uncertainties for many biominerals. An inherent assumption is that racemization follows simple, reversible first-order kinetics. While this assumption is met during the early stages of racemization, most mollusk and foraminifera shells deviate from predicted kinetics in the later stages of diagenesis (e.g., Figure D8). This has led several researchers to utilize an empirically derived parabolic kinetic model (Figure D10) that more closely approximates the observed change in D/L with time (Kaufman, 2000, 2003) instead. A common approach to absolute dating is to calibrate the reaction rate on a sample for which the age is independently determined, and then use the same rate constant for other samples in the same region. For Quaternary samples, a reasonable assumption is that a last interglacial calibration has an integrated thermal history that is a reasonable estimate for most of the Quaternary, and the calibrated rate constant can then be used to date other samples in the region to at least 1 Myr.

Conclusions

Amino Acid Geochronology offers a simple, but powerful relative dating tool (Aminostratigraphy) that provides temporal constraints beyond the range of radiocarbon dating. In all but the hottest regions, this includes all or most of the middle and late Quaternary. When independent dates are available, the extent of racemization can be used to reconstruct past thermal histories with a precision of $\pm 1^\circ\text{C}$. Moreover, with suitable

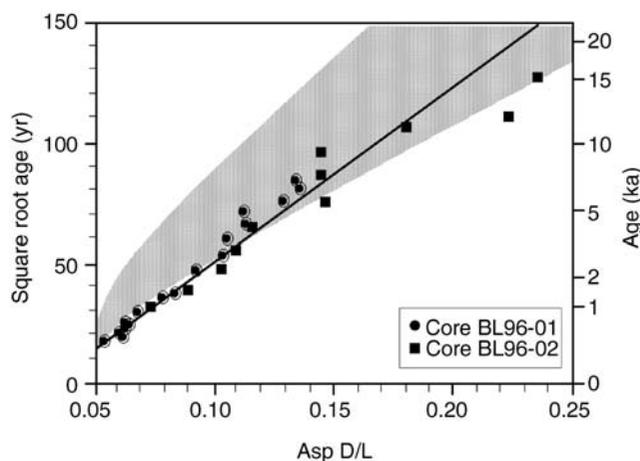

Figure D10 Plot of aspartic acid racemization (D/L Asp) against the square root of time for the ostracod genus *Candona* in two independently dated sediment cores from Bear Lake, Utah/Idaho, showing an essentially parabolic relation between D/L and time. Gray area shows the expected racemization ($\pm 1\sigma$) based on equations in Kaufman (2000), with temperature set to 4°C . Modified from Kaufman (2003).

calibration, racemization levels can be converted to reliable absolute ages. Although the measured extent of racemization depends heavily on temperature, the racemization reaction does not involve the loss of reactants. For the most stable amino acids, the concentration of the summed D - and L -forms at racemic equilibrium is about the same as the concentration of the original L -amino acid, providing there has been no diffusional loss from the biomineral matrix. Consequently, the precision of the method is almost as good at the end of the time range as at the beginning, unlike radiocarbon, where the loss of the primary isotope, ^{14}C , means that dates close to the limit of the method are susceptible to large analytical errors and trace levels of contamination.

DATING, BIOSTRATIGRAPHIC METHODS

Historic overview

Biostratigraphers study the distribution of fossils in sedimentary strata. They have two motives – reconstructing the history of life and developing a relative time scale for other geologic studies. More than two hundred years ago, before formulation of the theory of evolution, it became apparent that the same general succession of faunas could be recognized in different rocks at widely

separated locations. Trilobites appeared before ammonites, for example, and dinosaurs became abundant before mammals. Such observations led to the major divisions of the Phanerozoic time scale – the Paleozoic, Mesozoic, and Cenozoic eras – and to attempts to resolve much finer subdivisions using fossil species. These subdivisions enable time correlation – the identification of strata in different places that were deposited during the same time interval. The resolving power of correlation improved significantly when petroleum companies began to apply sequences of microfossil species to the task. The Deep Sea Drilling Project standardized high-resolution subdivisions based on microfossils extracted from cores of the ocean floors.

The basic practices of biostratigraphic correlation adapted to the availability of radioisotopic dates and personal computers. Initially biostratigraphy sought to divide the geologic time scale into biozones based on index species. Radioisotopic dates changed the focus to the age-calibration of species appearances and disappearances, which could then be used as biohorizons for indirect dating. Personal computers made determination of the likely sequence of large numbers of uncalibrated biohorizons practical.

The fundamental challenge in the use of biostratigraphy as a means of dating is the discrepancy between biostratigraphic horizons and time horizons (Figure D11). To step from biostratigraphic description to time correlation, it is necessary to compensate for the ecological and stochastic factors that inevitably cause the time of appearance and disappearance of fossil species to vary from place to place. In spite of some contention about the best way to handle this problem, it is evident that, in practice, there has been no more cost effective, more generally successful, or more readily available means than fossils to correlate rock strata (Ludvigsen et al., 1986).

Terms and basic data

A biozone is a body of rock characterized by the fossils it contains (Salvador, 1994). The bounding surfaces of such a unit are almost certainly diachronous; that is, the ages of the highest and lowest finds of the definitive species usually vary from place to place. The reasons are simple and unavoidable: new species evolve at unique places and times; their ranges expand to wider but patchier distributions that change over time; the geographic range dwindles more or less rapidly as the species is replaced by others; and incomplete preservation leaves a fossil record of the species that is patchier still. Furthermore, even

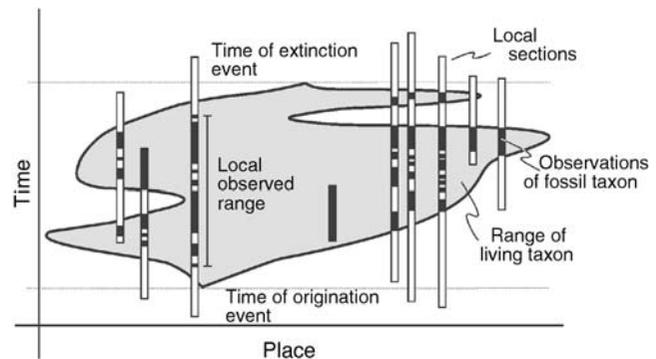

Figure D11 Range of a taxon in life (gray), the observed range of the fossil taxon (black) in stratigraphic sections (rectangles), and the time lines defined by the origination and extinction of the taxon.

deep marine sequences of sedimentary strata do not accumulate continuously (Aubry, 1995); they include gaps at all scales and some observed ranges end artificially at such gaps.

Portions of the bounding surface of a biozone are biohorizons – stratigraphic surfaces characterized by a faunal change, such as the lowest or highest local observations of a fossil taxon. The observed biozone is smaller than the range of the living species because of the vagaries of fossil preservation and collection. The corresponding time interval (chronozone) extends beyond the living range to encompass all the rocks deposited during the life span of the species, whether or not they contain the fossil. In spite of their essentially diachronous nature, biozones and biohorizons are routinely used to estimate the position of datum surfaces that correspond everywhere to the time of origination or extinction of a taxon.

The raw data of biostratigraphy are faunal lists – inventories of fossil taxa that coexist in the same stratum. Ideally, numerous faunas can be placed in sequence at individual stratigraphic sections, permitting local range charts to be constructed that show the span of strata from the lowest to the highest find of each taxon (Figure D12). The range ends, highest and lowest local finds of a taxon, are local estimates of the first and last appearance datums (FADs and LADs). The diachronous nature of biohorizons becomes evident when lines connecting the horizons of numerous highest and lowest finds are drawn between stratigraphic sections to form a fence diagram (Figure D13). Typically many of the correlation lines cross one another and it is clearly not possible to consider them all time-lines.

Biozones

Although many types of biozone have been proposed (Salvador, 1994), they result from only two significantly different practices. The choice is often dictated by the nature of the available data – faunal lists or range charts. One practice characterizes zones by their content, typically the co-occurrence of two or more taxa. Sequences of such “assemblage” zones (Figure D12) can be extracted from analysis of faunal lists alone (Guex, 1991; Alroy, 1994), but precise placement of the zone boundaries can be elusive. The other practice is more conducive to very fine subdivision (Murphy, 1994); it defines the limits of “interval” zones to coincide with highest- or lowest-find biohorizons. This practice requires good range charts. It seeks to avoid the inherent diachronism in biohorizons by selecting from all possible horizons only a subset that is always observed in the same sequence (Scott, 1985). Contradictory sequences of observed range ends can be observed only for taxa whose true ranges overlap in time. Consequently, the quest for robust sequences of range ends succeeds most readily if the range end events are widely spaced.

Resolving power is retained by selecting, as “index fossils,” short-lived species from rapidly evolving lineages. Ideally, these species are also abundant, distinctive, and widespread. Most are pelagic or wind-borne; e.g., conodonts (Ordovician-Triassic), graptolites (Ordovician-Silurian), ammonoids (Devonian-Cretaceous), foraminifera (Cambrian-Recent), calcareous nannofossils (Jurassic-Recent), diatoms (Cretaceous-Recent), radiolaria (Cambrian-Recent), spores (Silurian-Recent) and pollen (Pennsylvanian-Recent).

(b) Range ends culled to those found in the same sequence in all 7 sections. (c) Adjustment of all range ends to the sequence that best fits all local observations.

FADs and LADs (biohorizons)

Rather than using a few biohorizons to define zones, modern biostratigraphy seeks to retain as many biohorizons as possible and determine the sequence of the corresponding datums. An essential difference is that this approach must evaluate and adjust the local biohorizons (Figure D13c). The elimination of cross-cutting biohorizons (Figure D13a, b) removes the most obvious appearance of diachronism but does not guarantee that the remaining correlation lines are isochronous. Three means of correction for diachronism are noteworthy. The first uses the gaps within the preserved ranges to add confidence intervals to the observed range ends (Marshall, 1990); it corrects only the stochastic component of the difference between biostratigraphy and time. The second method uses radioisotopic dates and calibrated paleomagnetic reversals to determine the age of range ends at different locations. It is best developed for Neogene FADs and LADs in cores from the ocean floor. The third strategy uses the observed sequences and/or coexistences in many locations and the principle of parsimony: it searches for a composite sequence of events to which all the local range charts can be fit with the minimum of adjustment. Assuming that most observed ranges are shorter than the true range, observed ranges are extended as necessary to fit them to a single global sequence. Initially, the method was implemented graphically as a form of regression (Shaw, 1964). Now, computer algorithms search for the best-fit sequence (Sadler, 2004). If available, horizons of known age, such as dated ash falls and calibrated paleomagnetic reversals, may be included to constrain the search for the best sequence.

Sometimes, especially over short distances, it is possible to exploit ecologic factors to achieve finer correlation. Short-lived changes in global temperature or the pattern of winds and ocean currents may become correlatable events when they cause changes in the relative abundances of pollen or foraminiferan taxa, for example. Distinctive fluctuations in stratigraphic trends of the relative abundances of taxa may then indicate correlative strata in different locations.

Resolving power

In favorable situations, zonation based upon pelagic marine organisms can resolve intervals that are on average less than one million years in duration. Usually such sets of zones are based upon a single biological clade. Conventional ammonite zones and subzones in the Mesozoic resolve 0.4–0.75 million year intervals, on average. Mesozoic zones based on foraminifera and calcareous nannofossils resolve 2–3 million years. Cenozoic zones and subzones for the same microfossils have average durations of 0.75–1.0 million years. Often, it is necessary to establish separate sets of zones for different climate belts. For Cenozoic radiolarians there are 32 low latitude zones and 11 mid latitude zones, for example. Ordovician conodonts support “North Atlantic” and “Mid continent” zones with resolving power of the order of 2–4 million years. For the Ordovician and Silurian, finer resolution (1–3 million years) is afforded by the more cosmopolitan graptolite zones.

Biohorizons offer the promise of better resolving power. For the Ordovician and Silurian, over 3,000 graptolite appearance and extinction events have been sequenced. For the Cenozoic there are of the order of 100 calibrated biohorizons each for foraminifera and calcareous nannofossils. Average resolving power of the order of 0.25 million years or better would appear to be possible by using biohorizons from more than one fossil

clade. Whether this is attempted by recourse to radioisotopic calibration or computer optimization of observed sequences, however, there are always clusters of range-end biohorizons whose relative age remains irresolvable. Nevertheless, the resolvable events and clusters of events are often sufficient to increase the resolving power 5- to 10-fold over traditional biozones (Harries, 2003). It appears that biostratigraphically based timescales might soon resolve intervals as short as 500,000 years, and even less, through most of the Phanerozoic. This approaches the size of analytical errors quoted for radioisotopic dates on Paleozoic ash falls. It is likely shorter than the time taken by many taxa to spread from their point of origin to their full geographic extent – an inevitable source of discrepancy between biohorizons and time lines. These figures concern the resolving power of timescales for global correlation. As the distance of correlation is reduced, more biohorizons and strata approximate time lines and potential resolution improves (Harries, 2003). The actual resolving power of any given correlation will be limited by the fossil content of the strata.

DATING, DENDROCHRONOLOGY

Introduction

Dendrochronology is the science that deals with the absolute dating and study of annual growth layers in woody plants such as trees. The name derives from the Greek root words *dendron* for tree and *chronos* for time. The notion that variability in ring widths in trees relates to variability in climate dates back at least as far as Leonardo da Vinci, whose writing translates thus: *The rings from cut stems or branches of trees show their*

number of years, as well as those years that are more moist or dry, according to the size of their rings.

In addition to Leonardo, others also noted that ring width and climate were linked, and that patterns in trees could be matched across space and time. However, it was never pursued to the extent that chronologies were built and reconstructions of climate into the past were attempted. The development of dendrochronology as a scientific field came later, in the early twentieth century, under the guidance of Andrew Ellicott Douglass.

Douglass was an astronomer residing at the Lowell Observatory in Flagstaff Arizona (Webb, 1983). In 1904, he found that a distinct pattern of narrow and wide growth rings in conifer log sections, cut from the Flagstaff area, could be matched with trees from as far away as Prescott, some 150 kilometers distant. This led him to recognize the nature of a general control on tree-growth that was variable on an annual time scale and was most likely related to climate. Later, in 1911, Douglass recognized the real significance of his observation, and determined that the influence of climate was the major contributor to the common variability evident in the annual radial growth of trees. He recognized that, in the arid American Southwest, precipitation was the factor most limiting to tree growth. Therefore, tree growth could in turn be used as a proxy for rainfall before the time of the instrumental record.

Douglass had developed and utilized the principle of *cross-dating*, or pattern matching, as the basis for the science of dendrochronology. He realized that the simple counting of growth rings could result in errors of years or even decades over a span of hundreds of years of record. Douglass' procedure involved the rigorous detection of "locally absent" and "false" rings through sample replication and reproducibility of specific patterns. This procedure, facilitated by graphical *skeleton plotting* (Stokes and Smiley, 1968), allowed Douglass to accurately assign calendar dates to rings even when growth was highly stressed, as in the case of arid site conifers (Douglass, 1919). Through the development of *master chronologies* he was able to use this powerful new tool to compare and match growth patterns across a very broad region, allowing for the exact dating of annual rings from both living and dead trees. It was not long before this process led to the dating of aboriginal ruins from across the desert Southwest (Haury, 1962), making dendrochronology one of the most significant tools in the field of archaeology.

Dendrochronology makes use of distinct annual growth ring patterns as markers in time. Wood volume (ring width) and density are the two most common features used for the cross-dating procedure. By matching the patterns of growth from living trees of known age with similar patterns in the wood from progressively older trees, one can extend the time scale backward into the distant past. These distinct patterns can then be used for the accurate dating of events that somehow affected the growth or life of individual trees (Fritts, 1976). Any event that kills one or more trees, or otherwise leaves an impact at a particular year, can be fixed accurately in time through dendrochronology and crossdating. Examples of this can be seen throughout the literature, from the dating of buildings and other wooden artifacts (Haury, 1962; Baillie, 1982), to the determination of precise years of earthquake movements (Jacoby et al., 1989; Sheppard and Jacoby, 1989), and to the detection of epic droughts that caused mass mortality in the early North American settlements (Stahle et al., 1998). The application of dendrochronology can be used as an

important tool in many different fields, including ecology, archaeology, geomorphology, hydrology, and biogeography, to name a few. However, in no field has dendrochronology played a more significant role than in the field of climatology (see *Dendroclimatology*).

Dendrochronology is possible because climate influences tree growth across space and time to such an extent that there will be common variability expressed in the pattern of annual radial growth across broad regions (Douglass, 1919; Fritts, 1976; Hughes et al., 1982; Cook and Kairiukstis, 1990). The extent to which climate exerts its uniform influence determines how strong the agreement between trees will be. For that reason, the tree ring chronologies with the greatest fidelity are from regions where climate is at its most limiting to growth, and most regionally coherent. Extremes of temperature and moisture availability produce the greatest variability in annual radial growth, and are therefore the areas where crossdating is most readily achieved. Trees growing in regions with little climate variability and optimum conditions for growth are less likely to produce the high variability in growth pattern that allows for accurate crossdating. This simple tenet has become known as the *Principle of Limiting Factors* (Fritts, 1976), and along with crossdating forms the nucleus for the field.

The annual growth ring

The annual growth layer or "tree ring" is central to the science of dendrochronology. It can be described as a growth band in the xylem of a tree or shrub with anatomically definable boundaries, and is formed during a single annual period of cambial activity (Kozłowski, 1971; Fritts, 1976; Esau, 1977; Salisbury and Ross, 1992). Growth rings are actually sheaths of cells generated in the vascular cambium, between the prior year's growth and the bark, and they appear as concentric rings in a cross section of the stem. The annual growth cycle is described using the simplest case scenario of a temperate zone conifer. In the spring when moisture is plentiful, energy is devoted to the production of new growth cells. These first new growth cells are large, but as the summer progresses, cell size decreases until the short days and cool temperatures of autumn arrive and growth stops altogether. This process is called "hardening off," where the cell walls thicken in preparation for the freezing temperatures of winter. New growth begins anew the following spring with the arrival of longer days and warming temperatures. The contrast between the smaller, thicker-walled old cells of the end of the growth season (*latewood*) and the following year's larger, thinner-walled new cells (*earlywood*) forms the visible ring boundary typical of conifers (Figure D14). Initiation of cambial activity in the spring appears to be related to the resumption of bud growth, while its termination is likely correlated with the cessation of shoot extension (Digby and Wareing, 1966). While initial cambial activity has been linked to the downward movement of growth substances from the expanding buds, continued cambial growth is driven by a local source of auxin that is probably supplied by the differentiating xylem (Samish, 1954; Sheldrake, 1971).

During cambial activity, the newly formed cells differentiate into phloem and xylem. The phloem forms on the bark side of the cambium and serves as a conduit for transporting photosynthate downward from the leaves, while the xylem grows on the inner side of the cambium and transports water and nutrients upward (Nobel, 1974; Shigo, 1984). In some sense, each new ring can be viewed as a whole new functioning tree that completely envelops and replaces the previous year's

growth flush (Shigo, 1984). While there is some interaction between the latest, active growth rings and their predecessors, growth rings become effectively non-functional with time (Esau, 1977; Shigo, 1984).

Though conifers comprise the most widely used trees for dendrochronology, they are not the only trees used for chronology building. Many of the angiosperms, both deciduous and evergreen, have been successfully used. However, the growth rings in many of these species are often far less visible, and entirely different criteria must be used (Figure D15). Multiple, annual growth bands may occur under certain conditions but there are few documented cases of consistent, systematic multiple-banding in trees. Many tropical regions have few species that exhibit clearly defined annual banding that can be detected by conventional dendroclimatic methods, and it is this

fact that has hampered such studies in the tropical regions (Jacoby, 1989; Buckley et al., 1995; Worbes, 1995). Without being able to absolutely identify annual banding in a given species it is not possible to pursue dendrochronological studies.

Factors affecting tree growth

When annual growth rings are formed in trees, it is likely that those layers reflect the environmental conditions under which they were formed (Douglass, 1914; Fritts, 1966). Annual variability in ring width (or some other characteristic such as density or isotopic composition), when synchronous in many trees within a region, indicates a common set of external factors that are influencing tree growth within that region. Such external forcing factors, particularly where they are spatially-extensive, are most likely related to climate, as no other external factors are likely to act over a similar range in the space, time and frequency domains (Fritts, 1976; Hughes et al., 1982). It is therefore possible to extract the climatic “signal” from the annual record of tree growth in such instances, and it is this objective that forms the underlying basis for dendroclimatology research (see *Dendroclimatology*).

Tree growth, in an absolute sense, is an integration of all aspects of the operational environment. Climate is arguably the most important factor controlling overall growth. However, annual radial growth is also strongly influenced by stand dynamics effects that are related to the competition for light, water, and nutrients. Other factors that influence growth include the type, texture and mineral content of soils; the drainage, latitude, elevation, slope and aspect of the site; and the amount of solar radiation, available moisture and average temperature during the growing season, and perhaps previous seasons (Fritts, 1976). Natural disturbances, such as earthquakes and landslides, snow avalanches, fire, volcanic eruptions and ash fall, and herbivorous insect attack, can all influence tree growth for one or more seasons. Anthropogenic factors that can affect growth include groundwater pollution, fire, cutting, gouging and harvesting of shoots and leaves. Nearby disturbances that affect drainage or the availability of light may also play a significant role in ring width variability.

In addition to the effects of such external factors, there are several internal factors that can influence growth. These include the availability of nutrients, minerals, growth regulators, enzymes and water (Nobel, 1974; Fritts, 1976; Salisbury and Ross, 1992). Such internal factors are, however, influenced by external forcing from temperature and moisture availability, and typically play no role in the annual variability of growth. The genetics of a given species may be important in regulating these internal factors in a general sense. However, external variables (particularly those related to climate) may be more

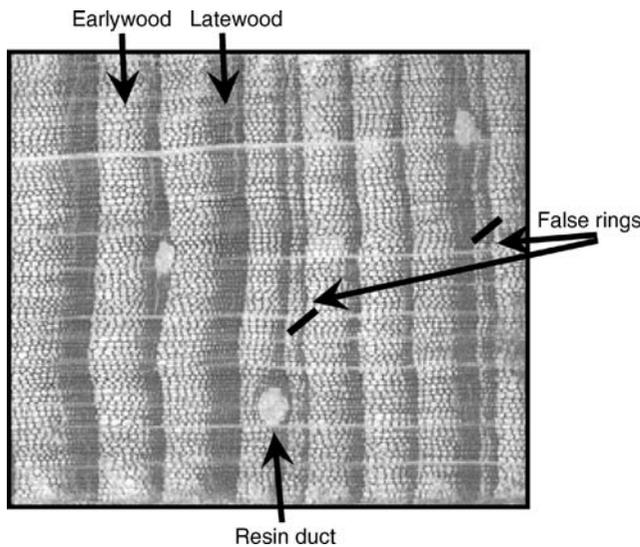

Figure D14 Typical conifer growth rings and associated features. This transverse view of *Pinus merkusii*, from north Thailand, reveals the cells that comprise the annual growth ring. Individual cells are divided into two general types: earlywood (light color) and latewood (dark color). The earlywood cells form at the beginning of the growth season and are usually larger, thinner-walled, and far less dense than latewood cells due to a lesser degree of lignification. The latewood cells form near the end of the growth season as part of the “hardening off” period before dormancy, in this case induced by annual drought. It is the delineation between these two cellular types that allows for the identification of annual growth rings in some trees, and hence crossdating of annual ring sequences. Two “false rings” are indicated that are the result of intra-annual periods of dormancy that result from intermittent drought.

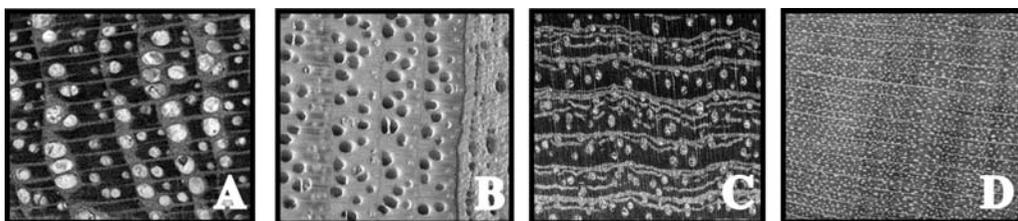

Figure D15 Different types of growth rings. (a) *Tectona grandis* (teak) from Indonesia classified as semi-ring porous to porous wood; (b) the ring porous wood of *Fraxinus americanus* (white ash) from New Hampshire; (c) the semi-porous rings of *Gluta usitata* of the family Anacardiaceae from Thailand; and (d) the diffuse porous wood of *Acer saccharum* (sugar maple) from New York State.

important on a year-to-year basis and are therefore reflected in the annual variability of ring width. It is this fact that makes absolute crossdating of ring sequences, and therefore dendrochronology, possible (Fritts, 1966).

Importance of site selection

Dendrochronology can only be successful if the trees selected are sensitive enough to climate to exhibit some annual variability (Fritts, 1976; Hughes et al., 1982). There are two basic principles of dendrochronology underlying climatic sensitivity in trees, which therefore relate directly to site selection: the *Principle of Limiting Factors*, and the *Principle of Ecological Amplitude* (Fritts, 1976).

The Principle of Limiting Factors states that a biological process such as growth cannot proceed faster than is allowed by its most limiting factor. Although the same factors may limit growth to some extent in all years, the degree and duration of their limiting influence may vary annually. When one factor is no longer limiting (e.g., when adequate moisture is available to drought-stressed trees), growth will systematically increase until another factor becomes limiting (Fritts, 1976). This becomes important in dendrochronology because tree rings can only be cross-dated when one or more environmental factor is *uniformly* limiting to growth across time and space.

The Principle of Ecological Amplitude refers to a species' range of potential habitats. Every species may grow and reproduce over a certain range of habitats, dependant upon certain hereditary factors that determine its phenotype (Fritts, 1976). Species that thrive on a wide range of habitats are said to have a large ecological amplitude, while those restricted to very specific habitat requirements have a small ecological amplitude. Near the center of its ecological amplitude, a species may be found on the widest range of sites, and climate may only rarely be limiting to growth. Near the margins, however, it may be restricted to very specific habitats, and it is in these marginal zones where climate is likely to be the most growth-limiting factor, and the most climatically sensitive trees should be found (Fritts, 1976; Hughes et al., 1982).

Site selection, therefore, becomes a matter of maximizing the desired climatic signal by sampling trees on sites where that parameter is likely to be growth limiting. In a dendroclimatic study of rainfall, such trees might be found in areas of steep slope, with well-drained, rocky soils, and an aspect facing the direct rays of the sun (Stokes and Smiley, 1968). It would also be advantageous to search for a species growing near the limits of its ecological amplitude, with regard to its need for moisture. If the aim of the study is to reconstruct temperature, trees should be sampled from the altitudinal or latitudinal limits of the species range where temperature should be the factor most limiting to growth. Dendrochronology can therefore only be successful if the following conditions are met:

1. There must be quantifiable variability in some aspect of the climate in the region of interest. For example, there must be a distinct wet and dry, or warm and cold, phase of the annual cycle. There must also be measurable annual variability within these seasons.
2. There must be at least one tree species available within the study region that exhibits distinct, annual growth rings with reasonably uniform ring widths. In some regions of the world, such as in the tropics, there are few species with distinct annual growth boundaries, and some may also exhibit intra-annual banding, where more than one growth ring is formed in some
3. Some definable aspect of annual growth (e.g., ring width or latewood density) must be uniformly variable in all trees at the site, so that sequences of wide and narrow, or dense and less dense, rings can be matched between trees. This "cross-dating" of annual ring sequences assures the temporal control that is central to dendrochronology.
4. The researcher must be able to link the common, synchronous variability in growth of all trees at a site to some recorded climatic parameter (e.g., rainfall, temperature, or mean sea-level pressure). If the climate/tree growth link is significantly strong, then a reconstruction of the selected climatic parameter can be considered.

A conceptual model for tree growth

A simple way of conceptualizing tree growth, in terms of dendrochronology, is the *linear aggregate model* developed by Cook (1990). The equation for this model is as follows:

$$R_t = A_t + C_t + dD1_t + dD2_t + E_t \quad (1)$$

where

R_t = the observed ring-width series;

A_t = the age-size-related trend in ring width;

C_t = the climatically-related environmental signal;

$D1_t$ = the disturbance pulse caused by a local endogenous disturbance;

$D2_t$ = the disturbance pulse caused by a stand wide exogenous disturbance;

E_t = the largely unexplained year-to-year variability not related to the other signals.

The model is expressed in linear form for purposes of simplification, in spite of known non-linear relationships associated with ring-width, such as that between the mean and standard deviation (Fritts, 1976). However, such relationships can be made linear by log transformation, indicating the intrinsically linear nature of the process (Cook, 1990). The d associated with $D1_t$ and $D2_t$ is a binary indicator of the presence or absence of either class of disturbance at some time t in the ring widths: when $d = 1$ the disturbance is present, when $d = 0$ it is absent. Therefore A_t , C_t , and E_t are all assumed to be continuously present in R_t , and depending on whether the intervention of some disturbance has occurred at some time t , $D1_t$ and $D2_t$ may not be present (Cook, 1990).

The age-size-trend (A_t) is a non-stationary process that partially reflects the geometrical constraint of adding a volume of wood to a stem of increasing radius (Fritts, 1969). If this constraint is the primary source of the trend then A_t will exhibit an exponential decay as a function of time, subsequent to the juvenile period of increasing radial growth (Fritts, 1976; Cook, 1990). This type of growth trend is typified by trees that grow in very open environments, where the effects of competition and disturbance are minimized (Stokes and Smiley, 1968; Fritts, 1976). In closed canopy stands where the effects of competition and endogenous disturbances are more frequent, the behavior of A_t may be strongly influenced in ways that may not be synchronous in all trees in the stand (Fritts, 1976; Cook, 1985, 1990). Figure D16 illustrates some typical growth trends found in ring width data. There is no predictable shape for A_t , in that it does not necessarily arise from any family of

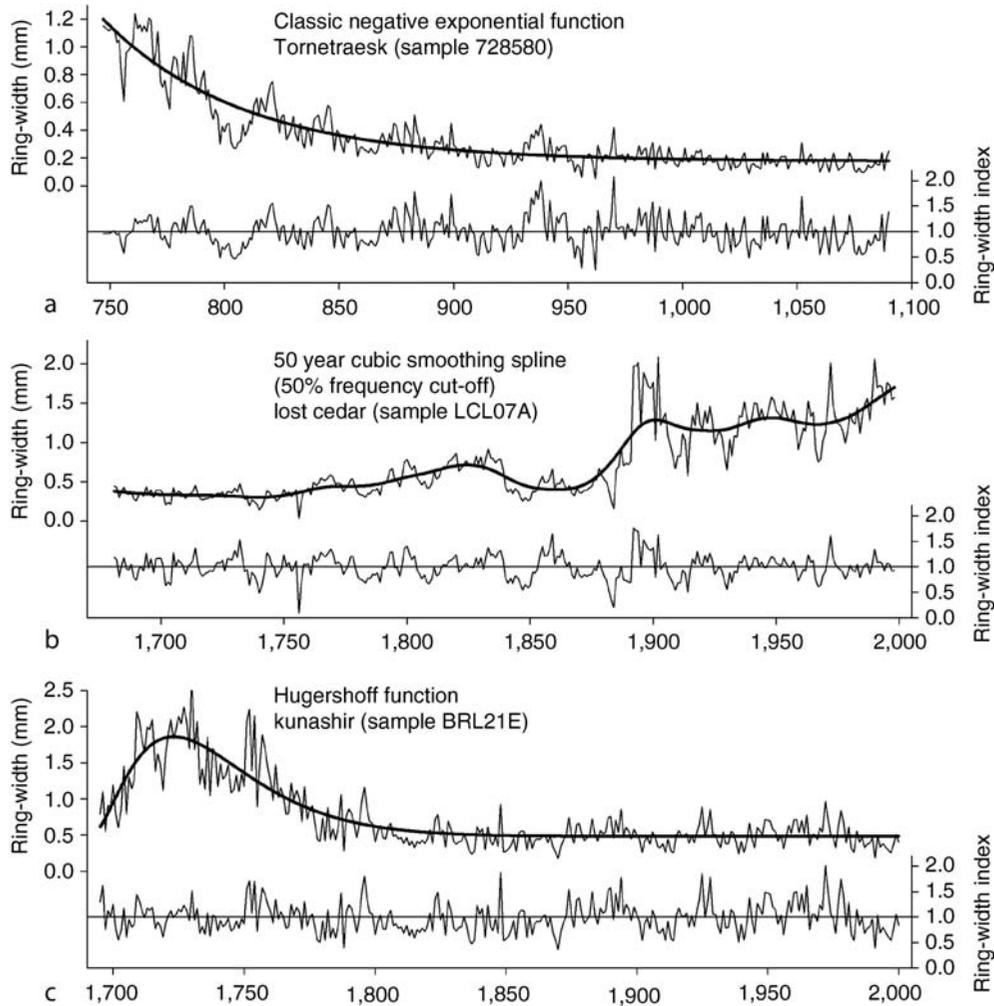

Figure D16 Three common growth trends associated with tree-ring time series and their standardized indices. (a) (top) represents a *Pinus siberica* tree growing in the Tornetraesk region of Fennoscandia. This tree shows a “classic” negative exponential growth trend that results from adding a given volume of wood to a cylinder of increasing diameter. The resulting indices generated from fitting this curve to the data are shown below the raw measurements. This type of growth trend occurs when effects of competition and disturbances are minimal, such as in open canopy forests. (b) (middle) is from a talus slope stand of *Thuja occidentalis* from the Bruce Peninsula of Ontario, Canada that has experienced the effects of rock fall and a large fire in the 1880s. This series illustrates the effects of disturbances (localized or regional) on the expected negative exponential growth curve, resulting in a disturbance pulse and an increasing trend that is removed here with a flexible smoothing spline. (The cubic smoothing spline was developed to remove disturbance effects from individual time series, while maximizing the common signal amongst all trees in the stand. If indiscriminately applied, this type of curve fitting can result in loss of signal). (c) (bottom) shows a Hugershoff curve fit on a *Quercus crispula* time series from Kunashir, in the Kurile Islands north of Japan. This type of growth curve is typical of a tree beginning as an understory tree, shaded from direct sunlight and in greater competition for resources, before emerging into the canopy and commencing an approximate negative exponential growth trend.

deterministic growth curve models such as the negative exponential curve. It should instead be thought of as a non-stationary, stochastic process that may, in special circumstances, be treated as a deterministic process (Cook, 1990; Cook et al., 1990a).

C_t is representative of the aggregate influence of all climate variables on tree growth. The typical variables that comprise C_t include precipitation, temperature and solar radiation. These variables combine to influence tree growth by controlling photosynthesis and the amount of available moisture for physiological activity within the constraints of the phenology of a given species (Fritts, 1976; Salisbury and Ross, 1992). It is the broad scale quality of these climate variables that is

typically of interest to the dendroclimatologist, as all trees in a stand will be affected in a similar manner, thereby maximizing the common signal (Fritts, 1976). These climate variables may usually be thought of as stationary, stochastic processes, though there may be some persistence in an autoregressive sense (Cook, 1985, 1990).

The endogenous disturbance pulses represented by $D1_t$ vary from tree to tree. They are typified by gap-phase stand development in which trees are removed from the canopy by localized processes affecting only those trees adjacent to the gap (White, 1979). They usually create patterns of suppression and release in the ring widths of affected trees. Truly endogenous disturbances are random events in space and time,

and the corresponding effect in a ring width series will be largely uncorrelated with similar pulses in other trees, even from the same stand (Cook, 1990). Exogenous disturbances, denoted by $D2_t$, are characterized by stand-wide disturbances attributed to such phenomena as fire, insect damage, disease, logging effects and pollution, though they may also result from episodic climate-related events like frost, wind or ice damage. The key factor, which may distinguish $D2_t$ from $D1_t$, is the synchrony in time of the former across the stand, unlike the latter, which will exhibit non-synchronous, random behavior in individual trees (Fritts, 1976).

The final term in the equation is E_t , which represents the variance in the ring widths that remains unexplained after accounting for A_t , C_t , $D1_t$, and $D2_t$ (Cook, 1990). Sources for this unexplained variance include micro-site characteristics such as variability in soil quality or type across the stand, hydrological gradients across the site or measurement error. It is assumed that E_t is serially uncorrelated within, and spatially uncorrelated between, trees in the stand.

Chronology building

The development of a master chronology series, or chronology *indices*, involves much more than just the averaging of individual tree ring measurements. The single most important, and undoubtedly controversial, aspect of chronology development is *standardization*. Standardization is the procedure by which tree ring time series, each having their own mean, standard deviation and overall growth characteristics, are converted to dimensionless indices that can be compared with one another. The first step is a curve-fitting procedure aimed at removal of a "biological growth trend" that is thought to be unrelated to climate. The idealized biological growth curve would be negative exponential in character, based on the geometry of adding a constant volume of wood to a cylinder of ever-increasing size. The "signal" that makes dendrochronology possible is the annual variability of climate forcing that is superimposed on the growth curve and commonly expressed in all trees. Thereby, traditionally, the measured ring width values would be divided by the "expected" values for each year, resulting in a set of standardized indices with a mean of 1.0 and the growth trend removed (Fritts, 1976). Often the growth trend takes on a form other than negative exponential, however, and in such cases other *a priori* detrending methods are routinely applied (Cook and Peters, 1981; Cook and Kairiukstis, 1990).

Standardization becomes increasingly complicated in more closed-canopy forests due to the effects of endogenous stand dynamics that may be the source of the principal low-frequency "signal" (Cook, 1985, 1987). Such disturbances can often introduce a low-frequency trend to the data that masks or negates the putative biological growth curve described above. In addition, variable rates of growth through time pose another problem for dendrochronologists, due to the *heteroskedastic* nature of tree ring series (i.e., changing variance through time due to direct relationship between mean and standard deviation). Comparing periods of growth between trees of different age and growth rate requires a normalization procedure to stabilize this changing variance, because this (like growth trend) is also unrelated to climate. Importantly, the annual variability superimposed on these growth rates will be proportional through time, resulting in the ability to crossdate the samples by their annual departures from the local mean. So, individualized local trends in data (i.e., not common among all trees at the stand) are typically removed through curve-fitting procedures such as the cubic smoothing

spline (Cook and Peters, 1981), a data-adaptive curve that can be altered to remove more or less of the trend in mean associated with such growth.

After the de-trending procedure has been applied individually to a suite of crossdated tree ring series, they can be averaged together into the master site chronology. It is this normalized chronology index that is used for further study. Thus, the purpose of the standardization procedure is to remove non-climatic trends, correct for heteroskedastic variance and equalize the resulting overall growth rate from tree to tree. It is important to note that Douglass (1919, 1928) had recognized these concepts, but it required the tremendous iterative power of high-speed computers to accomplish them for large numbers of trees.

The "traditional" method for generating indices (i.e., using division to produce ratios of the actual values divided by the expected values) has been shown to potentially introduce bias into the indexing procedure that may result in "over-fitting" the data, particularly in the outer end of the time series (Eriksson, 1989). This bias may have the effect of exaggerating recent trends in growth, and thereby any inferences of climate made from them. The source of the bias is related to the inherent asymmetry of radial growth in trees, where growth has a defined lower boundary of zero, and a poorly defined, highly variable maximum value. This asymmetry fosters dependence between the local mean and standard deviation by roughly defining the overall corridor within which a tree can respond to environmental inputs such as climate. Trees growing at faster rates have a wider corridor within which to respond to climate than do slower growing trees. Thus, the variance increases in proportion to the mean, and the effect of division on the resultant index can be highly non linear, especially where the estimated growth curve approaches zero.

A method described by Cook and Peters (1997) and first used by Cook et al. (1992) eliminates this potential bias by using residuals instead of ratios from the growth curve. The series are transformed prior to standardization by using a data adaptive power transformation based on the relationship between the local spread and level (standard deviation S , and mean M , respectively) for the best power transformation (Emerson and Strenio, 1983). The model is as follows:

$$\log S = k + b \log M \quad (2)$$

which is a simple linear regression in logarithmic space, where $S = cM^b$ and $k = \log c$, and b is the slope of the spread versus level relationship. This being the case, then $p = 1 - b$ is the appropriate value for the exponent used for the power transformation (Emerson and Strenio, 1983). Following this variance stabilization procedure, the residuals are taken rather than the ratios, resulting in unbiased estimates of tree growth (Cook and Peters, 1997).

Estimating the mean value function

Three general methods have been used for estimating the mean value function, subsequent to detrending of ring-width series: the arithmetic mean, a mean based on testing for a mixture of normal distributions in the sample and the biweight robust mean that discounts outliers (Cook et al., 1990a). The latter method automatically discounts the influence of outlier values in the computation of the mean, thereby reducing variance and bias likely to be caused by these outliers (Mosteller and Tukey, 1977; Cook, 1985). Outlier values may result from

endogenous disturbances that behave as random events in space and time, particularly in ring-width series from closed-canopy, mesic forests like those used for this study (Cook et al., 1990b). The biweight mean for a given year t is computed through iteration as:

$$\bar{I}_r = \sum_{j=1}^m w_j I_t \tag{3}$$

where

$$w_t = \left(1 - \left(\frac{I_t - \bar{I}_r}{cS_{I_r}} \right)^2 \right)^2 \tag{4}$$

when

$$\left(\frac{I_t - \bar{I}_r}{cS_{I_r}} \right)^2 < 1 \tag{5}$$

The weight function is denoted by w_t and is symmetric and therefore unbiased in its estimation of central tendency, provided that the data are symmetrically distributed (Cook, 1985). S_{I_r} is a robust measure of the standard deviation of the frequency distribution, which is defined here by the median absolute deviation, or MAD, calculated as follows:

$$S_{I_r}^* = \text{median} \{ |I_t - \bar{I}_r| \} \tag{6}$$

and c is a constant, often given as six or nine (Mosteller and Tukey, 1977). This constant, c , determines the point at which an outlying value is given a weight of zero, at which point the outlier is discounted and has no influence on the estimation of the mean index (Cook et al., 1990b). When c is set to nine, for example, any value exceeding ± 6 standard deviations from the mean is rejected (Mosteller and Tukey, 1977). A potential drawback of using the biweight robust mean is its lower statistical efficiency compared to the arithmetic mean when the sample population is devoid of outliers and approximates a Gaussian distribution (Cook, 1985). However, in most closed-canopy forests the biweight robust mean is justified as insurance against outliers in the estimation of the mean value function.

Autoregressive modeling, based on ARMA time-series modeling (Box and Jenkins, 1970), has also been shown to be an effective way of generating a more statistically efficient estimate of the mean value function (Cook, 1985; Guiot, 1987). This is particularly true where autocorrelation within individual time-series is high and out-of-phase between series. Tree ring indices can be expressed as an ARMA process of order p and q , in difference equation form as:

$$I_t = \phi_p I_{t-p} + \dots + \phi_1 I_{t-1} + e_t - q_1 e_{t-1} \dots - q_q e_{t-q} \tag{7}$$

where e_t values are serially random inputs or shocks driving tree growth as reflected in the ring widths, the ϕ_i values are the p autoregressive (AR) coefficients and the q_i values are the q moving average (MA) coefficients. These two coefficients combine to produce the characteristic persistence or “memory” exhibited in the I_t (Fritts, 1976; Cook, 1985). For each ring-width series, the values for e_t are assumed to be a combination of inputs related to the factors C_t , $D1_t$ and E_t as outlined in equation (1). The age-size trend, A_t , is considered to be either nonexistent in the raw ring width series (in other words $I_t = R_t$) or sufficiently removed by the detrending process (Guiot, 1987).

Tree-ring indices can be modeled and prewhitened as AR(p) or ARMA (p,q) processes in order to remove the effects of unwanted, disturbance-related transience on the common signal (Cook, 1985; Guiot, 1987). The Akaike Information Criterion, or AIC (Akaike, 1974) is a criterion for selecting the correct AR model and can be used to effectively determine the order of the process (Cook, 1985). Prewhitening is carried out following the estimation of the ARMA (p,q) coefficients, and converts the tree-ring series to *white noise* (Cook, 1985), calculated in difference equation form as:

$$e_t = I_t - \phi_1 I_{t-1} - \dots - \phi_p I_{t-p} + q_1 e_{t-1} + \dots + q_q e_{t-q} \tag{8}$$

The result is an e_t that represents the contributions of C_t , $D1_t$, and E_t , while $D2_t$ is assumed to be absent (Cook et al., 1990b). The transient effects of the endogenous disturbance pulses are also reduced, and thus foster an increase in fractional common variance in the mean-value function of e_t . Combined with the biweight robust mean for the computation of e_t , an improved estimate of C_t is derived. However, this estimate of C_t , in the form of e_t , is lacking the natural persistence that is related to climate and tree physiology (Fritts, 1976; Hughes et al., 1982; Cook and Kairiukstis, 1990), and during climatic reconstruction the persistence from the original climate calibration variable must be added back to the reconstructed series.

In order to completely model the common signal within an ensemble, it is necessary to estimate the common persistence structure among all detrended tree ring series. A pooled estimate of autoregression is computed directly from lag-product sum matrices of the ensemble, including information on persistence both within and among series (Cook, 1985). This pooling procedure is quite robust for dealing with high levels of out-of-phase fluctuations among series that are the result of endogenous disturbances, and is easy to apply for pure AR models. However, it is not easily applied to the ARMA modeling procedure due to the highly nonlinear MA coefficients (Cook, 1985; Cook et al., 1990b). A final tree-ring chronology (I_t) can be created, following the estimation of the common signal components as outlined above, by convolving the pooled AR coefficients with the e_t upon the selection of appropriate starting values (Cook, 1985).

Retaining low frequency variance

Perhaps the prime concern regarding tree-ring standardization procedures is the potential for a loss of low-frequency climate information due to “over-standardizing.” An important paper by Cook et al. (1995b) discussed the need for maximizing individual segment length of tree-ring series, due to a maximum retention of variance of about two-thirds the length of the segment. The segment length curve means that chronologies comprised of trees averaging 100 years in length, even if the overall chronology extends for 3,000 years, will only retain low frequency information on about a 66 year timescale. Aggressive detrending can remove even more of the low frequency variance, resulting in high-frequency “white noise” time series. This has become hugely important in recent debate about global warming, because of the need for placing recent trends in the context of natural variability (Cook et al., 1995a).

Two recent, very important and controversial papers, Mann et al. (1999) and Esper et al. (2002), used tree ring data for reconstructing Northern Hemisphere temperature for the past millennium. At the center of the controversy were the standardization of tree ring data and the retention

of low-frequency variance. The Mann reconstruction shows an extremely marked warming trend in the recent century that is virtually unmatched for the past 1,000 years. There is little evidence of a Medieval Warm Period (MWP) or a Little Ice Age (LIA) signature, such as has been indicated from prior tree ring studies (Jacoby and D'Arrigo, 1989). The Esper reconstruction uses entirely different standardization procedures designed to maximize low-frequency variability, and only long individual tree ring series from selected sites. This reconstruction shows a millennium of more prolonged changes with a clear MWP and LIA. The debate over these two reconstructions, their underlying methodologies and their implications for the global warming debate, has served a valuable purpose for the paleoclimate community. It is through such, often heated, exchanges that major advances are made in the field.

There is little doubt that tree rings have played an important role in the global warming debate, due to their ability to reproduce high resolution, absolutely dated records of climate over broad geographic areas and for the past millennium and beyond. This should continue to be the case for the foreseeable future, largely due to new techniques that will allow for use of previously unworkable species and environments. For example, recent improvements in isotopic research are allowing scientists to explore variability in the tropical regions that have not previously been allowed through traditional ring width analyses (White et al., 1994). These authors produced high-resolution oxygen 18 ($\delta^{18}\text{O}$) records from a *Podocarpus neriifolius* section from north Thailand, a tree with very faint growth rings that are difficult to crossdate visually. Since the species can attain ages that are estimated to be greater than three or four centuries (Buckley et al., 1995), it is a species worth pursuing. The $\delta^{18}\text{O}$ tracks the seasonal cycle in the growth for a period of 6 years following deliberate wounding in 1992, and re-sampling in 1999. The changes in $\delta^{18}\text{O}$ are related to changes in relative humidity and gives hope for pursuing dendroclimatic studies with species that have proven difficult with traditional methods (Poussart et al., 2004). This and other dendrochemistry techniques will ensure that tree rings will continue to provide new and important information to the paleoclimate community for many decades to come.

Examples of tree ring dating

The earliest examples of using tree rings for dating purposes, as noted at the beginning of this chapter, were in the American Southwest. Douglass' tree ring research on wood from pueblo ruins across the region firmly established the history of occupation and abandonment, and more importantly placed these human events in the context of past climate (Douglass, 1929; Haury, 1962). The dating of a charred beam from one such ruin, marked as HH-39, resulted in the extension of Douglass' Flagstaff living-tree chronology back to A.D. 1237. By continuing to date pueblos across the region, Douglass pieced together a regional chronology back to A.D. 700, and dated hundreds of pueblos against this regional master. This work was immensely important for archaeology as it established the occupation history across much of the American Southwest. Since that time, dendrochronology has been used as a dating tool for buildings and other wooden structures throughout the world.

Any event that kills or leaves its mark in the woody tissue of a tree, or groups of trees, can be dated to the precise year or season in which the event occurred. This principle has been used to date a wide range of geomorphic events. For

example, Yamaguchi (1985) dated volcanic eruptions on Mount St. Helens and determined that there was a 2-year interval between prehistoric events. Palmer et al. (1988) built a floating chronology from trees buried by the eruption of Mt. Taupo in New Zealand, and fixed a tentative date by radiocarbon dating the outer rings. McCord (1990) used flood scars in addition to ring width data to reconstruct past hydrology and maximum flow events. Jacoby et al. (1992) dated past landslides under Lake Washington in Seattle, using the rings of trees that had been submerged, still rooted, for the past thousand years. Wiles et al. (1995) used tree rings to date glacial fluctuations in Alaska, as trees "pushed" by glacial moraines are scarred in the season of the injury. Dendrochronology has proven to be a valuable dating tool for a wide range of events. Future application of dendrochronology as a dating tool is only limited by the imagination of those who would use it.

DATING, FISSION-TRACKS

Fission-track (FT) dating is a powerful and relatively simple method of radiometric dating that has made a significant impact on understanding the thermal history of the upper crust, the timing of volcanic events, and the source and age of archaeological artifacts. Unlike most other dating techniques, FT dating is uniquely suited to dating low-temperature thermal events with common accessory minerals over a very wide geological range (as much as 0.004–4,000 Ma and typically 0.1–2,000 Ma). The method involves using the number of fission events produced from the spontaneous decay of ^{238}U in common accessory minerals to date the time of rock cooling below closure temperature. Most current research using FT dating focuses on: (a) thermochronological studies of orogenic belts, (b) provenance and thermal analysis of basin sediments, (c) age control of poorly dated strata including tephrochronology, and (d) archaeological applications.

FT dating relies on the formation of damage zones, or fission tracks, in a crystal from the spontaneous decay of uranium. Unlike other isotopic dating methods, the daughter

used in FT dating is an effect in the crystal rather than a daughter isotope. As such, the technique requires measurement of the parent isotope (^{238}U) and the daughter-like effect (fission tracks shown in Figure D17). Note that uranium and thorium also disintegrate through the process of α -decay through decay series that result in lead isotopes; this forms the basis of U-Pb dating. Both processes of nuclear disintegration (α -decay and fission) occur simultaneously, but the rate of fission decay ($\lambda_f = \sim 7 \times 10^{-17} \text{ yr}^{-1}$ for ^{238}U) is about 1 million times less frequent than that of α -decay ($\lambda_a = 1.5 \times 10^{-10} \text{ yr}^{-1}$ for ^{238}U). The vast majority of fission events in typical Phanerozoic rocks are from ^{238}U , due to its abundance and spontaneous fission decay rate.

Fission tracks are produced and retained in a number of minerals and solid materials (Fleischer et al., 1975), but currently the only routinely dated minerals are apatite, zircon, and to a lesser extent titanite (sphene). Fission-track dating is possible in garnet, pyroxene, and epidote among other common rock forming minerals, but these are rarely exploited. The nearly exclusive use of apatite and zircon in current studies stems from their very common occurrence as accessory minerals in sedimentary rocks and granites and their metamorphic equivalents. Fission tracks are also routinely measured in volcanic glass (Westgate, 1989).

Fission tracks form when two sub-equal fission fragments recoil and create end-to-end zones of disorder in the crystal lattice. This zone, long considered a result of the charged fission fragments stripping electrons from adjacent atoms (i.e., the “ion spike” mechanism of Fleischer et al., 1975), is a narrow zone, or trail, in the crystal. Once enlarged by chemical etching, typical tracks in apatite are ca. 14 μm and ca. 12 μm long in zircon, although they shorten when brought to elevated temperatures. While these zones of disorder were recognized in the late 1950s (Silk and Barnes, 1959), it was not until the early 1960s when researchers at General Electric in Schenectady, NY realized that these tracks were susceptible to

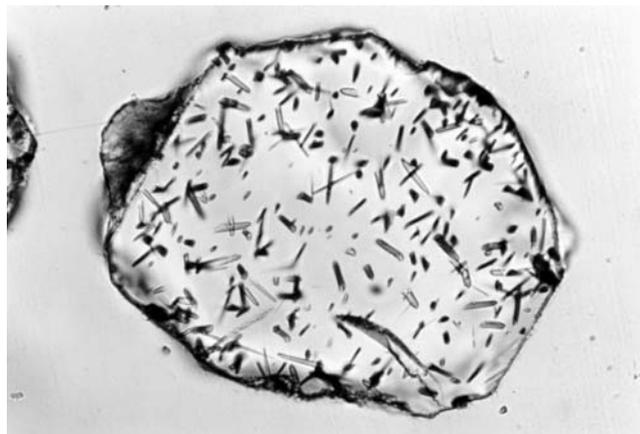

Figure D17 Photograph of fission tracks in a detrital apatite crystal from the mid-Cretaceous Jackass Mountain Formation, British Columbia. This apatite has a mid-Tertiary cooling age, so the strata were buried, heated, and then cooled in the Eocene. This apatite is about 150 μm across and horizontal tracks are about 12 μm long. This apatite crystal is mounted in epoxy, polished so an internal surface is exposed, and the chemically etched tracks are oriented in all directions, so some are short vertical track tips, while others are nearly horizontal and a full length can be seen. (Photo: J. I. Garver.)

chemical attack, and as such could be etched large enough to be visible with an ordinary optical microscope (i.e., 200x to 1,500x – Fleischer et al., 1975). Thus the technique of FT dating was born and the first reported fission track ages on ordinary minerals were reported soon thereafter (Fleischer et al., 1964).

The FT methodology is technically simple and requires little in the way of specialized equipment (Naeser, 1976). Fission-track ages are now routinely determined in many academic laboratories and several commercial labs throughout the world. The most common approach to FT dating is through the external detector method using a *zeta* calibration factor, which is based on repeated measurements of standards of known age (Fleischer and Hart, 1972; Hurford and Green, 1983). For an age to be calculated, the spontaneous track density (or fossil track density – ρ_s) and the uranium concentration in a single crystal need to be determined. Together these measurements are accomplished by mounting the crystals in a solid medium (epoxy or Teflon[®]), polishing to expose crystal interiors, and then enlarging the tracks with a chemical etchant. The measurement of uranium is typically accomplished by neutron irradiation, but other methods could in principle be used. In this step, the mount is covered with an external track detector (mica or plastic), and irradiated in a nuclear reactor with slow neutrons. This thermal neutron irradiation causes uranium to fission in the minerals of interest, and some fission fragments are ejected into the overlying external track detector. Because the thermal cross-section for fission of ^{235}U is large relative to that for ^{238}U , the track density on the external detector is a function of the thermal neutron flux (or fluence) and the concentration of ^{235}U . To determine total uranium, the ratio of $\text{U}^{235}/\text{U}^{238}$ is assumed to be constant. In practice, therefore, an age is determined by measuring the spontaneous track density (ρ_s), the induced track density (ρ_i), and the thermal fluence as determined from a dosimeter with known uranium concentration (ρ_d).

Fission tracks are constantly formed through the spontaneous fission of uranium, but only the ^{238}U isotope contributes significantly to the total accumulated fission tracks due to its abundance and relative decay rate (Roberts et al., in Fleischer et al., 1975). Tracks are only preserved in the crystal when temperatures fall below the annealing temperature (similar to the closure temperature of other isotopic systems), which varies from mineral to mineral and is the basis for determining low-temperature vs. time histories. While the details of closure temperatures are complicated, they are approximately 100–110 $^{\circ}\text{C}$ for typical apatite, ca. 230–250 $^{\circ}\text{C}$ for zircon, and ca. 300 $^{\circ}\text{C}$ for titanite. As with other isotopic systems, closure temperature is affected by the rate of cooling (Gallagher et al., 1998).

Tracks anneal by shortening or disappearing if they reside at elevated temperatures for an appreciable time. As such, it was discovered that the statistical distribution of track lengths could be used to understand the amount of time a sample spent at temperatures sufficient to anneal or partially anneal tracks. The partial annealing zone (PAZ) is generally regarded as the temperature range at which fission tracks are progressively shortened. Quantitatively this is regarded as the temperatures between 90% annealing and 10% annealing. At temperatures below the PAZ, fission tracks are more or less fully retained. At temperatures above the PAZ, fission tracks are formed, but then fully erased over geological times.

The relationship between track-length distributions and annealing rates is well established for apatite, but no other

minerals (Gallagher et al., 1998). For apatite, crystal composition controls annealing rates and the relative proportions of Cl, F, and OH appear to be most important. In laboratory and geological experiments, F-rich apatite is more resistant to annealing than Cl-rich apatite. For zircon, radiation damage appears to be the major influence on annealing rates and temperatures (Brandon et al., 1998).

The FT technique is widely used in understanding the thermal structure of the upper crust, especially in orogenic settings. Studies include understanding the offset of faults, the local exhumation of rock and regional denudation, the relationship between exhumation and orogenic relief, and the large-scale movement of rock in deforming orogenic wedges. These exhumation studies of the tectonic evolution of orogenic belts are perhaps the most widely used application of the FT technique. FT dating is also widely applied to understanding sedimentary basins and specific applications are aimed at deciphering the thermal history of sedimentary basins in the context of the thermal maturation of oil generation, and the provenance of sedimentary detritus (Naeser et al., 1989; Garver et al., 1999). Fission-track dating has also seen a variety of other uses including dating burnt coal seams, diatreme eruption, volcanic ash deposition, meteoritic impacts, tektite strewn fields, and the formation of precious metal deposits (Wagner and Van den Haute, 1992; Fleischer, 1998). In archeological applications, FT dating has been used to understand the age and source of obsidian artifacts, and fire-heated implements and hearthstones. The technique has also been used to date uranium-doped glasses and vases that are less than 200 year old (Fleischer et al., 1975; Wagner and Van den Haute, 1992).

DATING, LUMINESCENCE TECHNIQUES

Introduction

Quartz, feldspar, zircon, and calcite are the most important minerals for luminescence geochronology, and they can produce several different types of luminescence. Thermally stimulated luminescence (or thermoluminescence, TL) is a cold light that is emitted upon heating minerals to a temperature (e.g., 450 °C) below that of incandescence (Aitken, 1985). Photon-stimulated luminescence (PSL) is emitted when minerals are exposed to visible or infrared wavelengths of light, and radioluminescence (RL) is emitted during mineral exposure to nuclear radiation (e.g., gamma rays). Other terms for PSL dating are optical dating or OSL dating. Through optical filters the PSL signal is observed at shorter wavelengths (higher photon energies) than the stimulating light (“anti-Stokes” emission). TL dates the last heating and last daylight exposure, while PSL and RL date only the last exposure to daylight, providing a family of related dating procedures for heated and unheated sediments (Aitken, 1998; Wagner, 1998; Krbetschek et al., 2000; Troja and Roberts, 2000).

Both quartz and potassium-(K)-rich feldspars are ubiquitous in natural sedimentary deposits, and both emit strong TL and PSL signals (and RL in the case of K-feldspars). The TL and PSL emissions from zircon crystals and from volcanic and archeological glass have also been used for dating, but these materials are more problematic and restricted in their application. The age range of luminescence sediment dating is from decades to 500 kyr (or 800 kyr in favorable circumstances, Berger, 1995), depending on the particular mineral and luminescence signal used. The significance of luminescence geochronometry lies not in the attainable precision (usually 5–15% at 1 σ), but in the ability to date directly, in calendar years, the burial or heating age of ubiquitous minerals, and to exceed the usual range (35–40 kyr) of ¹⁴C dating.

Concepts

Luminescence dating methods are based on the principles of radiation dosimetry. Buried sediments and artifacts are exposed to a continuous flux of low level, ambient ionizing radiation (α , β , and γ nuclear radiations, plus a smaller intensity of cosmic radiation). These generate a *dose rate* (D_R) (absorbed energy/unit time: Gray (Gy) kyr⁻¹, 1 Gy = 1 J kg⁻¹) that gives rise to the production of free charge carriers (electrons and holes) inside the mineral grains. Some electrons and holes are trapped at crystal lattice defects for several millions of years (having long *lifetimes* because they reside at energetically deep

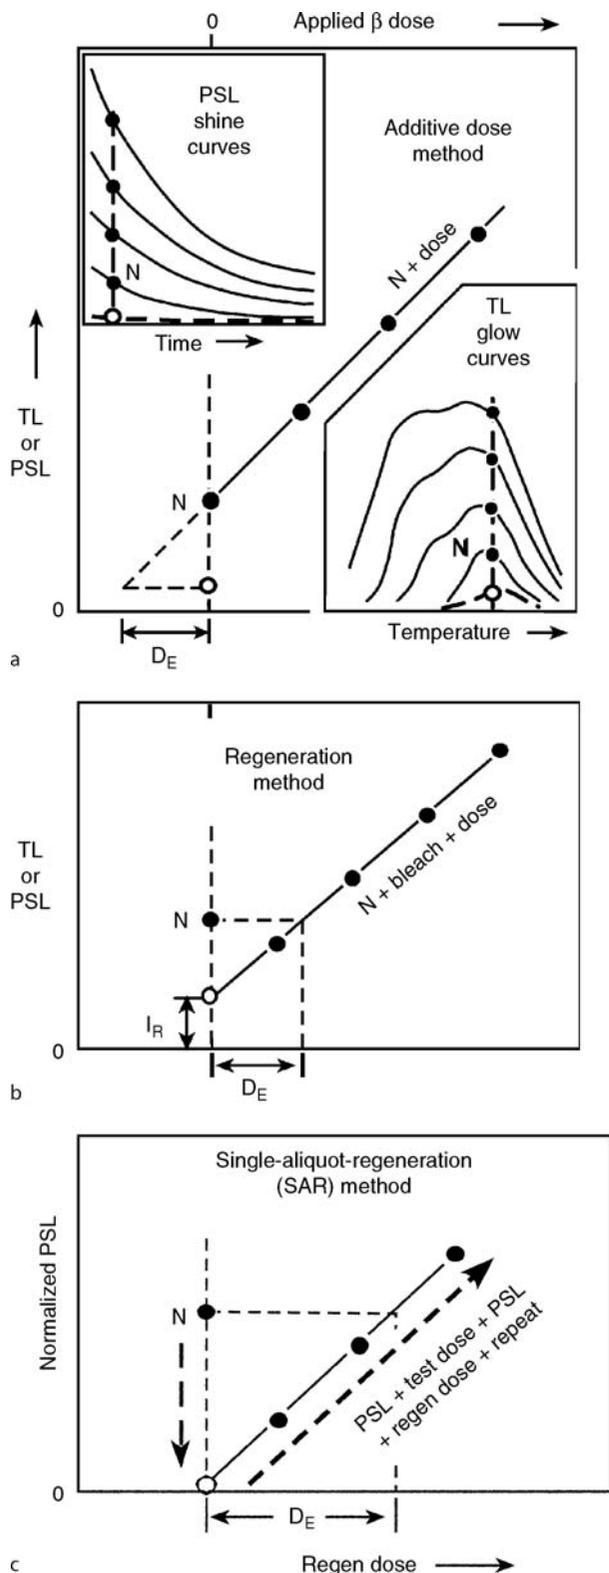

Figure D18 (a) Form of the luminescence readout curves for PSL and TL, and the construction of an “additive-dose” response curve to obtain a D_E value. N means unirradiated or “natural.” The open circle represents either a light-resistant signal (TL) or a combination of such with a

traps). However, in some zircons and some feldspars (e.g., of volcanic origin), significant leakage (by “quantum mechanical tunneling”) of electrons occurs from deep traps at ambient temperature, resulting in *anomalous fading* of the TL and PSL signals, causing under-estimation of age. The population of deeply-trapped electrons increases with further irradiation and hence with time, though filling of the traps leads to “saturation” and an upper age limit, dependent upon several variables. One may call this method “trapped electron” dating.

When the electron traps are emptied in the laboratory, TL, PSL or RL emissions arise from the recombination of ejected electrons with holes trapped at “luminescence centers” (ionized crystal defects, usually chemical impurities). The type of center determines the color of the luminescence. Typical impurities in quartz generate ultraviolet emissions, sometimes red; those in feldspars, violet, yellow-orange, and sometimes deep red. The intensity of the luminescence at a particular color (or wavelength) is proportional to the time since traps were last emptied. The clock-zeroing event is either daylight exposure (which empties light-sensitive traps) or heating (which empties all traps).

Historical development

The physics-concept foundations for luminescence dating were laid only in the late 1940s. TL dating of fired ceramics was first successfully developed at the University of Oxford (England) during the 1960s and 1970s (Aitken, 1985), following some pioneering work in North America during the 1950s and 1960s using TL from rock minerals for characterization. The potential for TL dating the last exposure of unheated sediments to sunlight was first recognized by Morozov and Shelkopyas (1968–1971) at the Ukrainian Academy of Sciences in Kiev. TL sediment dating was then developed into practical, accurate procedures at Simon Fraser University (Canada) in the late 1970s and early 1980s, with the use of laser-light (or photon) stimulated luminescence (PSL) also originating at Simon Fraser University, in 1985.

Since then there have been two major methodological developments in PSL dating: (a) the introduction and refinement of “single-aliquot” procedures, and (b) their extension to single grains. Previously, multiple aliquots were required for measurement of each D_E (equivalent dose – see below) value. The first attempt to obtain a PSL D_E value from only two aliquots was made at the University of Wales (UK) in 1991, and subsequently modified for true single-aliquot dating at the University of Edinburgh (UK) in 1996. The single-aliquot approach was first adapted for single grains (of feldspar) at the University of Quebec at Montreal (Canada) in 1994. The first successful use of single aliquots and single grains for dating employed sand-sized quartz grains from Australia in 1998. Methods were later refined to a universally adopted single-aliquot procedure (Murray and Wintle, 2000). The essentials of “single-grain” dating of quartz were clearly outlined by Olley et al. (1999). Single-grain dating of thousands of sand-sized grains per sample is now automated, using a micro-focused, scanning, high powered laser (Duller et al., 1999).

thermal-transfer signal (PSL). This “residual” is always proportionately much smaller for PSL than for TL. (b) An interpolation procedure for obtaining a D_E value. I_R is near zero for PSL. (c) A simplified illustration of the regeneration procedure used for single aliquots or single grains. The required heating steps are omitted for clarity.

Techniques

To derive an age in calendar years, two independent tasks are performed: (a) the measured natural luminescence signal is compared to that induced in subsamples (“aliquots”) by known radiation doses from calibrated laboratory sources (usually β or γ), thus scaling the natural signal and yielding an *equivalent dose* (D_E) or *paleodose* value (in Gy); and (b) the burial dose rate D_R is calculated from elemental measurements on portions of the sample grains and the surrounding sediments. This yields a luminescence age = D_E/D_R , independent of any other geochronometric technique.

Dose rate

Assuming secular equilibrium, one can use the concentrations of the ^{40}K , ^{238}U -series, and ^{232}Th -series radionuclides (Aitken, 1985) along with measured inter-grain water concentration, plus estimates of cosmic-ray flux (at the sample’s altitude, depth, and geomagnetic latitude) to calculate the dose rate. Inter-granular water absorbs ionizing radiation, so it must be estimated. Thick-source α -particle-counting can be used to provide the absorbed energy contributions from the several α -emitting nuclides in the U and Th decay series. This is more accurate than methods (e.g., neutron activation) that determine the concentration only of the parent nuclides, if there is or has been radon escape or other disequilibria, but is not generally as accurate as high-resolution γ spectrometry. If disequilibrium occurs (e.g., in sandy fluvial deposits), it is more likely to be in the ^{238}U series than in the ^{232}Th series.

If sand-sized grains are dated, then corrections (Aitken, 1985) must be made for the attenuation of β particles (2 mm range) across the dimensions of the grains. The effects of α particles (20 μm range) can be removed by HF-acid etching, or ignored for feldspars. The internal K concentration of feldspars needs to be determined in representative populations of grains. This is most accurately accomplished by the use of SEM-EDX (scanning-electron-microscopy-energy-dispersive-X-ray analysis) discrete-grain mapping for K (usually the highest-K grains are the brightest luminescence emitters).

Equivalent dose

Quartz and K-rich feldspar grains are selected most often for dating, using either sand-sized (e.g., 100–300 μm diameters) grains or the fine-silt (5–10 μm) fraction. The traditional multi-aliquot method for measuring D_E values is to extrapolate a dose-response curve to its intersection with some residual (light-insensitive) TL or PSL value (Figure D18a). This is done at each of successive intervals in the readout curves. In TL, a “plateau” in such D_E values can indicate a thermally stable signal. Alternatively, an interpolation procedure (Figure D18b) can be more precise, but most samples exhibit a change in slope (“sensitivity change”) of the regeneration curve compared to the additive-dose curve that is difficult or impossible to accommodate.

The single-aliquot-regeneration (SAR) technique (Murray and Wintle, 2000) overcomes the effect of such a sensitivity change by the use of a constant “test dose” (Figure D18c) and consequent normalization of signals. Relatively high precision in SAR D_E values can be attained. The greatest advantage of the single-aliquot and single-grain procedures is their potential ability to sort aliquots/grains that have not been exposed to much daylight from those that have (Figure D19). Age overestimates would be expected with the application of multi-aliquot methods to most fluvial (and similar) deposits.

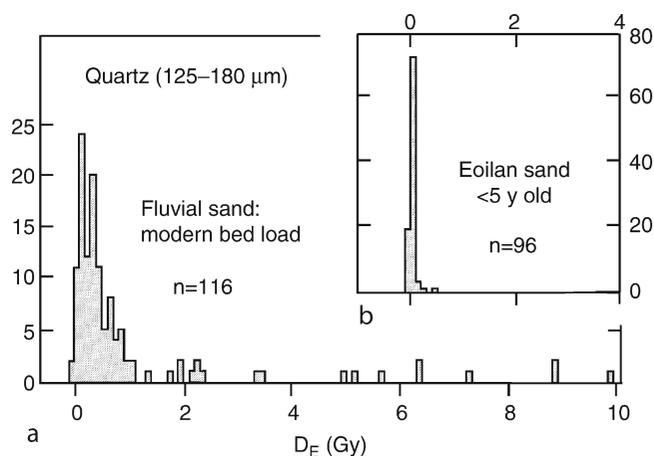

Figure D19 Histograms of D_E values for small (60–100 grains) single aliquots of quartz grains from (a) a modern fluvial bed-load sand, and (b) a modern (<5 year) eolian sand (modified from Olley et al., 1998).

Applications

Applications of multi-aliquot TL and PSL procedures have been reviewed by Aitken (1998) and Berger (1995). Applications of single-aliquot and single-grain PSL procedures have been reviewed by Lian and Roberts (2006), Murray and Olley (2002), Stokes and Walling (2003) and Wallinga (2002). Applications are being extended to types of deposits and regions of the globe (e.g., polar) previously considered impracticable. Quartz SAR can now date eolian deposits precisely at the century and decadal scale (e.g., special issue of *Quaternary Science Reviews*, 2003, 22(10–13)). However, unless the dose rates are unusually low (e.g., $<1 \text{ Gy kyr}^{-1}$), the upper age range of quartz remains ca. 150 kyr. Feldspars can be used further back in time, but more testing is required to understand how universal anomalous fading is, and what can be done about it.

Conclusions

There has been a rapid evolution in luminescence dating technique since the introduction of PSL methods in 1985, attaining a revolution in capability with the development of single-grain techniques. Remaining problems concern how to interpret histograms of SAR D_E values, and how to finesse internal age-consistency checks. Some approaches involve isolation and testing of properties of PSL signals having different lifetimes (so-called “fast,” “medium,” and “slow” components in quartz PSL). There is increasing interest in extracting the red emissions from feldspars to overcome the perennial problem of anomalous fading.

DATING, MAGNETOSTRATIGRAPHY

Introduction

Magnetostratigraphy refers to the application of the well-known principles of stratigraphy to the observed reversal pattern of the geomagnetic polarity recorded in rock sequences. This recording of the ancient geomagnetic field reveals successive intervals with alternating normal and reversed polarity in lava piles and sedimentary sequences. Normal means parallel to the present-day magnetic field (north-directed), while reversed refers to an antipodal south-directed field (Figure D20). As a rule, it appears that these successive intervals of different polarity show an irregular thickness pattern, caused by the irregular duration of the successive polarity zones. This produces a “bar code” in the rock record, which often is distinctive. Polarity intervals have a mean duration of some 250,000 years during the last 35 Myr, but large variations have occurred, ranging from 20,000 yr to several Myr. Once a calibrated “standard” or a so-called “geomagnetic polarity timescale” (GPTS) is constructed, dated by radiometric methods and/or by orbital tuning, one can match the observed pattern with this standard and hence derive the age of

the sediments. Magnetostratigraphy and correlation to the GPTS has become a standard tool in Earth sciences, especially because it can be applied to a wide variety of rock types (volcanic, sedimentary) and in different kinds of environment (continental, lacustrine, marine, etc.) (Butler, 1992; Opdyke and Channell, 1996; Tauxe, 1998; McElhinny and McFadden, 2000).

Historical background

In 1269, Petrus Peregrinus carried out a remarkable series of experiments with a spherical lodestone from which he deduced the dipolar nature of the magnet, and he reported his conclusions in his famous “*Epistola de Magnete*,” which is regarded as the first scientific treatise ever written. He also found that the magnetic force is both strongest and vertical at the poles, and became the first person to formulate the law that like poles repel and opposite poles attract. William Gilbert in 1600 published the results of his experimental studies in magnetism in “*De Magnete*.” He investigated the variation in inclination over the surface of a spherical lodestone and concluded for the first time that “*magnus magnes ipse est globus terrestris*” (the Earth itself is a great magnet). Apart from the spherical form of the Earth, magnetism was the first physical property to be attributed to the body of the Earth as a whole. The physical property of gravitation came 87 years later with the publication of Newton’s “*Principia*.”

Paleomagnetic studies of igneous rocks provided the first reliable information on reversals. In 1906, Brunhes observed lava flows magnetized in a direction approximately anti-parallel to the present geomagnetic field, and suggested that this was caused by a reversal of the field itself, rather than by some physicochemical property (“self-reversal” mechanism) of the rock. Matuyama (1929) demonstrated that young Quaternary lavas were magnetized in the same direction as the present field (normal polarity), whereas older lavas were consistently magnetized in the opposite direction. In the earliest 1950s, Jan Hospers and his supervisors were the first to realize that the polarity of lava flows could be a powerful stratigraphic correlation tool (Irving, 1988). Improved techniques and the undertaking of extensive investigations in many parts of the world have drastically increased the amount of paleomagnetic information and have now provided us with a very detailed GPTS (e.g., Berggren et al., 1995).

The geomagnetic polarity time scale

For the construction of the “bar code” pattern of magnetic polarity intervals, scientists rely on two fundamentally different records of geomagnetic polarity history: the marine magnetic anomaly record and the magnetostratigraphic record. Surveys over the ocean basins carried out from the 1950s onward found linear magnetic anomalies, parallel to mid-oceanic ridges, using magnetometers towed behind research vessels. During the early 1960s, it was suggested and soon confirmed that these anomalies resulted from the remanent magnetization of the oceanic crust. This remanence is acquired during the process of seafloor spreading, when uprising magma beneath the axis of the mid-oceanic ridges cools through its Curie temperature (The temperature at which thermal vibrations overcome the tendency toward magnetization. The Curie temperature of magnetite is 575°C) in the ambient geomagnetic field, thus acquiring its direction and polarity (Figure D21). The continuous process of rising and cooling magma at the ridge results in magnetized crust of alternating normal and reversed polarity, which

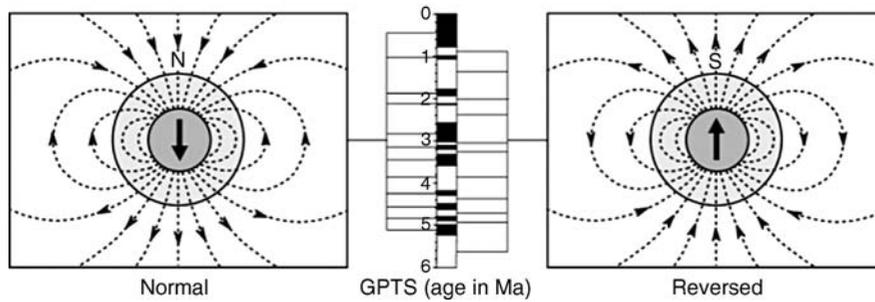

Figure D20 Schematic representation of the geomagnetic field of a geocentric axial dipole (“bar magnet”). During normal polarity of the field, the average magnetic north pole is at the geographic north pole, and a compass aligns along magnetic field lines, the inclination being positive (downward-directed) in the northern hemisphere and negative (upward-directed) in the southern hemisphere. Conversely, during reversed polarity, the compass needle points to the south, and the inclination is negative in the northern and positive in the southern hemisphere. In the GPTS, periods of normal and reversed polarity are represented by black and white colored intervals, respectively.

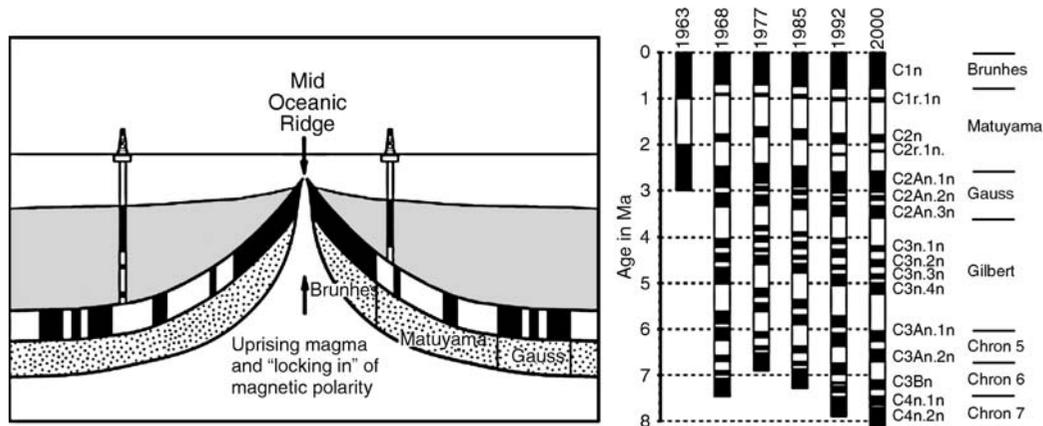

Figure D21 Formation of marine magnetic anomalies during seafloor spreading (*left*). The oceanic crust is formed at the ridge crest, and while spreading away from the ridge it is covered by an increasing thickness of oceanic sediments. The black (white) blocks of oceanic crust represent the original normal (reversed) polarity thermoremanent magnetization (TRM) acquired upon cooling at the ridge. The black and white blocks in the drill holes represent normal and reversed polarity depositional remanent magnetization (DRM) acquired during deposition of the marine sediments. Development of the geomagnetic polarity time scale (GPTS) through time (*right*) shows that the initial assumption of periodic behavior (in 1963) was soon abandoned as new data became available. The first modern GPTS based on marine magnetic anomaly patterns was established in 1968. Subsequent revisions show improved age control and increased resolution.

produces a slight increase or decrease of the measured field: the marine magnetic anomalies. It was also found that the magnetic anomaly pattern is generally symmetric on both sides of the ridge, and, most importantly, that it provides a wonderfully continuous tape recording of the geomagnetic reversal sequence.

The template of magnetic anomaly patterns from the ocean floor has remained central for constructing the GPTS from the late Cretaceous onward (110–0 Ma). In addition, combined magnetostratigraphic, biostratigraphic and radiometric results of deep-sea sediments (see *Deep Sea Drilling Project (DSDP)*) and land-based sections have confirmed and refined the general validity and accuracy of the GPTS.

The development of the GPTS continuously shows increasing detail and gradually improved age control through time (Figure D21). Periods of a predominant (normal or reversed) polarity are called chrons, and the four youngest ones are named after persons: Brunhes (normal) who suggested field reversal, Matuyama (reversed) who proved this, Gauss (normal) who mathematically described the field, and Gilbert (reversed) who discovered that the Earth itself is a big magnet. Chrons may contain short intervals of opposite polarity called

subchrons, which are named after the locality where they were discovered, e.g., the normal Olduvai subchron within the Matuyama reversed chron is named after Olduvai Gorge in Tanzania, and the Kaena reversed subchron within the Gauss normal chron after Kaena Point on Hawaii. Older periods of the GPTS have been subdivided into polarity chrons designated by the numbers correlated to oceanic magnetic anomalies (e.g., C3An). The polarity chron nomenclature has evolved progressively to accommodate additional polarity chrons (C3An.1n; C3An.2n) according to the chron nomenclature described in Cande and Kent (1992).

The oldest substantial parts of oceanic crust remaining in ocean basins are late Jurassic in age. The determination of the GPTS for older intervals must therefore be done by paleomagnetic studies of exposed stratigraphic sections on land. The best age control for Mesozoic sequences is in the late Triassic, where magnetostratigraphy in combination with cyclostratigraphy on long scientific drill cores in the continental sequences of the Newark basin (NE America) provided a high-resolution, astronomically calibrated GPTS (Kent and Olsen, 1999). For other Mesozoic and older periods, our knowledge of the polarity

time scale is much less refined and various intervals are still subject to lack of data and often to serious controversies.

The latest development in constructing a GPTS comes from orbital tuning of the sediment record (see *SPECMAP*). It differs essentially from the conventional GPTS where reversal ages are interpolated between a limited number of (radiometric) calibration points, essentially assuming constant sea-floor spreading between these calibration points. In the astronomically tuned time scale, each reversal boundary – or any other geological boundary for that matter, e.g., biostratigraphic datum levels or stage and epoch boundaries – is dated individually (Hilgen et al., 1997). This directly determines the age of each reversal and has important consequences for (changes in) spreading rates of plate pairs. Instead of having to assume constant spreading rates between calibration points, one can now accurately determine these rates and changes therein. The astronomical polarity time scale (APTS) has provided a breakthrough in dating of the geological record and has significantly increased our understanding of, for example, the (paleo)climate system, since astronomical tuning relies on deciphering and understanding environmental changes driven by climate change, which in turn is orbitally forced (see *Cyclic sedimentation (cyclothem)*).

The paleomagnetic signal in rocks

The ancient geomagnetic field can be reconstructed from its recording in rocks during the geological past (Figure D22). Almost every type of rock contains magnetic minerals, usually iron (hydr)oxides or iron sulfides. During the formation of rocks, these magnetic minerals (or more accurately: their magnetic domains) statistically align with the then ambient field, and will subsequently be “locked in,” preserving the direction of the field as a natural remanent magnetization (NRM): the paleomagnetic signal.

The type of NRM depends on the mechanism of recording the geomagnetic signal, and we distinguish three basic types: TRM, CRM and DRM. A thermoremanent magnetization

(TRM) is the magnetization acquired when a rock cools below the Curie temperature of its magnetic minerals, thereby “locking” the magnetic domains to be statistically aligned along the ambient field. A chemical remanent magnetization (CRM) is the magnetization acquired when a magnetic mineral grows through a critical “blocking diameter” or grain size. Below this critical grain size, the magnetic domains align along the ambient field, while above it the field will be locked and the acquired remanence may again be stable over billions of years. A depositional remanent magnetization (DRM) is the magnetization acquired when magnetic grains, either of detrital origin or formed in situ, and thus already carrying a TRM or CRM, are deposited. The grains statistically align with the ambient field as long as they are in the water column or in the soft water-saturated topmost layer of the sediment. Upon compaction and dewatering, the grains are mechanically locked – somewhere in a “lock-in depth zone” – and will preserve the direction of the ambient field.

As a rule, the total NRM is composed of different components. Ideally, the primary NRM, i.e., originating from the time of rock formation, has been conserved, but often this original signal is contaminated with or even completely overprinted by remanence components acquired later in its geological history, e.g., through weathering, metamorphism or tectonics. A parasitic component or partial overprint can be removed through “magnetic cleaning” or demagnetization procedure. This implies that rock samples must be subjected to various methods to remove stepwise any unwanted or non-original magnetization component, either by increased temperatures or alternating magnetic fields. Such experiments are routine paleomagnetic lab procedures, aimed at retrieving the original acquired magnetization that has recorded the ancient geomagnetic field.

Applications

Once the originally recorded geomagnetic field has been retrieved with sufficient accuracy and resolution, the successive intervals of normal and reversed polarity can be faithfully

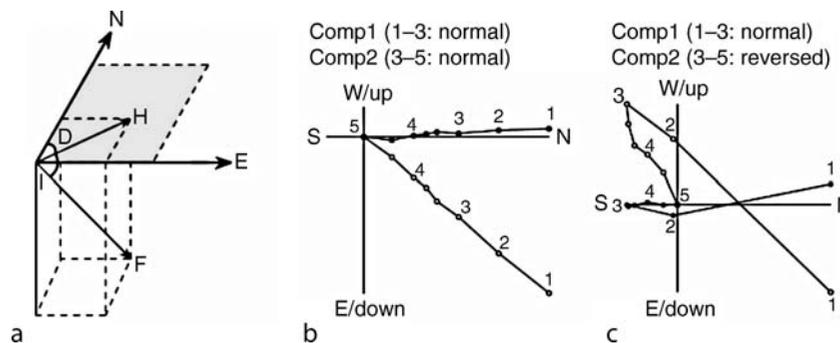

Figure D22 (a) The magnetic field on any point on the Earth's surface is a vector (F) that possesses a component in the horizontal plane called the horizontal component (H), which makes an angle (D) with the geographical meridian. The declination (D) is an angle from north measured eastward ranging from 0° to 360° . The inclination (I) is the angle made by the magnetic vector with the horizontal. By convention, it is positive if the north-seeking vector points downward and negative if it points upward. (b,c) To resolve the different magnetic components that can be acquired in a rock during its geological history, rock samples are subjected to a process of stepwise demagnetization. The standard method for presentation and analysis of the results of demagnetization are called Zijderveld diagrams (after Zijderveld, 1967). Changes in vector magnetization during demagnetization involve both its direction and its intensity. The orthogonal vector Zijderveld diagrams show both the changes in intensity and direction. The endpoint of the vector measured after each demagnetization step is then projected both onto the horizontal plane (*closed symbols*) and onto the vertical plane (*open symbols*). Difference vectors (*lines between end points*) then show the behavior of the total vector upon stepwise removal (see text for details).

determined. Still, there are several prerequisites for a successful application of magnetostratigraphy as a dating technique for sedimentary sequences. First, one needs to have some approximate (biostratigraphic or radiometric) age control. In addition, the studied sequences must represent a sufficiently long period to reveal a characteristic pattern of reversals (generally >1 Myr during the Cenozoic) to be unambiguously correlated with the standard (GPTS or APTS). Naturally, hiatuses and major changes in sedimentation rate may obscure this “fingerprint” pattern, requiring careful field observations, while sampling resolution must ideally be several times higher than the shortest duration of (sub)chrons (20–30 kyr).

Often, these prerequisites can be met, enabling magnetostratigraphy to be used as a high-resolution age control, which has several fundamental advantages over other dating techniques. Contrary to biostratigraphic datum levels, reversals of the geomagnetic field are fundamentally globally-synchronous events, within sampling resolution, allowing precise correlations between different parts of the world and between different environments (marine vs. continental), regardless of their fossil content or radiometric suitability. Hence, it can be used to study the paleogeographic evolution and paleoclimatic history of different regions over long periods. This enables, for example, detailed continental-marine correlations and hence the determination of synchrony or diachrony of regional or even global paleoclimatic or tectonic events. A successful correlation of the recorded polarity pattern to the GPTS provides accurate ages of every recognized reversal boundary, allowing establishment of rates and rates of change.

Finally, it is very compelling to combine magnetostratigraphy with astrochronology, because (a) it can be used to improve the age control of the standard GPTS (since individual reversals can be directly dated), and (b) it can help increase the resolution of the standard GPTS, since subchrons shorter than 30 kyr are generally not resolved from the ocean floor anomaly patterns. The reliability and completeness of the GPTS is not only crucial for geochronological purposes, but also for understanding the long-term statistical properties of the geomagnetic field.

DATING, RADIOMETRIC METHODS

General principles

The discovery of radioactivity by Henri Becquerel in 1896 had a profound impact not only in the fields of physics and chemistry, but also in the earth sciences. Naturally occurring radioactivity immediately solved the problem of controversy over the Earth's internal heat. Lord Kelvin had used Earth's internal heat to estimate the age of the Earth as being about 20 Myr. This estimate, which assumed that the Earth's internal temperature structure was purely the result of passive heat diffusion since the formation of the planet, was highly unpopular with the geologists of the day, who argued that the processes that they witnessed on the Earth's surface required far more time. In one stroke, an otherwise unknown heat source could be invoked to extend the Earth's apparent age.

Radioactivity was also seen to provide a standard and reliable clock that had not yet existed in the earth sciences. As early as 1904, Rutherford proposed the use of U decay and its production of the newly discovered element, helium, as a method of dating rocks. This oldest of radiometric dating methods, though long abandoned, has made a recent come-back and is in the midst of a renaissance for dating near-surface processes. For an excellent overview of the history of radiometric dating methods and their basic principles, see York and Farquhar (1972) and also Faure (1986).

Radiometric dating methods rely on the presence of naturally occurring radioactive isotopes that decay into stable daughter products. Radioactivity is the process by which unstable atomic nuclei change into more stable and long-lived forms. The most important decay processes for earth scientists involve the expulsion of a ^4He nucleus (alpha particle, or α decay), an electron (β^- decay), or the capture of a free electron by the nucleus (electron capture or K-capture). A rare decay form that, for the purposes of radiometric dating, is equivalent to K-capture, involves the expulsion of a positron from the nucleus (β^+ decay).

These radioactive decay mechanisms involve not only the release of considerable amounts of energy (typically in the neighborhood of 1 million electron Volts or 1 MeV per decay) but they also transform the parent isotope into an isotope of another chemical element. The utility of radioactive decay to the field of geochronology derives from it providing the possibility of detecting either the buildup of decay products or the

decay of radioactive parent isotopes. From laboratory measurements over the past century, it has been possible to measure directly the rate at which radioactive isotopes decay. The energies involved in radioactivity are many orders of magnitude greater than the energies involved in normal chemical processes (typically about 1 eV). Furthermore, the physical scale of the nucleus is tiny compared with the cloud of electrons surrounding the nucleus that are involved in chemical reactions. This leads directly to the first assumption made in all radiometric dating techniques: radioactive decay processes are immune to the effects of chemical reactions or the presence or absence of other atoms.

This is almost certainly true for the α and β decay systems. However, there is a slight caveat with respect to the K-capture decay system, where high pressure can increase the electron density in the vicinity of the nucleus and therefore it can slightly raise the natural decay rate. This effect has been documented for the decay of ^7Be , but for the extremely important decay system involving the decay of ^{40}K into ^{40}Ar , it is not expected to be significant, even for pressures experienced in the upper mantle. In any event, the dating of material involved in the study of paleoclimates will always involve near surface processes, and the possible variability of K-capture decay is not likely to be a concern.

The second critical assumption in radiometric dating is that the process of decay is a random event and that the probability of the decay happening per unit time is a constant. This leads directly to the essential differential equation of radioactivity:

$$\frac{dP}{dt} = -\lambda P \quad (1)$$

where P is the concentration of the parent isotope and λ is called the decay constant. For geologically important isotopes, it is given in units of yr^{-1} . Equation (1) merely states that the rate of decay of a radioactive isotope is a simple linear function of the isotope's concentration. The solution of Equation (1) is given by:

$$P(t) = P_0 e^{-\lambda t} \quad (2)$$

where P_0 is the parent isotope concentration at formation or at zero time. One can also solve Equation (2) for the time that it will take for the parent isotope concentration to be one half of its original value, or its half life ($t_{1/2}$), and this time is given by $\ln(2)/\lambda$. The decay of the parent isotope as a function of half-lives is shown in Figure D23.

Short-lived systems

An important class of radiometric dating methods uses the decay of short-lived radioactive isotopes. In this case, $t_{1/2}$ is much lower than the age of the Earth, and the parent isotope is continually being produced in nature, usually by the action of energetic cosmic rays on the atmosphere or the Earth's surface. Typically, the daughter product is a common isotope and its buildup is not detectable. Instead, the concentration of the parent is measured, and the age equation for this class of methods can be solved from Equation (1) by:

$$t = \frac{1}{\lambda} \ln\left(\frac{P_0}{P}\right) \quad (3)$$

where P is the present day isotope concentration, and P_0 is the concentration at time zero.

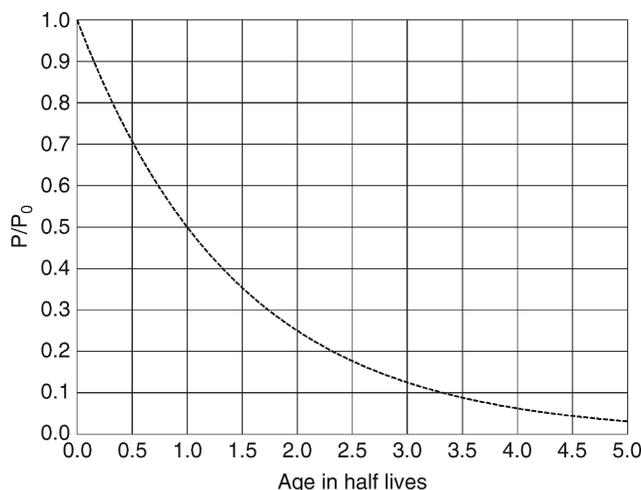

Figure D23 Decay of parent as given by Equation (2).

A critical assumption common to all of these dating methods is that one must know the value of P_0 . Frequently, this is based on the present day production rate of the isotope and it is assumed that this production rate has remained constant through time. Unfortunately, this assumption is often only approximately correct. The Earth's magnetic field strength, which varies significantly over both historical and geological time scales, can modulate the flux of cosmic rays and solar wind particles striking the Earth, and the assumption of constant production rate is not, strictly speaking, correct. However, there are often other methods that can be used to calibrate the parent isotope production rate, such as the use of dendrochronology to calibrate the ^{14}C technique.

From Equation (3), it can be determined that the highest parent isotope concentration is occurring now, and the parent isotope concentration will be lower for older and older samples. Eventually, for material older than about 10 half-lives, the measured concentration will only be less than 1/1,000 of the original value and will be very difficult to estimate accurately. This means that there is a basic time limit for short-lived decay methods, and they are most accurate for relatively young samples (Figure D23).

Ideally, one would like an independent test for, or a correction for, the assumption that the parent isotope's production rate is constant. Using two different parent isotopes as independent chronometers can sometimes achieve this. Specifically, by combining the decay of ^{10}Be and ^{36}Cl , and assuming that their production rates keep the same proportion, it is possible to eliminate uncertainties in the absolute production rate.

Long-lived systems

Typically, for samples that are more than a few half-lives old in short-lived systems, one must employ a different strategy, in which the daughter product of a long-lived radioactive isotope is measured. Such a parent isotope has to exist since the formation of the Earth, and therefore its half-life will be measured in billions of years. Examples of useful isotopes with this property are ^{40}K , ^{87}Rb , ^{147}Sm , ^{235}U , and ^{238}U . For such systems, the ratio of the daughter isotope to the parent isotope in the laboratory is

a monotonically increasing function of the geological age of the sample. The differential equation that governs the buildup of the daughter isotope D is given by:

$$\frac{dD}{dt} = \lambda P \tag{4}$$

As with Equation (1), the rate of daughter product production is a simple linear function of the concentration of radioactive parent (see Figure D24). When combined with the solution to Equation (1), the fundamental equation of long-lived radiometric dating systems results:

$$t = \frac{1}{\lambda} \ln \left(1 + \frac{D}{P} \right) \tag{5}$$

Here D is the present-day concentration of the daughter product that is present in the sample due to radioactive decay, and P is the present-day concentration of the radioactive parent. One of the simplest examples for the use of Equation (5) is for the Rb-Sr chronometer, where P is the concentration of ^{87}Rb and D is the concentration of “radiogenic” ^{87}Sr . “Radiogenic” means that the ^{87}Sr present in the rock is present due to the decay of ^{87}Rb .

Related to the long-lived clocks are a host of systems that, instead of measuring a radiogenic daughter product, measure some effect that slowly increases in the sample either due to in situ radioactive decay or some external source of radiation. Examples include fission track dating, where the “parent” is naturally fissionable ^{238}U and the effects are tracks of crystal damage due to collisions from the fission fragments; thermoluminescence (TL), where the effects are photons released from meta-stable electrons trapped in crystal defects; and cosmic ray exposure ages (e.g., Ne dating), where the effect is a build up of a nucleogenic product from the interaction of energetic cosmic rays. Many of these techniques require the estimation of a radiation dose rate, and some (e.g., TL) have an effective upper limit to the age they can measure. That is, the effect saturates and after a certain amount of crystal damage, no more time can be recorded.

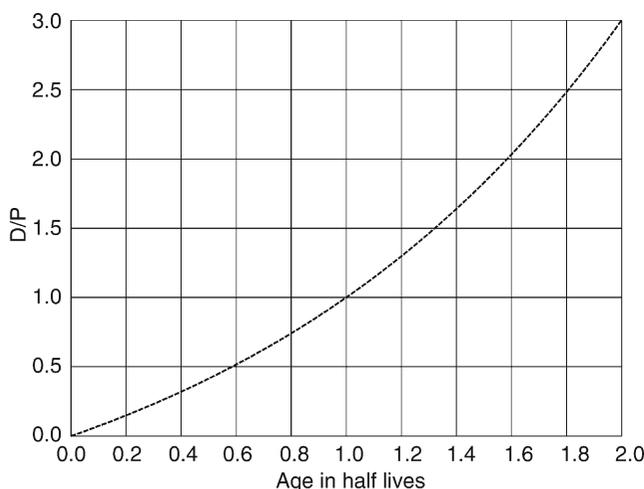

Figure D24 Graphical representation of the solution to Equation (4).

What makes a good clock?

A good geological clock, like a good wristwatch, must run at a known rate and it must record events faithfully. What does that mean in a geological setting? First, the rate of decay of the radioactive parent into the daughter product should be constant over time. This is essentially true for all radiometric systems. Second, the clock must record an event. This involves some chemical reaction that either isolates the parent isotope from the environment, in the case of short-lived systems, or it involves the chemical separation of the parent chemical from the daughter for long-lived systems. This event essentially “resets” the clock. Thereafter, the isotopic clock must record time faithfully, which means that the concentrations of both parent and daughter are only determined by time, and not by the geochemical environment. For example, in the Rb-Sr system, one wants a rock or mineral that has an enrichment of Rb and a removal of all radiogenic Sr from the sample at some zero time, such as at the mineral’s formation. Subsequently, there should be no addition or loss of either Rb or Sr until the sample can be analyzed in the laboratory. Under such conditions, Equation (5) will correctly give the age of the sample.

Unfortunately, perfection in a radiometric clock is hard to achieve. For example, some chronometers, such as Rb-Sr and Sm-Nd often only have small separations of parent isotopes from daughter isotopes during formation or alteration, so there is frequently a significant quantity of daughter isotope present at time zero. However, there are usually other non-radiogenic isotopes of the daughter element (e.g., ^{86}Sr) that can be used to correct for the presence of initial daughter isotope concentrations.

The most powerful short-lived clocks have a homogeneous concentration of the parent isotope until time zero, whereupon the parent is perfectly isolated from the environment and its decay faithfully records geological time. The most powerful long-lived radiometric clocks have extremely efficient separations of parent isotopes from daughter isotopes, thereby clearly resetting the clock at a distinct time. Subsequently, the rock must tenaciously retain both the parent and radiogenic isotopes. Currently, the most widely used short-lived system is based upon the decay of ^{14}C and the event measured is the time for an organic sample to become isolated from the environment’s homogeneous concentration of ^{14}C relative to the stable isotope of carbon, ^{12}C . The most powerful long-lived radiometric systems are based on the decay of ^{40}K to ^{40}Ar , or the decay of U isotopes into isotopes of Pb. In both of these cases, geologically important events can cause extremely large separations of parent from daughter and the retained radiogenic daughter isotopes are relatively easy to identify.

What does an “age” mean?

This is a central philosophical concept in the whole field of radiometric dating that is sometimes not considered by people trying to use this kind of data. Simply put, a radiometric date is a measure of the time needed to go from some known or presumed initial isotopic state to the state measured in the laboratory. For ^{14}C , this will be the time since the sample was isolated from the biosphere’s C reservoir; for Ar, it is the time since the sample started to retain Ar; for Sr, it is the time needed to increase the measured $^{87}\text{Sr}/^{86}\text{Sr}$ ratio above a known initial value. What starts the clock may be the formation of the rock or mineral, as is frequently the case for U-Pb ages of zircons

and Ar ages of young volcanic sanidine crystals, but it might be something more subtle.

Chemical alteration or other metamorphic processes can partially or completely reset the radiometric clock; the apparent age may therefore be the time of metamorphism or a value between formation and alteration. Some chronometers are especially sensitive to temperature, such as fission track, TL, K-Ar dating of feldspars, and the U-Th-He system. In such cases, the age that is measured is often the time since the sample has been cool enough to retain either the buildup of an effect (e.g., crystal damage as in TL and fission track) or the retention of a daughter isotope (e.g., ^4He , ^{40}Ar). Such ages are often referred to as “blocking temperature” ages, where the age represents the time since the sample cooled below the temperature at which the slow resetting of the clock is blocked. This is a particularly powerful concept for the U-Th-He system, where the effective blocking temperatures are extremely low and thus the clock is very useful for measuring the exposure ages of rapidly uplifted and cooled terranes.

Thus, it is important to take into account the context of the material that is being measured when assessing radiometric ages. The sample’s physical form and knowledge of the processes that can “reset the clock” are vital for understanding the numbers produced by the laboratory instruments.

Methodology

For the vast majority of radiometric dating methods, the basic instrument that is used is the mass spectrometer. Mass spectrometers take samples, separate them by mass into constituent isotopes, and measure the relative concentrations of these isotopes with electronic detectors. The instrument consists of three main parts: an ion source in which the sample’s atoms are ionized and accelerated by an electric potential; an analyzer region in which the ions are separated by mass, typically by bending the path of the ions with a magnetic field; and a detector section where the ions are collected and measured.

Ion sources

The first main distinction between different mass spectrometer types occurs at the ion source end. The choice of machine is largely determined by the element to be analyzed and how difficult that atom is to ionize. The elements with the highest ionization potential and that are the most difficult to convert to positive ions are the noble gases. For these elements, the ionization method of choice is the electron bombardment source. In this type of ion source, an electron beam with an energy of about 100 eV bombards the sample, knocking off an electron and converting the sample atom into a positive ion. The sample must be introduced under vacuum into the source in gas form and hence these machines are often called gas source mass spectrometers. This type of ion source is ideal for Ar dating, but it is inconvenient for other metallic radiogenic elements, such as Sr, Rb, or Pb, where it is difficult to convert the sample into a gas.

Fortunately, most metals have much lower ionization potentials than the noble gases. For them, the machines of choice are thermal ionization mass spectrometers (TIMS). In TIMS machines, the sample is chemically separated from other elements and it is dissolved in an aqueous solution. This solution is loaded onto a thin filament of a refractory metal such as tungsten or rhenium. After the filament is loaded into the ion

source and a high vacuum is achieved, an electric current is passed through the filament to heat it to a high temperature. In some cases, the metal is ionized by thermal energy directly on the original filament, but in other cases, the sample is expelled from the original filament as a neutral atom and contacts another hot filament where it is ionized. In any case, the method works using the relatively low energy ($\sim\text{eV}$) available from the white-hot filament material. For positive ion sources, it is also necessary for the sample element to have a significantly lower ionization potential than the filament material, otherwise the ions produced will mostly be from the filament itself. This means that hard to ionize elements like tungsten, hafnium, and the platinum group elements are difficult or impossible to measure using TIMS machines.

Sometimes, however, the tenacity with which sample atoms want to retain electrons can be used as an asset. For osmium, for example, thermal ionization produces a significant number of negative ions, where the sample atoms actually steal electrons from the filament metal. Negative thermal ionization mass spectrometers (NTIMS) are similar in form to TIMS machines, but all of the ion acceleration potentials and magnetic fields must be reversed.

Electron bombardment can ionize anything, but requires that the sample be in gas form. TIMS can be used for most, but not all metals. An ion source that can ionize almost any element and that has gained considerable favor in the past two decades is the inductively coupled plasma (ICP) source (Halliday et al., 1995). This source uses a high-powered radio-frequency induction coil to create plasma in a carrier gas, usually argon. Samples are dissolved in a liquid and introduced into the plasma using an aerosol device. The plasma itself is a gas of argon ions and free electrons that interacts with the sample atoms, ionizing them in the process. The energies available in an ICP source are typically about 5–10 eV, and are therefore intermediate between the ionization energies possible for electron bombardment and TIMS sources.

For in situ ionization of elements within a rock or mineral, the method of choice is frequently a focused ion beam that strikes a sample under vacuum, causing not only ablation of a variety of elements, but also causing ionization as well. This method is the front end of ion microprobes and with advances in analyzer sections and detection systems, these machines can collect precise isotope ratio data on elements in extremely small spots. There are a host of difficulties involved with this approach, not least of which is the fact that many different ion species are produced, thereby requiring an extremely high mass resolving power to separate ions that might only differ in mass by a few parts per thousand. However, the ion microprobe technique has been extremely valuable in geochronology, especially for U-Pb dating of zircons, which frequently have complex mixtures of domains of different ages. The high spatial resolution afforded by ion microprobes is essential, in such cases, for unraveling the detailed histories often recorded within a single grain.

Mass analyzers

Isotopes are separated for analysis by three main types: electrostatic analyzers (e.g., quadropoles), magnetic sector machines, and time of flight instruments. In electrostatic analyzers, the ion beam accelerated out of the source is put through a region of static and oscillating electric fields. It is possible to tune the frequency of the oscillating field such that nearly all isotopes

follow a path that is unstable and causes collision with the sides of the analyzer section. Only isotopes with masses within a narrow range of values follow an oscillating path narrow enough to survive the trip all the way through the analyzer and into the detector section. Electrostatic instruments have several advantages: they are relatively inexpensive; they tolerate a wide range of instrument pressures; and they can be small and light, making them attractive for space science applications. Traditionally, quadropole machines have been comparatively low precision machines because it has been difficult to establish conditions where the selected isotope has perfect transmission all the way from source to detector, making the measurement of extremely accurate isotope ratios harder to achieve than with magnetic sector machines. However, when isotope ratios do not need extremely high accuracy, and when mass resolution requirements are not too high, quadropoles can be very useful. In particular, they seem to be the instrument of choice for U-Th-He dating.

The vast majority of instruments used for precision radiometric dating utilize a magnetic sector analyzer. Simply put, the ion beam is fired into a zone where there is a strong magnetic field at right angles to the direction of flight of the ions. This causes a sideways acceleration, which in turn forces the ions into a circular path. The mass separation occurs because heavy isotopes "corner" this race-track in a wider arc than do light isotopes. This geometry has the additional advantage that there is a natural focusing effect so that ions leaving from a small spot in the ion source are refocused into a similarly small region at the detector. Thus, it is possible to have very high resolving power between similar masses and it is possible to assure that all of the ions of a given mass that leave the source can arrive at the detector. Determining which mass strikes the detector is done by varying the magnetic field, the accelerating voltage, or both.

Ion microprobes sometimes use a time-of-flight mass analyzer. In this type of analyzer, atoms are released from a spot on a sample using a short burst of ions, ionized, and accelerated down a flight tube by an accelerating voltage pulse that is precisely timed to coincide with the formation of the ions. To keep our race-track analogy, the time-of-flight machine is like a straight sprint. The lightest ions rush out in front of the heavier ions. In this type of machine, the mass separation occurs at the detector, which must be able to time resolve individual ions striking within microseconds of each other. This calls for both a sensitive and a fast detector.

Detectors

The simplest kind of ion detector, and the detector of choice when high precision is essential and where sample size is not a limitation, is the Faraday detector. This detector is simply a metal bucket placed at the end of the analyzer, which is in turn electrically connected to an electrometer. An electrometer is an exceptionally sensitive ammeter that converts the ion current entering the bucket into a measurable voltage using a high-sensitivity pre-amplifier and a high resistance feedback resistor. For Faraday detectors, the dominant form of noise is usually thermal or "Johnson" noise caused by thermal agitation within the feedback resistor. The importance of thermal noise can be minimized by having as high a value of resistance as possible, and this is typically 10^{11} Ohms. That means that an ion current of 10^{-11} A will create and output signal of 1 Volt. The performance of Faraday detectors is limited by thermal noise, slow

response due to capacitative effects, and non-ideal behavior in high value resistors. When the sample size is large enough, however, Faraday detectors can have extremely high precision.

The highest precision isotope ratios are measured using multiple collector (MC) Faraday detector systems. In MC-TIMS or MC-ICP machines, having multiple collectors allows for simultaneous collection of different mass isotopes. This eliminates any difficulties caused by instabilities in the source region (especially important for ICP sources), and it is often possible to quickly measure isotope ratios to within a few parts in 10^6 .

When speed or extremely high sensitivity is required, a "multiplier," or related device is almost always used. This might be an electron multiplier directly detecting individual ions, or it could be a so-called Daly detector, which fires off a few electrons from the ion impact site and those electrons in turn cause a flash of light at a scintillation window. The light is then amplified using a photo-multiplier. Multipliers operate as extremely high-gain, low-noise amplifiers by creating an ever-increasing cascade of electrons from a single ion/electron/ photon impact. Multipliers can operate in analog mode, where the incoming ion stream is merely amplified, usually by 10^4 to 10^6 or so. In this mode, the effectiveness at low levels is limited by so-called dark current, where a small current flows through the multiplier with no input signal.

The best performance is achieved when multipliers are operated in ion counting mode, where each incoming ion produces a discrete current pulse that is individually counted, thereby providing for single atom detection. There are limits to the effectiveness of multipliers, however, as they have a fundamental quantum noise limit (so-called "shot noise"). The counting of individual ions is similar to a public-opinion survey, and it is governed by the same Poisson statistics. This means that if, in a given time period, one counts n ions, that rate is representative of the true concentration only to within about the square root of n and the relative error estimate for the measurement will be the reciprocal of the square root of n . Therefore, to be able to measure to within one part in 10^5 , a precision quite achievable for Faraday detectors, about 10^{10} ions must be counted. The maximum count rate for multipliers is typically about 10^6 ions per second, which means a single channel would need to be counted for almost 3 h to match Faraday precision. For most cases, multipliers are used for low intensity ion beams where extremely high precision is not necessary.

Accelerator mass spectrometers

Accelerator mass spectrometers (AMS) are a class of machines that combine many of the techniques mentioned above with extremely high accelerating voltages in the analyzer sections, typically more than 1 million Volts. AMS has especially revolutionized the field of ^{14}C dating by allowing for the direct detection of miniscule quantities of ^{14}C in a vast ocean of other isotopic species or molecular fragments. This is accomplished by analyzing only negative ions (eliminating the ubiquitous ^{14}N) and using the high voltage to smash apart possible interfering molecules by passing the ions through a foil or gas barrier. The combination of methods allows for extremely high sensitivity, and AMS machines are vital for measurement of other rare short-lived species, such as ^{36}Cl .

Analysis and interpretation techniques

Mass spectrometers are excellent at measuring isotope ratios, but it is very difficult to directly measure absolute quantities

of material. For this reason, almost all interpretation involved in radiometric dating involves the use of isotope ratios. In fact, when an absolute concentration measurement is needed, it is usually performed with a technique called isotope dilution, where a known quantity of a rare isotope (a “spike”) is added to a sample and the sample’s concentration is deduced by the ratio of its main isotope to that of the spike. An example of this is in U-Th-He dating, where a known volume of the extremely rare ^3He isotope is added to the ^4He in the sample, and the sample concentration is calculated from the measured $^4\text{He}/^3\text{He}$ ratio.

In some cases, resetting the radiometric “clock” involves such an efficient separation of parent from daughter that at zero time there is essentially no daughter isotope present. In such cases, the daughter to parent ratio can be immediately measured and Equation (5) can be used to calculate an age. However, in most systems, there is a significant presence of daughter isotope in the sample inherited at time zero. A variety of methods that can be generally classified as “isochron” techniques have been developed to allow for the presence of initial daughter isotope and to calculate the amount of daughter present due to the in situ decay, i.e., the radiogenic component. As usual, one of the simplest systems to illustrate this is the Rb-Sr system, where the isotope method is almost always crucial for an accurate age determination.

Isochron analysis in the Rb-Sr system assumes that all of the mineral phases of a rock share the same initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio, where ^{87}Sr is a daughter product of the radioactive parent ^{87}Rb , and ^{86}Sr is non-radiogenic. Different minerals will tend to have varying Rb/Sr ratios, however. At the limit of zero Rb, the measured $^{87}\text{Sr}/^{86}\text{Sr}$ ratio should be the initial Sr isotopic composition inherited at time zero. For mineral phases with non-zero Rb, the measured $^{87}\text{Sr}/^{86}\text{Sr}$ ratio should be a linearly increasing function of Rb concentration whose slope is in turn a function of the age of the sample. This relationship is given by:

$$\frac{^{87}\text{Sr}}{^{86}\text{Sr}} = \left(\frac{^{87}\text{Sr}}{^{86}\text{Sr}}\right)_0 + (e^{\lambda t} - 1) \frac{^{87}\text{Rb}}{^{86}\text{Sr}} \quad (6)$$

In practice, different mineral separates or chemical leaches are analyzed for Rb and Sr, and the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are plotted

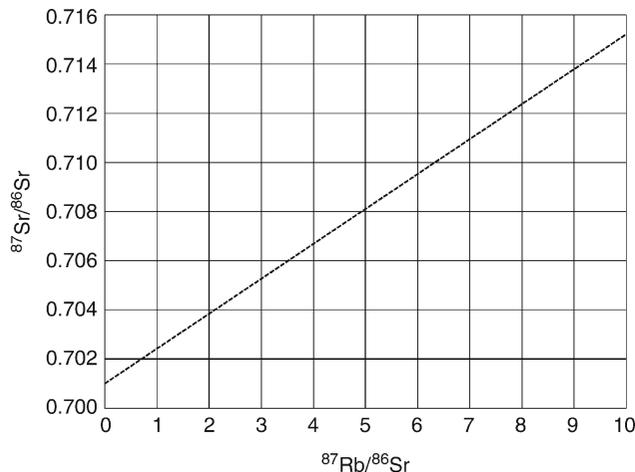

Figure D25 Synthetic isochron plot for a 100 million year old rock with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.701.

against $^{87}\text{Rb}/^{86}\text{Sr}$. If the isochron assumptions are valid, the data points will form a linear array where the intercept yields the initial Sr isotopic composition and the slope give a measure of the sample’s age (Figure D25).

All of the radiometric techniques have some analogous analysis system and some complexities (e.g., U-Th disequilibrium). Consult the individual topics listed under “Cross-references” for more details.

DEEP SEA DRILLING PROJECT (DSDP)

The Deep Sea Drilling Project (1968–1983) was a 15 year program of exploration of the sediments on the ocean floor and the upper part of the underlying crust, recovering cores from 624 sites throughout the oceans (Figure D26). In 1981, Emiliani described it as “*unquestionably . . . the largest and most successful program of geological investigation ever undertaken by man.*”

Origin

The idea of drilling a hole in the ocean floor originated in 1957 from a group of American geoscientists led by Walter Munk and calling themselves the “American Miscellaneous Society” (Emiliani, 1981; Winterer, 2000). They believed that a major advance in knowledge would result from sampling the Earth’s mantle, and that this could be most effectively accomplished in the ocean where the thickness of the Earth’s crust is minimal. The idea was to drill through the Mohorovičić discontinuity (“the Moho”), the level where a sharp increase in velocity of seismic waves is taken as defining the boundary between the crust and the mantle. This became known as Project Mohole. It was thought that some incidental information on the history of the Earth might also be obtained. At that time most American geologists considered the ocean basins to be permanent ancient features, and the deep sea to be an unchanging environment. It was assumed that its sediments would contain a monotonous 4 billion year history.

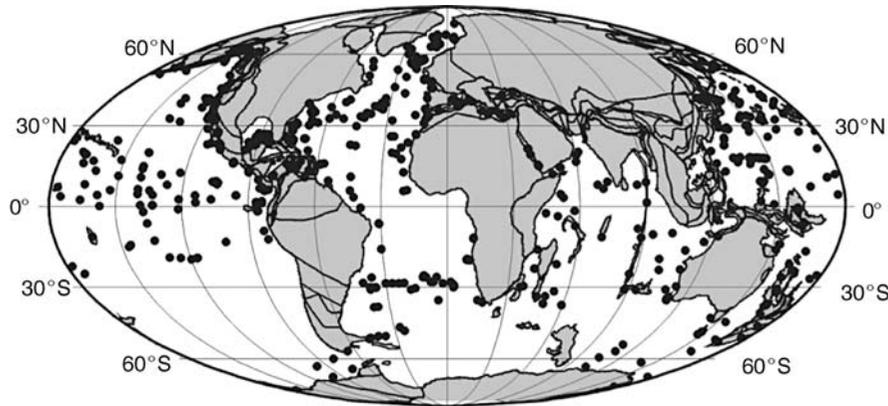

Figure D26 Sites cored by the Deep Sea Drilling Project (1968–1983). Map made using the ODSN plate tectonic mapping program (www.odsn.de).

To drill through the ocean floor in water 4–5 km deep would require that the drilling platform be nearly stationary for long periods of time. Anchors could not achieve this – the platform would need to be a vessel “dynamically positioned” by propellers. Further, it would be necessary to pull up the string of drill pipe, change the drill bit, lower the bit and pipe back down to the sea floor and re-enter the hole in the ocean floor. None of the necessary technology existed at that time.

Tests of the feasibility of drilling into the ocean floor were carried out as “Phase I” of Project Mohole, using a drilling barge, *CUSS I*, in the spring of 1961. For this work *CUSS I* was specially outfitted with outboard propellers and a system for positioning it relative to anchored buoys using radar. Its first test was in 948 m of water off La Jolla, California, penetrating 315 m of sediment. The barge was then moved to a site in 3,558 m of water 40 km east of Guadalupe Island off Baja, California, where it penetrated 170 m of sediment and 13 m of seafloor basalt. Encouraged by these results, Phase II of Project Mohole was to design the drilling vessel to reach the Moho. By 1966 the Phase II engineering had cost \$25,000,000 and the United States (U.S.) Congress cancelled the project.

Other geoscientists, notably Maurice Ewing and Cesare Emiliani, believed that much could be learned from the sedimentary record in the deep sea. At that time sediment cores were limited to the 20 m or so that could be recovered by piston coring devices. Ewing had approached several petroleum companies proposing a program of drilling and coring on a latitude-longitude grid. Emiliani argued that much more could be learned by drilling and recovering long sediment cores designed to investigate the history of the ocean (“Project LOCO”) rather than one single hole into the mantle. A LOCO advisory committee was established with scientists from several oceanographic institutions. Project LOCO was initiated using a small drilling vessel, *SUBAREX*, in November and December of 1963, coring late Tertiary and Quaternary sediments on the Nicaragua Rise.

Four oceanographic institutions, Lamont Geological Observatory (now Lamont Doherty Earth Observatory), Woods Hole Oceanographic Institution, Scripps Institution of Oceanography, and the University of Miami’s Rosenstiel School of Marine and Atmospheric Science then joined together as “JOIDES” (Joint Oceanographic Institutions for Deep Earth Sampling) in 1964. They proposed a program of coring a

transect of holes to depths of several hundred meters on the Blake Plateau east of Jacksonville, Florida. This was accomplished using the drill ship, *CALDRILL*, in 1965, with the Lamont Geological Observatory as the operating institution. A party of shipboard scientists from a variety of institutions was aboard and performed initial analysis of the samples. This was to become the model for future operations. The sediment cores were much more complete than those of the earlier feasibility tests, and it was evident that obtaining long sequences of sediment from the ocean floor was a practical endeavor.

Geology in the 1960s and the Deep Sea Drilling project proposal

In 1966 JOIDES proposed a program of ocean drilling as the “Deep Sea Drilling Project (DSDP)” to the U.S. National Science Foundation. The proposal was for 18 months of drilling on transects across the North Atlantic, South Atlantic, Caribbean Sea and Pacific Oceans. The project was proposed at a critical moment in the history of geology. When Project Mohole had been conceived it was widely accepted that the ocean basins were ancient features, but some geologists noted that there were odd features about the ocean floor: Why was there only an average of 0.5 km of sediment in the deep sea? Why was there no sediment on the ridge that extended down the middle of the Atlantic? Further, in 1954 Emiliani had discovered that oxygen isotope ratios in the shells of deep sea benthic foraminifera indicated the deep ocean to have been warm in the middle Cenozoic, not cold as it is today – challenging the idea of an unchanging environment. The mid-1960s saw the publication of geophysical data suggesting that the ocean basins were young dynamic features. Mapping of the Earth’s magnetic field over the ocean south of Iceland and west of British Columbia and Washington showed alternating bands of magnetization. These magnetic stripes were thought to be produced by rocks that had formed and acquired their magnetization when the Earth’s magnetic field was alternately “normal” (magnetic north near the North Pole) and “reversed” (magnetic north near the South Pole). The hypothesis was that ocean crust formed along the mid-ocean ridge system and then moved away as new crust was emplaced. Ocean crust is returned to the Earth’s mantle along zones of convergence, such as oceanic trenches. In effect, the ocean floor consists of several large rigid plates, with new crust being added on one side, and older crust being lost

on the other side. If these hypotheses of “seafloor spreading” and “plate tectonics” were true, then the scientific assumptions that had gone into the design of Project Mohole were wrong. A single hole into the Earth’s mantle would not have globally applicable results.

The engineering work that had been carried out for Project Mohole became important for the DSDP. The dynamic positioning system designed for the Mohole vessel became a reality, and the technology for re-entering the drill hole on the sea floor was further developed. In 1967, a ship already under construction for Global Marine Corporation was modified to have thruster propellers installed; these can move the ship sideways to help maintain position. The ship’s location on the sea surface, relative to the position of the hole on the seafloor, would be determined using sonic beacons dropped onto the sea floor before starting the drilling procedure. The computer program to carry out the necessary calculation was the first of its kind. The ship was also equipped with the first commercial satellite navigation instrument to assist in finding the site for drilling. A rapid method of recovering cores was developed for use in the project. “Wireline coring” involves dropping a core barrel down inside the drill pipe to latch into the drill bit. The core is taken through an opening in the center of the bit by drilling ahead. When the core barrel is thought to be full, a recovery tool is dropped down on a wireline. On impact with the core barrel, this tool unlatches the core barrel from the drill bit so that it can be hauled back up to the ship. The uniquely outfitted research drill ship was christened *GLOMAR Challenger* in honor of *HMS Challenger*, the British ship that collected samples from the ocean floor from 1872 to 1876 (Figure D27).

The initial phase of DSDP

Scripps Institution of Oceanography was selected by JOIDES to be the operating institution for the DSDP. The *GLOMAR Challenger* sailed from Orange, Texas on 20 June, 1968. The project consisted of nine two-month “Legs.” The first Leg, in the Gulf of Mexico and off the Bahamas, produced a series of surprises. Some of the first coring efforts recovered no sediment at all in the core barrel, but some smears of sediment were found on the drill bit and outside of the core barrel. It turned out that these small smears of sediment contained large numbers of calcareous nannofossils. The nannofossils, carbonate skeletal objects only a few microns across, suddenly became

Figure D27 The *GLOMAR Challenger* (DSDP archive photograph).

one of the most important tools for dating ocean sediments. The second site drilled was “Challenger Knoll” – one of the hills on the Sigsbee Abyssal Plain that floors the deep Gulf of Mexico. One of the cores recovered was oil-saturated sediment, and other cores showed that the Knoll was the top of a salt dome. This discovery showed that petroleum could be found in the deep sea, a revolutionary idea at the time. It also meant that a safety review procedure was needed to ensure that no sites that might cause pollution or endanger the ship would be drilled. Off the Bahamas, cores of early Cretaceous (120 million year old) sediment consisted of black shales rich in organic carbon, indicating that the deep sea had been anoxic at times in the past, a condition that geochemists at the time considered impossible. Leg 1 also drilled to “Horizon A,” a prominent seismic reflector that extends throughout much of the North Atlantic and that had been thought to represent the Cretaceous-Tertiary boundary. It turned out to be Eocene cherty turbidite.

Leg 2 was a transect across the North Atlantic from the U.S. to Africa, intended to be a test of the seafloor spreading hypothesis. Horizon A was drilled at several sites but drilling was stopped by hard layers of middle Eocene chert. Except at three sites, the chert layers prevented drilling into the basement. Evidence for seafloor spreading was favorable but not conclusive. However, the extent of chert accompanied by layers of abundant diatom and radiolarian remains in the central North Atlantic was a mystery. Today such deposits form only in upwelling regions in the polar oceans, along the equator, and along the western margins of the continents. How they came to be deposited in what was the middle of the North Atlantic at that time remains an unsolved puzzle even today. Leg 2 also made the discovery that carbonate ooze could be underlain by red clay. The boundary between carbonate ooze found in shallower depths today, and red clay, which is deposited in greater depths, had been discovered in modern sediments in the 1920s. It was interpreted as representing the level at which the rain of carbonate shells from planktonic organisms living in the upper ocean encounters carbonate-corrosive deep ocean waters, and was termed the “calcium carbonate compensation depth (CCCD).” In 1968 it was thought that the CCCD was either a pressure-induced phenomenon or the top of frigid bottom waters emanating from the Antarctic. The presence of red clay beneath carbonate ooze was contrary to the notion of subsidence of the sea floor away from the mid-ocean ridges and was interpreted as reflecting tectonic movement, a change in the depth of the CCCD, or a change in organic productivity. It was concluded that the latter was most likely.

Leg 3 was a transect across the South Atlantic from Africa to South America and yielded a most spectacular result. No chert was present and the holes were continuously cored to the basaltic basement. It became evident that the sediments immediately overlying the ocean crust were younger toward the Mid-Atlantic Ridge. A plot of the age of oldest sediment versus distance from the ridge crest produced a straight line indicating that the age of the ocean floor in the South Atlantic was a linear function of distance from the crest of the mid-ocean ridge. Although many geophysicists already believed in seafloor spreading and plate tectonics, it was the results of Leg 3 that convinced the geological community. The impact of Leg 3 on the history of geology was the serendipitous result of the concurrent development of a revolutionary hypothesis and the appropriate instrument – the *GLOMAR Challenger* – to test it. Leg 3 also confirmed that large fluctuations of the CCCD had taken place in the South Atlantic. The shipboard

party proposed that there had been vertical motions of the entire sea floor of 1 km or more.

In Leg 4, the DSDP investigated the Caribbean. The purpose was to recover complete reference sections rich in the fossils, particularly planktonic foraminifera, used for global stratigraphic correlation. Most of the information on the stratigraphic distribution of these fossils came from the margins of the Caribbean Basin, notably from Trinidad and Venezuela. The Caribbean was also interesting because its structure appears to be intermediate between continent and ocean basin. The expert stratigraphic micropaleontologists who were on board for this coring program were surprised that the stratigraphic sections in the Caribbean Basin were much less complete than along the margins. Much of the sediment had been deposited below the CCCD and contained no calcareous fossils at all. Synthesis of the CCCD records from this and earlier Legs suggested that it was related not to organic productivity or vertical motions of the seafloor but to changes in the water masses in the deep sea. The “floor” of the Caribbean was found to consist of basalt sills of late Cretaceous age, although older rocks were known from some of the Antilles islands. The origin of the Caribbean remained enigmatic.

The *GLOMAR Challenger* planned to explore the eastern Pacific by a multi-leg north-south transect. However, it was found that much of the stratigraphic record in the northern part of the transect had been destroyed by dissolution of the carbonate sediment. Plans were quickly changed to substitute an east-west transect in hopes of obtaining a more complete record. This showed that the location and strength of the equatorial upwelling system reflected not only the postulated northwestward movement of the Pacific Plate, but other less well-understood factors. Attempts to sample the oldest ocean crust in the western Pacific were unsuccessful, with the drilling often being stopped by layers of chert.

The results of Phase 1 of the DSDP are summarized in reports in Anonymous (1975).

The extensions of the DSDP

The DSDP continued with a series of proposals from JOIDES providing for extensions funded as amendments to the contract from NSF. From its beginning, DSDP had a unique structure for selecting scientific topics to be investigated. JOIDES selected drill sites using advisory panels composed of scientists from a number of institutions. In 1971 the DSDP was placed under the direction of a scientist, M. N. A. Peterson, as Project Director. From then on, the entire program was guided by scientists at the working level.

The first extension, Phase 2 of the DSDP, was for 30 months and almost immediately resulted in a major discovery. Seismic profiles off eastern North America showed a peculiar feature in some areas, reflectors that cut across strata but paralleled the sea floor. The suspicion was that these “bottom simulating reflectors” might represent the base of a layer containing gas hydrates. Gas hydrates are ices in which a cage of water molecules surrounds a gas molecule, usually methane. They are stable solids at temperatures above the freezing point of water and under the high pressures produced by several hundred meters or more of water. Leg 11 drilled a section on the Blake Outer Ridge, between the United States and Bermuda. The cores contained white ices, which rapidly decomposed. The discovery of gas clathrates in the deep sea had a number of implications. Originally it was thought that they might serve as seals for reservoirs of methane in the deep sea (as they do

in Siberia), and might be a major natural resource. Calculations of the volume of gas that might be trapped beneath and within hydrates indicated that these might be the largest deposits of methane on Earth although it was not clear how they might be exploited. They also serve to cement and stabilize sediment on the continental slopes. If gas clathrates were to suddenly decompose as a result of warming of the deep ocean, for example, slopes might become unstable, resulting in massive submarine landslides. These topics are actively being explored today.

It was always planned that after each extension, the program would return to the original problem of sampling the Earth’s mantle, but the difficulties of such a task became ever more apparent as experience was gained in drilling into the deep sea floor. An important problem was re-entry into the hole on the sea floor. The basic engineering design had been produced as a study for Project Mohole, and on Leg 15 in the winter of 1970–1971, the first successful re-entry was accomplished. The procedure involves setting a large steel cone on the sea floor, and drilling through a hole in its center until the drill bit must be changed. The drill string is then hauled back up to the ship and the bit changed. Sonar and a television camera are inserted into the drill bit and the drill string is lowered to the sea floor. The sonar seeks reflections from reflectors on the re-entry cone, and the ship is guided manually over it. The final location is determined by the television camera, and when the drill bit appears to be directly over the hole, it is dropped into the cone and, with luck, re-enters the hole in the sea floor. Over the years, this procedure has become routine, and by the end of the DSDP 124 holes had been outfitted with cones and re-entered.

Phase 2 included drilling in the North Atlantic, Mediterranean Sea, central Atlantic, North Pacific, southwestern Pacific, Indian Ocean, and Red Sea. Drilling and coring in the Mediterranean indicated that it had been cut off from the world ocean. The intense evaporation at this latitude had dried it out completely, so that it was a desert at the end of the Miocene. The “Mediterranean Salinity Crisis” was almost unimaginable to many geologists even though late Miocene gypsum and anhydrite deposits had been known from sections exposed on land around the Mediterranean. The basin was suddenly filled with ocean water again at the beginning of the Pliocene. It has remained flooded ever since.

Phase 3 of the DSDP allowed the ship to continue to explore the Indian Ocean and to go to high latitudes in both the Atlantic and Pacific Oceans, to initiate exploration of the history of the Arctic in the Norwegian-Greenland Sea, and of the Antarctic with drilling in the Southern Ocean and Ross Sea, and to return to the Mediterranean and explore the Black Sea.

The results of Phases 2 and 3 of the DSDP are summarized in reports (Anonymous, 1975, 1976).

The international program of ocean drilling (IPOD)

Expansion of JOIDES from the four original institutions began in 1968 with the addition of the University of Washington. However, in 1972, JOIDES member institutions began discussions with potential foreign partners. In 1975 the JOIDES membership was expanded to include institutions and funding from the USSR, the Federal Republic of Germany, Great Britain, France and Japan, and five other U.S. institutions, providing both additional expertise and funding. The new phase was designated the International Program of Ocean Drilling (IPOD). It continued for 76 months, ending on 19 November 1983. During this phase, the ship drilled extensively in the Atlantic and Pacific Oceans, focusing on a series of specific topics. During the IPOD, it became mandatory for the sites to

be cored continuously. This had the advantage that a large number of complete Neogene sections have been recovered, as shown in Figure D28, but the disadvantage that much less is known about the Paleogene (Figure D29) and the Cretaceous (Figure D30).

There were major technological advances achieved during the IPOD. The hydraulic piston corer was introduced in 1978.

This is similar in function to the piston corer used to take samples from oceanographic vessels, but it replaces the normal core barrel at the base of the drill string. A moving piston remains in place as the core barrel is pushed into the sediment, and the result is much less disturbance of the core in soft sediments. This device has made it possible to recover the upper part of the sedimentary sequence in exquisite detail, and

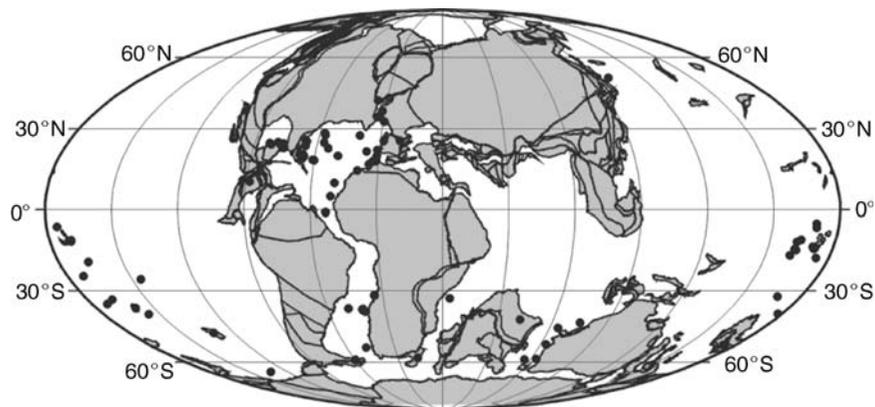

Figure D30 DSDP Sites penetrating the late Cretaceous. Recovery at Pacific sites is poor, and paleolocations in this sector are uncertain (ODSN plate tectonic mapping program).

permitted high-resolution analysis of the geologic record. Improved methods of measuring paleomagnetism in the cores, also introduced on board ship in 1978, made it possible to retrieve the magnetic signal from the cores much more reliably, with the result that determination of the magnetic stratigraphy could become a routine matter.

Coincidentally, refinement of methods of mass spectrometry made it possible to carry out measurements on stable isotopes on ever-smaller samples. It became feasible to measure isotopic ratios of oxygen and carbon on a massive scale and even to use these isotopic variations for stratigraphy. Again, this is an extraordinary example of serendipity in science, where the DSDP advances in core recovery technology and the advances in analytical technology combined to open new vistas.

The scientific results of the IPOD phase of the DSDP are summarized in reports in Anonymous (1979), Hay (1988), and Winterer (2000). Much of the work planned during IPOD carried over into the successor Ocean Drilling Program (ODP).

DELTAIC SEDIMENTS, CLIMATE RECORDS

Introduction

Deltas are low-lying alluvial plains formed near the mouth of a river, either along a lake or ocean shoreline, and commonly with a sizeable subaqueous deposit that extends offshore. The surface morphology of deltas typically consists of multiple

tributary channels that deliver sediment to different portions of the delta plain and nearshore. At the coast and onto the shelf, sediment deposition and morphological development in deltas are largely controlled by waves, tides, and riverine processes (Galloway, 1975). These factors dominate on shorter timescales of tens to hundreds of years. However, over millennial and longer periods it is generally agreed that delta evolution and sequence formation are controlled by: (a) climate, (b) tectonics, and (c) sea level. Unfortunately, these controls are not independent and so their relative roles in margin sequence development, particularly for deltas, remains a primary question in sedimentary geology.

Unraveling mixed signals of climate, tectonics, and sea level in deltas remains a difficult task, but the development of secular paleoclimate records in recent decades has, for the first time, allowed scientists to more faithfully (re)interpret stratigraphic and sedimentary records in the context of climate change. Previously, the impact of climate on delta systems had to be inferred through somewhat circular and indirect means (i.e., little independent confirmation of the presumed climatic forcing). Although this is also true of tectonics and sea level, the study of these controls had advanced decades before paleoclimate research and thus offered better-understood mechanisms and histories of change. However, it is now recognized that climate can vary at a much greater magnitude and more rapid rate than previously considered, and this dynamism prompts reconsideration of the role that climate plays in sedimentary processes and sequence development of deltas. Furthermore, significant advances in the numerical modeling of sedimentary and stratigraphic systems have for the first time allowed conceptual field-based models to be tested. In the case of climate records in deltas, this is particularly important because modeling can help deconvolve multiple forcing mechanisms and complex system responses.

Deltaic settings have not traditionally been targeted for paleoclimate reconstructions specifically because of their multiple environmental controls. Nevertheless, there remains intrinsic value in studying paleoclimate signatures in deltas because they serve both as: (a) primary receiving basins for land-derived erosional and weathering products, and as (b) point-sourced gateways for terrestrial fluxes to the ocean where many paleoclimatic records are deposited. Thus, the effects of climate change on entire watersheds are captured in deltaic deposits, which consequently filter climatic signals as they are transferred to marine repositories. Furthermore, deltaic settings and related marine deposits are generally important sites of carbon sequestration, closely tying carbon reservoirs with longer-term (>10⁴ yr) climate variations.

Influences of climate on deltas

Deltas can largely be considered a function of: (a) riverine water and sediment discharge to the continental margin, and (b) the interaction of these fluxes with coastal and marine processes. In this way, climate plays a major role in both the downstream forcing of the fluvial system and the modulation of sea level and coastal weather conditions. As such, there is strong overprinting of climate on deltaic systems, but precise signals are difficult to quantify because of complex feedbacks and secondary influences.

In the terrestrial realm of a delta system (i.e., the catchment basin), perhaps the most prevalent role that climate plays is via precipitation. With regard to sediment production, precipitation

is a primary control on glacial and fluvial incision, weathering, and slope failure. However, sediment is readily produced across a range of climates, from arid to humid and polar to tropical. What differs among such environments in terms of climate is hydrological runoff (=precipitation – evaporation) and thus the ability to transport sediment to the delta. In other words, sediment can be produced in many settings but is only transported to the delta with sufficient water discharge, which is primarily controlled by climate. Other important characteristics of precipitation include its phase (liquid vs. frozen), seasonality, and episodicity. First, the phase of precipitation controls the relative role of glacial and fluvial erosion in sediment production, as well as the timing and nature of water discharge (i.e., the river hydrograph). Each affects sediment-load grain size and weathering characteristics and, hence, the downstream development of delta stratigraphy. Second, the seasonality of river discharge affects the relative interaction of fluvial and marine processes, whereby strongly seasonal systems are subject to specific periods of river and marine-dominated conditions during the year. Similarly, the episodic discharge typified by storm-dominated or semi-arid river systems leaves a strong imprint on deltas, because sediments are delivered in large but infrequent pulses. Finally, precipitation exhibits strong secondary control on delta systems through the type and density of catchment vegetation, which affects runoff via overland flow and evapotranspiration rates as well as soil erosion rates. Quantitative modeling efforts have made progress in capturing the net effect of complex climate, hydrological, and sedimentary interplay, with Syvitski et al. (2003) recently showing that catchment-integrated temperature is a good predictor of fluvial sediment discharge. This strong relationship is linked directly with temperature's influence on precipitation, water phase, evaporation and consequently vegetation and discharge dynamics.

From the marine side of a delta, climate change plays primary roles in modulating both eustatic and relative sea level. Probably the strongest link between climate change and eustatic sea level has been the orbitally-tuned advance and retreat of continental ice sheets in the Plio-Pleistocene. The fate of deltaic systems under these 20–120 m sea level fluctuations has long been considered in the context of sequence stratigraphy (Vail et al., 1977), whereby the architecture and distribution of continental margin deposits has been used to reconstruct records of sea level change for much of the Phanerozoic. These general sequence models have been rigorously critiqued, though, with less than ideal results in reconstructing truly eustatic records of sea level change. However, among the major findings emerging from these studies are that sea level is not the overarching control previously thought and that influences of climate and tectonics on the terrestrial catchments are often of a similar magnitude to that for sea level (Shanley and McCabe, 1998). This further illustrates the frustratingly circular process of reconstructing climatic paleorecords based on stratigraphic sequences that are simultaneously being interpreted based on the same sequence-derived paleorecords. Hence, the secular derivation of climate history from lake, ice, and speleothem records bodes well for the unbiased interpretation of deltaic stratigraphic records.

Climatic signals in deltas

Because climate plays multiple roles in controlling deltaic systems, its signals and impacts may be looked for across a range of spatial and temporal scales. Typically, climate impacts on

larger fluviodeltaic systems are expected to be attenuated in the sizeable catchment, resulting in a weakened and delayed (10^4 – 10^5 yr) downstream signal (Castellort and Van Den Driessche, 2003). However, recent research has suggested that even large systems may respond rapidly to climate change when climate is a dominant control, such as in semi-arid and sub-tropical monsoon regions (Goodbred, 2003; Thomas, 2003). In smaller fluviodeltaic settings, high-frequency climate changes (10^{-1} – 10^2 yr) have a greater chance of influencing the entire sedimentary system and being preserved in the stratigraphic record, because the small catchment basin has limited storage capacity and signals are thus transferred more rapidly to the delta and shelf.

Climate impacts on deltaic systems may be manifested as geomorphic, stratigraphic, and sedimentological signals. Along the landward side of a delta, upstream of major subsidence (flexure) and accretion, geomorphic features are most likely to remain exposed and accessible for study. In such fluviually dominated reaches of a delta system, riverine terrace sequences and slackwater deposits have been used to reconstruct past hydrologic conditions. The terraces and slackwater deposits form at different elevations depending on the height of bankfull river stage, and hence water discharge. In several systems recently, the dating of bankfull features using cosmogenic radionuclides and optically stimulated luminescence have revealed that their timing and height correlates strongly with known Quaternary climatic variations (Repka et al., 1997; Yang et al., 2000). These records indicate that hydrologic conditions in fluviodeltaic systems vary significantly with millennial and orbital-scale climate change. A related manifestation of changing climate and hydrology is found in river planform morphology, which may vary in its degree of braiding and/or sinuosity (Bogaart and van Balen, 2000). Furthermore, river planforms reflect both sediment load and hydrology as they are largely controlled by ratios of total load/discharge and bedload/suspended load. However, as sediment load can also vary due to tectonic influences, river planforms are perhaps a more ambiguous link to climate than terraces and flood deposits.

Climate signals may also be preserved in delta stratigraphy, which similar to geomorphic signals, generally reflects changes in hydrology and sediment supply. Unlike upstream geomorphic records, though, delta sequences commonly preserve a relatively continuous stratigraphic record due to margin subsidence. Two signals of climate change recognized in delta stratigraphy include channelized-flood deposits, comprising coarse-grained sands to cobbles, and the architecture of deltaic strata and their stacking patterns, which reflect varying sediment inputs due to changing hydrological conditions. In hemipelagic deposits of the marine prodelta, climatically driven variation in river discharge are frequently recorded by alternations of bioturbated hemipelagic layers and organic-rich lithic sapropels reflecting dry and wet periods, respectively. The sapropels form due to high river discharge that: (a) supports high primary productivity and particulate carbon flux under elevated nutrient loading; and (b) enhances water-column stratification and the development of suboxic bottom waters, which limits organic matter degradation. For sedimentological records of climate change, such as microfossils, aeolian flux and grain size, these are also preserved in delta sequences but in many instances are overwhelmed by fluviually derived inputs. However, carbonate ooids that have formed locally off large sub-tropical river deltas likely reflect glacial period aridification and decreased fluvial discharge. Reduced discharge is implicated because modern ooids form

only in shallow waters of evaporative high-salinity settings. Furthermore, formation of carbonates at the rivermouths suggests limited sediment discharge, which would bury carbonate deposits and preclude their development.

Site cases

Until recently, few studies have specifically investigated climate signals and impacts in delta systems. The current knowledge base on this subject comes from several modeling groups, some field studies, and also by revisiting existing data with a better understanding of climate change from secular records. Although the list of site cases discussed below is not exhaustive, there are two relevant trends. First, the number of modeling studies equals or exceeds those based on field investigations, and second, the majority of delta systems in which climate has been investigated are located in the subtropics (the Rhine/Meuse a notable exception). Subtropical systems tend to be highly seasonal, receiving nearly all of their precipitation during the wet summer monsoon when the intertropical convergence zone (ITCZ) is most proximal. At orbital timescales, both the position and strength of the ITCZ varies in response to global boundary conditions (i.e., extent of continental ice sheets) and maximum summer insolation, respectively.

Nile delta (North Africa)

The Nile delta is located on the arid north coast of Africa, but the river's headwaters and main discharge source lie in East Africa where runoff is seasonally derived from the summer SW Asian monsoon. As such, water and sediment discharge to the delta have varied significantly with orbitally-tuned changes in monsoon precipitation. These variations are recorded in prodelta turbidites of the Nile system, which show alternating hemipelagic marls and organic-rich laminites that correlate with stable-isotope proxies for freshwater input. The individual marl/sapropel couplets track the 41-kyr precessional cycle, with packages at the 100-kyr and 400-kyr eccentricity cycles (Postma, 2001). These specific turbidite sequences are described from late Miocene to early Pliocene deposits. Younger records of climatic control have been recognized from fluvial terraces and channel planform along the Nile's middle reaches (Williams et al., 2000). Although these records are upstream of the delta, the changes in water and sediment discharge are almost certainly recorded at the margin but are yet to be described.

Ganges-Brahmaputra (South Asia)

The Ganges and Brahmaputra rivers drain the foreslope and backslope of the Himalayan front range, respectively. The two rivers coalesce near the Bengal margin to form the world's largest subaerial delta and deep-sea fan system. The rivers are also solely driven by the wet summer monsoon, when over 80% of water and 95% of sediment discharge occurs in only four months. Given global significance of the Himalayan/Tibetan uplift and its associated drainage systems, many portions of the Ganges fluvial delta system have been independently investigated in the past 15 years, revealing important variations in glacial activity, alluvial fan and floodplain development, delta evolution, and regional oceanography.

Taken together, the observed patterns show the immense Ganges dispersal system to respond to multi-millennial-scale ($<10^4$ yr) climate change in a system-wide and largely contemporaneous manner, and that major sedimentary signals are

transferred rapidly from source to sink with little apparent attenuation (Goodbred, 2003). Some of the major signals of climate change recorded in the delta stratigraphy include: (a) a thick (20–30 m) coastal mangrove facies that was deposited during rapid sea level rise in the early Holocene, and (b) a massive stored sediment volume stored during this period that reflects a sediment discharge at least 250% higher than the world's largest modern load of 1 billion tonnes (Goodbred and Kuehl, 2000). This high discharge period corresponds to the early Holocene hypsithermal, when peak regional insolation supported a stronger than present monsoon and associated precipitation. In contrast, signals recorded in the delta during the Last Glacial Maximum (18–20 ka) reflect aridification and very low river discharge. Carbonate ooids, typical of shallow, evaporative tropical waters, formed on the Bengal shelf at this time directly adjacent to the rivermouth (Wiedicke et al., 1999). Similarly, reconstructed planktonic foraminifera assemblages from the northern Bay of Bengal (Ganges discharge basin) indicate peak surface-water salinities corresponding to the LGM and apparently arid conditions (Cullen, 1981). These records from the delta and margin correlate well with findings from the catchment basin, and reflect the overall dominance of climate change in controlling this large fluviodeltaic system during the Quaternary.

Colorado, Brazos, and Trinity deltas (south-central North America)

These three rivers comprise a series of small catchments draining the semi-arid to moderately humid hills of central Texas, USA and discharging to the Gulf of Mexico. Presently, the rivers are driven by episodic floods and are forming small deltas at best. However, studies of the Texas shelf have revealed expansive fluviodeltaic sequences formed during a lower stand of sea level, and that they extend laterally and coalesce into an alongshelf composite delta system (Rodriguez et al., 1998). The shelf delta and its connection to upstream alluvial valleys are significantly larger than can be explained by modern hydrology and discharge, indicating an important change in climate or drainage basin character. The region is not tectonically active, but recent paleosol studies in the catchment reveal periods of significantly higher rainfall that are roughly correlative with the delta formation (Stiles et al., 2003). Although a definitive connection between the large Texas shelf deltas and a previously more humid climate has not been established, available data and examples from other similar systems imply a probable and significant linkage.

Rhine-Meuse delta (north-central Europe)

The Rhine-Meuse river drains central Europe and discharges to the southern North Sea coast. Much of the research on this system during the past decade has had a focus on understanding the signatures of climate and eustasy contained in the late Quaternary stratigraphy and geomorphology (Törnqvist, 1998; Veldkamp and Tebbens, 2001). Being a temperate river system, climatic forcings have probably not varied as dramatically as in the sub-tropical systems, but nonetheless the magnitude, timing, and nature of discharge appear to have played a role in shaping the fluviodeltaic system upstream of the hinge line. Terrace development in this river-dominated reach of the system is recognized as a primarily climate-controlled process through both modeling and field studies. However, the downstream impacts of such hydrological changes in the Rhine-Meuse

system appear to be insufficient to overcome the dominant influence of glacioeustasy during the Quaternary. There are likely climate impacts at the delta and margin but these are indistinguishable at the current resolutions of data and modeling.

Modeling studies

Climate has long been recognized as an important control on fluviodeltaic systems, but it has been difficult to confidently link observed stratigraphic and sedimentological signatures to climatic forcing. Such limits of field investigations are reflected in the relatively restricted results discussed above. However, exponential increases in computing power have allowed major advances to be made in the numerical modeling of fluvial and deltaic systems. Several current models offer the opportunity to compare results of system forcing by any combination of climate, eustasy, and tectonics, thereby helping to elucidate the specific character of climate impacts on stratigraphic sequences. In addition to modeling of the Rhine-Meuse mentioned above, the Niger delta sequence has also been investigated using an industry-based model (Van der Zwan, 2002). Investigation of the Niger was aimed at testing the impact of presumed Milankovitch-scale variations in sediment discharge over the Neogene. The orbitally linked forcing of regional climate and sediment occurred via global climate, insolation-control of monsoon strength, and vegetation. Results suggest that sediment supply does vary at both the large-scale (Ma) and Milankovitch-scale time frames under climatic forcings, and that there was a modest impact on stratigraphy. However, under icehouse conditions with rapid glacioeustatic sea level change, fluctuations in climate-forced sediment supply were greatly overshadowed. These findings echo those of other modeling studies in that climate is often found to be an important, but secondary, control on fluviodeltaic sequences. Furthermore, most modeling studies strongly suggest that climatic signals at the margin greatly lag the actual forcing in the catchment basin (Castelltort and Van Den Driessche, 2003). This notion conflicts with recent field evidence from several of the sub-tropical rivers discussed above. Much of these discrepancies likely arise from our limited knowledge of appropriate input values for pre-modern climate, riverine, and coastal conditions.

Conclusions

Deltas are heterogeneous systems controlled by a suite of processes, which altogether makes it challenging to isolate climate signals and their impacts. Nevertheless, climate is well recognized as a primary control of deltaic systems, and the ongoing reconstructions of secular climate records will allow better linkages to be made between climate and the stratigraphic record. If recent trends in both field and modeling efforts continue, then our understanding of climate's role in controlling river deltas and seaward basins is almost certain to advance quickly with the application of available paleoclimate records. Ultimately, our understanding of such systems will be sufficiently advanced that new information about climate change and its impacts can be determined by specifically targeting the complex, but high-resolution, archives contained in deltaic sequences.

DENDROCLIMATOLOGY

Introduction

Dendroclimatology is the branch of dendrochronology that utilizes absolutely dated and annually resolved growth layers in woody plants, such as trees, for the reconstruction and analysis of past climate variability. The same underlying principles of dendrochronology (described in *Dating, dendrochronology*) still apply. At the core of dendroclimatology lies the central tenet of all dendrochronological applications; the accurate *crossdating* of multiple tree ring samples that are all uniformly controlled by climate, such that the same signature of narrow and wide (or dense and less dense) rings can be identified in all of the sampled trees across time and space. The stronger the common “signal” between trees (i.e., the greater the degree to which narrow or wide rings are consistently narrow or wide), the stronger will be any reconstruction of climate that is derived from them. Methodologies have been developed for testing *signal strength* in chronology indices, and for *calibration* and *verification* of climate/tree-growth models, and these will be discussed in the ensuing sections.

As suggested above, climate may influence tree growth across space and time and can result in a high degree of common variability expressed in the pattern of annual growth rings in trees across broad regions (Douglass, 1919; Fritts, 1976; Hughes et al., 1982; Cook and Kairiukstis, 1990). The tree ring chronologies with the highest degree of strength in their common signal tend to be from regions where climate is at its most limiting to growth, and is most regionally coherent, and where other non-climatic factors such as competition and disturbance are at a minimum. Trees growing in regions with little climate variability and optimum conditions for growth are less likely to produce the high variability in annual growth necessary for robust reconstructions of climate. It is for this reason that *dendroclimatologists* seek out trees from those areas where trees are most likely to be limited by climatic factors such as temperature or drought, normally at the limits of their ecological range (see *Dating, dendrochronology*).

Describing tree-growth/climate relationships

The response of tree growth to climatic forcing involves the interaction of many complex factors. Due to this complexity there are no suitable theoretical models to allow for the extraction of a climatic signal from tree rings based on ecophysiological or mechanistic studies alone (Fritts, 1976; Hughes et al., 1982; Cook and Kairiukstis, 1990). Dendroclimatologists therefore rely upon semi-empirical relationships between tree growth and climate for calibrating the climate response of a given chronology (Fritts, 1976; Guiot et al., 1982). The multivariate statistical analyses used include principal component or eigenvector analysis, and canonical correlation and regression (Fritts et al., 1971; Fritts, 1976, 1991; Guiot et al., 1982).

The procedure that estimates the statistical growth-environment relationship is called *calibration*. The tree-growth/climate relationships revealed in this manner, called *response functions*,

may not necessarily reflect a directly coupled response. Rather, they may involve long chains of interacting cause and effect linkages that ultimately effect growth in the trees, resulting in enhanced or suppressed growth for a particular year. The climate response is evident because the elements of weather and climate affect the microclimates for individual trees, and thereby the physiological processes that in turn control growth (Gates, 1968a,b; Fritts et al., 1971; Fritts, 1976; Salisbury and Ross, 1992). When a sufficiently strong relationship has been established between tree growth and some parameter of climate (e.g., temperature or precipitation), the statistically-calibrated relationship can be used to generate a *transfer function* for the reconstruction of climate from tree growth for the period prior to the available climatic data set (Lofgren and Hunt, 1982).

For calibration, standardized tree ring indices (typically, ring width or maximum latewood density) are compared with the longest available instrumental records of climate, from meteorological stations that most closely represent conditions at the site. Long climatic time-series are required for a proper and robust statistical comparison (Fritts, 1976; Hughes et al., 1982; Cook and Kairiukstis, 1990). However, baseline weather data for a given tree site are usually lacking, and the nearest meteorological stations may be many kilometers from the location of the trees. This problem is compounded by the search for the oldest and least disturbed trees available, which are likely to be in areas remote from most weather stations, and at substantially higher elevations. Hughes et al. (1978) illustrated how the percentage of chronology variance explained by climate and prior growth, respectively, could change from 34% and 31% to 45% and 28%, respectively, when rainfall data from sites 60 km and 6 km distant were used. To some extent, this problem may be ameliorated by analyzing broad scale parameters such as sea level pressure (SLP) and sea surface temperature (SST) anomaly patterns, which may in turn influence local conditions at the site (e.g., Douglas, 1973; D'Arrigo et al., 2003). In most instances, temperature exhibits far less spatial variability than precipitation. It may therefore be more accurately represented by relatively distant instrumental records.

It is desirable to have monitored radial growth in conjunction with daily or even sub-daily environmental conditions over successive seasons at important dendroclimatic sites. This allows for a more mechanistically based climate/growth model. Such models are actively being pursued though at present they are limited to open-canopy, arid-site conifers with wide rings and uncomplicated growth structure (e.g., Fritts and Shaskin, 1994). Application of such mechanistic models to more mesic, closed-canopy forest environments is not yet viable.

In traditional dendroclimatological studies, tree growth for an entire season, as determined from the mean value function for each annual ring, is usually compared against monthly or seasonal climate parameters for the determination of the most significant factors affecting growth at the site (Fritts, 1982). In reality, climatic conditions on daily or even shorter time-scales may have a significant impact on the annual growth ring. Transient climate features such as severe frosts, very high temperatures, heavy snowfall, or windstorms may impact on growth for a given year, *t*. In most instances, however, such short-term factors can only be modeled when they leave obvious features in growth rings (e.g., traumatic resin ducts, frost-rings, false-rings), and monthly and seasonal data are more reliably modeled.

Some important assumptions and limitations exist for dendroclimatic reconstructions, which must be carefully considered:

1. It is assumed that the Uniformitarian Principle applies; i.e., the physical and biological processes that link the present environment with present variations in tree growth are the same processes that will have been in operation throughout any segment of the pre-calibration period (Fritts, 1976).
2. Similarly, the climatic conditions that produced past anomalies in tree growth are assumed to be analogous to the same processes enacting upon tree growth during the calibration period.
3. It is usually assumed that the systematic relationship between the limiting climatic parameter and the biological responder (tree growth) can be approximated by a linear mathematical expression. Lofgren and Hunt (1982) note, however, that in the case of transfer functions, the predictand set need not be a linear function of climate; e.g., the logarithm of a precipitation record could be used and therefore the linearity constraint is not so severe a restriction as it might first appear.
4. The data are assumed to be normally distributed when parametric statistics are tested for significance, as the effects of outliers and any other non-normal data may distort the testing of significance (Fritts, 1990). Non-normal data can be normalized prior to regression through several techniques outlined in Fritts (1976) and Cook and Kairiukstis (1990).
5. The observations must also be assumed to be independent of each other for most statistical testing procedures. A serial-dependence or autocorrelation among successive observations, or among observations in space, may seriously reduce the number of degrees of freedom used for statistical significance testing. The effects of autocorrelation may be removed by prewhitening the data through autoregressive modeling (e.g., Cook et al., 1992). Alternatively, prior growth can be included in the regression as a predictor variable, lagged up to m prior years.

It is clear that the assumptions listed above are not completely met by the climate/growth relationship used for calibration and climate reconstruction procedures. They may instead be regarded as comprising the limitations of the system (Fritts et al., 1971; Lofgren and Hunt, 1982) and, within these limitations, some percentage of the variability of climate will be explained by a dendroclimatic reconstruction. The quality and the length of both the tree ring and climatic data play a crucial role in the validity of the resulting models, and results derived from their calibrations and climate reconstructions should be verified, as discussed below.

Calibration of the climate response

The word *calibration* in dendroclimatology refers to the fitting of statistical models that can be applied to one or more *predictor* variables in order to estimate or reconstruct one or more *predictand* (Fritts, 1990). The term *response function* refers to the weights or coefficients of the statistical model that describes the manner in which trees respond to climate (Fritts et al., 1971; Fritts, 1976). The response function does not measure the climate-growth response directly but rather the effectiveness of a particular statistical model at predicting the element of tree ring variation forced by external factors (Hughes et al., 1982).

Climate parameters are often highly intercorrelated, making classical multiple regression analyses difficult to apply directly

for response function analysis. Instead, the principal components of climate are often used in order to provide orthogonalized data sets for use in regression (Fritts et al., 1971; Fritts, 1976; Guiot et al., 1982; Briffa and Cook, 1990). Additional complications may arise from the autoregressive properties of the tree ring series, where the growth in a particular year is not only dependent upon conditions in the season of growth but also in one or more previous seasons (Fritts et al., 1971; Fritts, 1976). Some form of prior growth parameter is often employed through lagging the tree ring series up to m prior years. Alternatively, both the tree ring time-series and the climate data can be prewhitened through autoregressive modeling to remove the effects of autocorrelation prior to response functions analysis (e.g., Cook et al., 1992).

There are several response function procedures in use at present. The primary differences relate to the manner in which relatively unimportant predictor PCs are removed from consideration during regression screening (Briffa and Cook, 1990). Blasing et al. (1984) noted that this is not always a straightforward procedure. Decisions regarding the number of climatic variables to include, confidence limits, and the number of eigenvectors to allow as candidate predictors in the regression, can affect the response function in unpredictable ways, leading to errors in interpretation. Blasing et al. (1984) recommended using the correlation function as an initial, interpretive guide prior to response function analysis, since the correlation functions are easier to understand, easier to replicate, and more difficult to alter subjectively. They also demonstrated how prior tree growth variables used in the regression can mask true climatic effects, and noted the usefulness of the correlation function for detecting such masking. The effect of prior growth variables can lead to mistakenly attributing real climatic effects to prior growth. They should therefore be considered separately from the response functions.

The simple correlation functions between the tree ring chronologies and the climate variables are used to interpret the climate response. Both the tree rings and the climate variables (where warranted) are first prewhitened as an order- p autoregressive (AR) process of the form:

$$X_t = \sum_{i=1}^p f_i X_{t-i} + e_t \quad (1)$$

where X_t is the time series being modeled, the f_i are the p autoregressive coefficients, and e_t is the series of random shocks or white noise residuals unexplained by the AR(p) model (Box and Jenkins, 1970). The e_t of the tree rings and climate variable are used to develop the regression model and subsequent climate reconstructions, with persistence due to climate added back (where warranted).

Reconstructing climate

Transfer functions are statistically derived equations that relate two sets of variables for which a causal relationship can be described, but for which the derivation of an analytical expression cannot be achieved (Fritts et al., 1971; Lofgren and Hunt, 1982). In the case of dendroclimatology, one set of variables consists of the tree ring indices, and the other the climatic parameter of interest (e.g., temperature or precipitation). The calibrated function of tree growth with the appropriate climate parameter can then be used to transfer the annual patterns of tree growth into yearly estimations of the climate variable, for

periods of time prior to the recording of that variable (Fritts, 1976; Lofgren and Hunt, 1982).

For many studies, PC regression analysis can be used to transform tree ring indices into estimates of a single climate variable (i.e., temperature). Prior to regression, the tree ring chronologies and climate variables are pre-whitened as order- p AR processes, as per Equation (1). The reconstruction of climate (Y) is therefore accomplished by estimating the regression equation over the calibration period as:

$$Y = Xb + E \quad (2)$$

where matrix X is the tree ring predictor set, b is the column vector of standardized regression coefficients used to estimate climate from tree rings, and E is the column vector of errors due to unexplained variance in the regression model. b can be estimated by ordinary least squares (OLS) as:

$$b = (XTX)^{-1} \cdot X^T Y^1 \quad (3)$$

where the superscript T denotes the transpose of matrix X and $(X^T X)^{-1}$ denotes the inverse of $X^T X$. In the form of normalized departures, estimates of climate from tree rings (\hat{Y}) can be obtained by multiplying X by b as follows:

$$\hat{Y} = Xb \quad (4)$$

When PCA is performed on the tree ring chronologies, values of X are multiplied by the eigenvector loadings (E), producing a new set of predictors:

$$U = XE \quad (5)$$

These are the PC amplitudes or *scores*. Prior to regression, each amplitude is normalized by the square root of its respective eigenvalue. The yearly variations in each amplitude reflect the relative importance of its eigenvector in describing the overall pattern of variance seen in the original data.

At this stage, a subset of amplitudes that explain most of the original variance in each data set is selected for regression analysis, after deleting the higher order eigenvectors. The eigenvalue-1 criterion (e.g., Guttman, 1954) is used here for screening predictors, deleting those eigenvectors with eigenvalues less than 1.0. This selection criterion is conservative in that it only retains around 20–40% of the eigenvectors, which may explain 60–70% of the total variance in the original data (Cook et al., 1994). In this way, the number of candidate predictors is reduced and, therefore, so is the potential for artificial predictability that might arise from the inclusion of too many predictors in the model (Davis, 1976; Lofgren and Hunt, 1982).

Once a subset of the predictor eigenvectors is selected, the predictand is regressed on selected predictor PCs, and the standardized regression coefficients are nothing more than the simple correlations between the two. The best-order regression model is selected by the minimum AIC criterion (Akaike, 1974), and the regression model is then:

$$Y = U' B' + E \quad (6)$$

where the prime denotes the reduced-order model of PC amplitudes and regression coefficients selected by the AIC. The matrix B' of regression coefficients can then be expressed in terms of the original predictors as

$$b = E' B' \quad (7)$$

This back-transformation to coefficients on the original predictors eliminates the interpretational disadvantage of working with regression weights of the PC amplitudes (Cook et al., 1994).

Verification of results

The statistical verification of climatic reconstructions is an integral part of dendroclimatology (Fritts, 1976; Hughes et al., 1982; Cook and Kairiukstis, 1990). Both response function and transfer function procedures can be verified through statistical analyses. The climate response equations are verified by comparing estimated values of tree growth with the actual values over an independent period (Briffa, 1984; Briffa and Cook, 1990). For this purpose, the climatic data are split into two equal segments (Figure D31). Identical predictor-selection criteria are used for both time periods to enable a more direct comparison of results, as recommended by Briffa and Cook (1990). Standardized periods of analysis, each of sufficient length to minimize sample-to-sample variability in the PC loading patterns (i.e., usually greater than 25–30 years) are also used. The problem of determining the confidence limits, both on R^2 and on the original climate predictors, is due to the fact that the selection of final PC predictors is an a posteriori decision, with an unclear definition of what the correct degrees of freedom are (Briffa and Cook, 1990).

The reliability of a particular model is assessed directly by calculating a number of verification statistics that measure the degree of similarity between independent estimates of climate from the model, and the corresponding instrumental data from independent time periods (Gordon, 1982; Fritts et al., 1990). Verification procedures may employ several statistics: parametric statistics that involve assumptions of the underlying probability distributions of the data, and are therefore sensitive to violations of these assumptions, and nonparametric statistics that are insensitive to such violations.

Following are several verification statistics that are commonly used: the Pearson product-moment correlation (R_p), the sign test (ST), the reduction of error test (RE), the product means test (PM), and the coefficient of efficiency (CE). Full descriptions of these tests can be found in the following: Fritts et al., 1990; Cook et al., 1992, 1994; Salinger et al., 1994.

The R_p statistic is one of the simplest and most commonly used verification statistics. It measures the relative variation (covariance) between two data sets, and is completely insensitive to differences in the mean and variance between the two (Fritts et al., 1990). Since it reflects the entire spectrum of variation (both high and low frequencies) its value can be affected by trends in the two data sets. This is resolved by calculating a new correlation coefficient from the first differences of the two data sets, thereby measuring only the high-frequency variance in common. The data sets are assumed to be normally distributed, and the variance is assumed to be linearly related (Fritts, 1976; Fritts et al., 1990).

The ST is a nonparametric measurement of reliability that counts the number of times the signs of the departures from the sample means agree or disagree, and offers the advantage of measuring the associations at all frequencies. Results are based on two possible outcomes: (+1) when the estimate and observations agree (i.e., are on the same side of the dependent data mean) and (−1) when they disagree (Fritts et al., 1990). A successful ST is indicated when the signs of the estimates are correct more often than would be expected from random numbers.

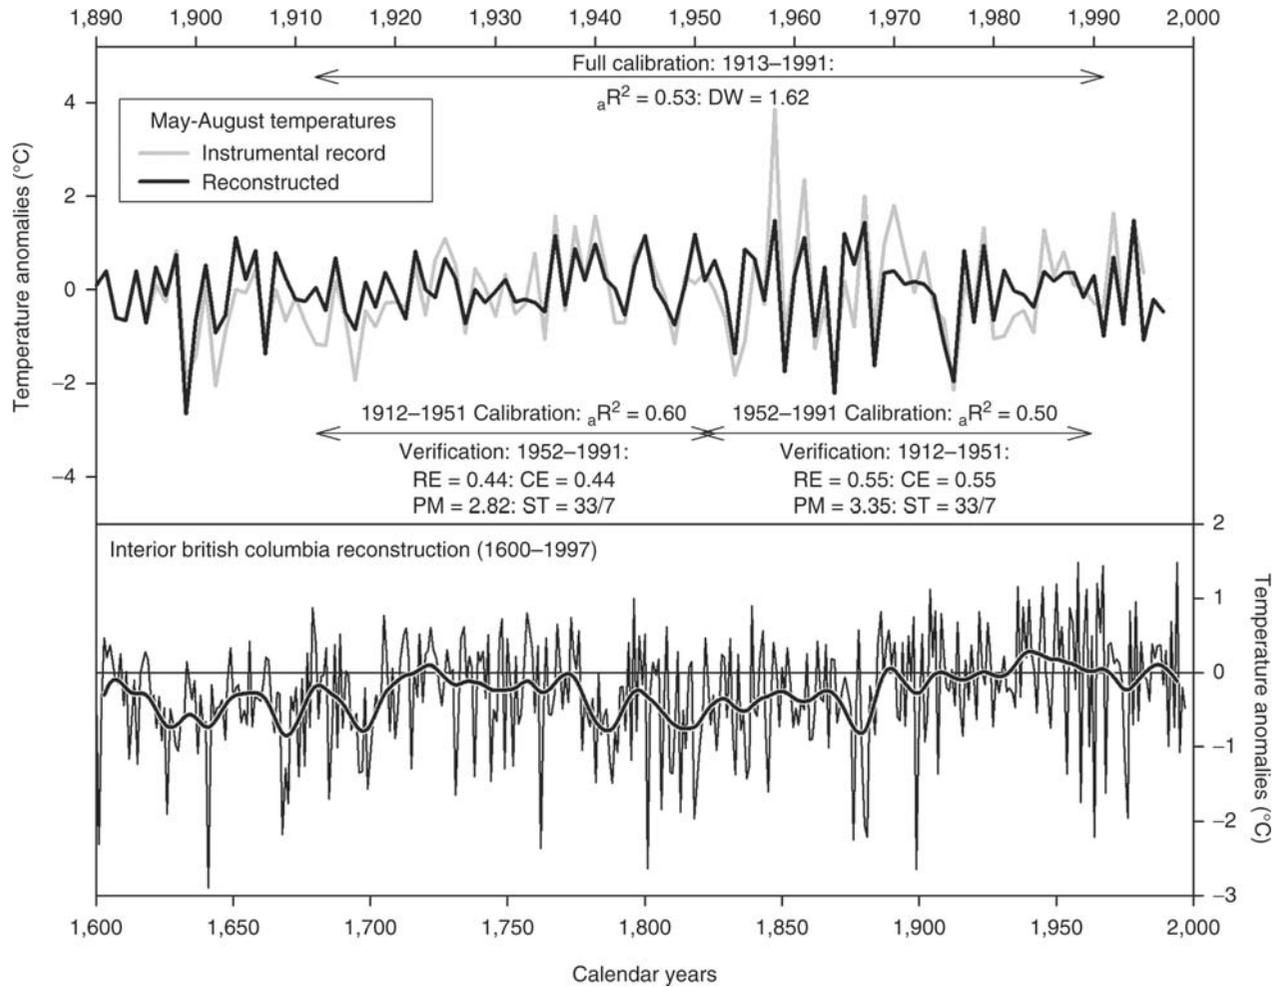

Figure D31 Tree ring reconstruction of temperature anomalies from Interior British Columbia (*bottom*), showing calibration and verification statistics and comparisons between actual and reconstructed temperatures (*top*). The full calibration period explains 53% of the variance in the original temperature series. Calibrating with the early (1912–1951) and late periods (1952–1991) independently, explains 60% and 50%, respectively, reflecting better fidelity in the early half of the record (data courtesy of R.J. Wilson).

The RE statistic offers a highly sensitive measure of reliability. It is similar to the explained variance statistic obtained with the calibration of the dependent data, and values range from negative infinity to a maximum of 1.0, which indicates a perfect estimation (Fritts et al., 1990). The RE is calculated by dividing the sum of the squared differences between actual and estimated values by the sum of the squared differences between actual values and the mean of the calibration period, then subtracting that value from 1.0. The significance of RE cannot be tested, though positive values indicate some degree of model skill. Errors are unbounded, so that even one extreme error in an otherwise nearly correct set of estimates may result in a negative RE and unfounded rejection of the model. While RE does estimate the explained variance with considerable accuracy (Gordon and LeDuc, 1981), the size of the sample being analyzed (n') may markedly affect its significance. For example, with $n' = 20$, an RE of zero was roughly equivalent to the 0.95 confidence limit, but for $n' = 10$ or 15 an RE statistic significantly different from zero would have to be greater than 0.25 and 0.12, respectively (Fritts et al., 1990).

The CE was introduced into dendroclimatology by Briffa et al. (1988) and is very similar to the RE, with values ranging from negative infinity to a maximum value of 1.0. The only difference is that the CE statistic uses the mean of the verification period in the denominator, instead of the mean of the calibration period. Consequently, if the verification and calibration means are identical, then $CE = RE$. However, when the means are not equal, RE will be greater than CE by a factor related to that difference (Cook et al., 1994). Since the value of the CE statistic will usually be less than for RE, it is an even more difficult test to pass. Although there is no significance test for CE, any value greater than zero indicates some degree of model skill (Cook et al., 1994).

The PM test takes into account both the sign and magnitude of the departure from the calibration average, and is computed from the product of the actual and estimated annual departures from the mean, with positive and negative means summed separately (Fritts, 1976). The product is positive when the departure sign is estimated correctly, and negative when incorrectly estimated. If randomly guessed, the means of the positive

and negative products are approximately the same (ignoring their signs); while for a correct reconstruction, the mean is larger for the positive products (Fritts, 1976). The difference between positive and negative products is tested with the t statistic, and is considered statistically significant when the value of t is higher than the expected value at the appropriate confidence level. A mean positive product that is significantly larger indicates a tendency for both actual and estimated departures from the average value to be large when the sign is correctly estimated, and small when the sign is incorrectly estimated. The latter case indicates that approximately average conditions both occurred and were estimated, thereby indicating the correctness of the reconstruction in spite of its incorrect sign (Fritts, 1976).

Reconstructions of climate from tree rings

Through his research on trees of the arid American southwest (see *Dating, dendrochronology*), A.E. Douglass came to understand the connection between climate and tree growth. In one of his earliest attempts to reconstruct climate, Douglass (1909), in his paper “*Weather cycles in the growth of big trees*,” described the connection between available moisture, food supply and annual incremental growth, and extrapolated long records of Ponderosa pine as proxy records of rainfall for northern Arizona. All of the methodological applications were done manually; curve fitting, standardization and chronology building, and all correlation analyses were done without the benefit of computers. This, of course, limited the numbers of trees used and the numbers of calculations made. For the next few decades, much work was done in this manner and climate reconstructions were laboriously produced.

Harold C. Fritts introduced a more biological, plant physiology-based research focus to the field of dendrochronology in the 1950s and 1960s (e.g., Fritts and Fritts, 1955; Fritts, 1956, 1960a). He employed the use of dendrographs that measured daily changes in stem growth to help in understanding the climate tree growth relationship in greater detail. He also introduced high-level statistical methods and the use of main-frame computing to process large sets of data (e.g., Fritts, 1960b, 1962, 1963). In addition, his work introduced the use of canonical regression and large regional networks of tree ring chronologies for the spatial reconstruction of climate (e.g., Fritts et al, 1971). These were highly innovative and important

works, made possible by the use of computers, which led to major advances in the methodology used for reconstructing climate from tree rings. The list of researchers who made significant contributions to the field of dendroclimatology, both before and after the work of Fritts, is impressive, but goes far beyond the scope of this chapter. Some important highlights are noted below.

One of the more important reconstructions of climate from tree rings was a reconstruction of streamflow from the Colorado River (Stockton, 1976; Stockton and Jacoby, 1976) shown in Figure D32. This work was important because it demonstrated that the estimates for overall streamflow of the Colorado River, upon which western states water rights were calculated, had substantially overestimated the average annual amount of water by more than 4 million acre feet (maf). The official measurements of 17.3 maf were dominated by data from the early 1900s, which Stockton’s work showed to encompass the wettest 30-year period of the past 500 years. The overall average based on the long tree ring reconstruction was 13.5 maf, and clearly illustrated the pitfalls of making decisions based on short-term data.

With the development of microcomputing in the 1970s and 1980s it became possible to generate large numbers of iterations of data, making it reasonable to reconstruct climate from multiple well-replicated tree ring chronologies. This has led to the present day scenario where synoptic scale reconstructions of climate can be made from hundreds of tree ring chronologies built from thousands of trees, using desktop computers. A recent example of such spatial reconstruction work is Cook et al. (1999) who reconstructed drought indices for the contiguous USA based on a gridded network of 425 moisture-sensitive tree ring chronologies that were calibrated and verified against 286 grid-points of PDSI (Palmer drought severity index). The reconstruction spanned the period from 1700–1978. This work has recently been expanded to include 835 tree ring series, and an increased overall length of reconstruction back to 1 AD for the western USA. The chronologies and PDSI grid points now extend into Canada and Mexico, giving far greater scope to the analyses of past drought. A drought area index (Figure D33) for the western USA shows evidence of a prolonged period of drought that lasted for much of the 10th–13th centuries, coinciding with the Medieval Warm Period (MWP). A current, prolonged drought in the western USA can now be better assessed within the

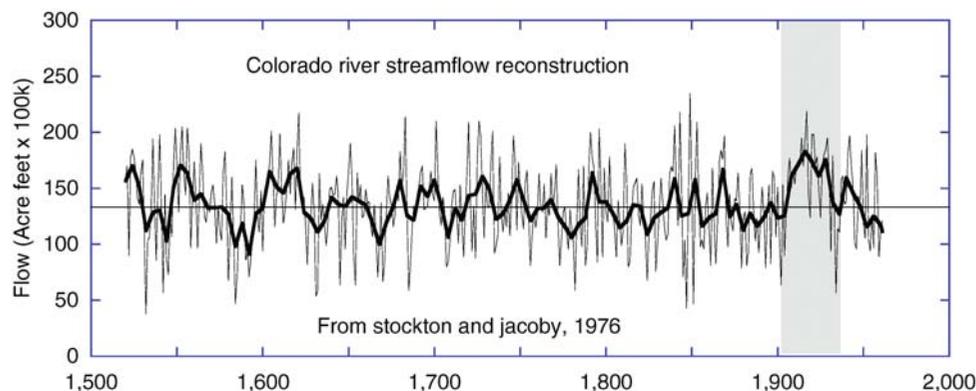

Figure D32 Colorado River streamflow reconstruction based on tree ring sites from the river’s catchment. The grey shaded area shows the period that the Colorado River Treaty was based on, which turned out to be the wettest period of the past 500 years. More water was divided between states than existed for the long-term mean.

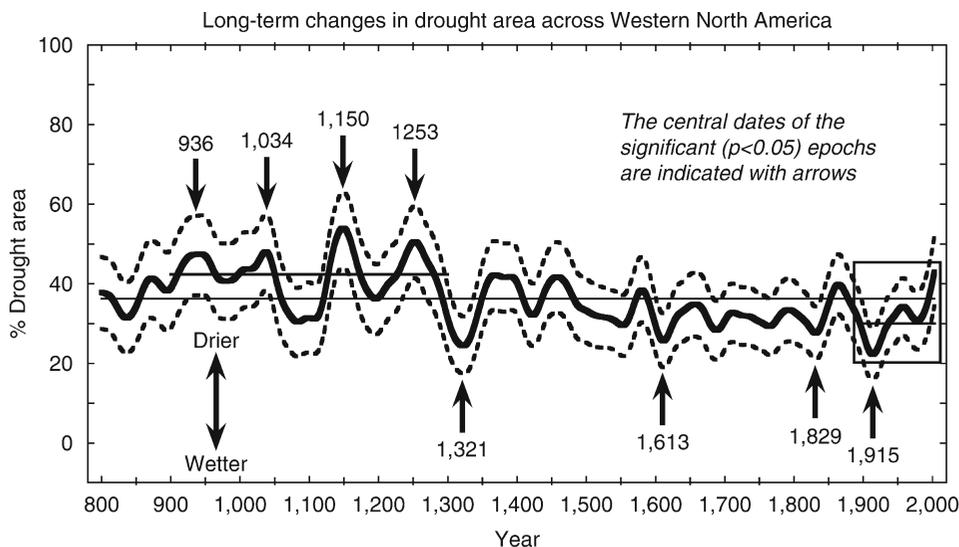

Figure D33 Tree ring based reconstruction of drought indices for the western USA depicted as drought area indices (DAI), expressed as percentage of area in drought with a PDSI of <-2 . This is a smoothed plot that accentuates decadal scale variability. Of particular interest is a "Medieval Dry Period" of extended drought from the mid 10th to late 13th centuries that is unmatched in intensity for the past 1,200 years (data courtesy of E.R. Cook).

context of the natural variability for the past 2,000 years. The current drought is shown to be orders of magnitude less than the MWP drought, suggesting dire consequences to a water-hungry society if MWP-like conditions returned. Much of these data and their reconstructions, as well as numerous other climate reconstructions from tree rings can be downloaded from the NOAA paleoclimatology website and the International Tree-Ring Data Bank (<http://www.ncdc.noaa.gov/paleo/>).

Tree rings and global warming

Tree rings have proven to be one of the most important proxies of climate in the global warming debate. This is due to their ability to reproduce high-resolution, absolutely dated records of climate over broad geographic areas for the past millennium and beyond. This work has been largely centered on tree ring sites from the boreal forests where temperature is the most limiting factor to growth. Early work in Alaska by Giddings (1938, 1943) showed the potential for working with northern treeline trees and explored their relationship to climate. Jacoby et al. (1985) followed up on this research, producing reconstructions of degree-days in Alaska. Meanwhile some of the first attempts to reconstruct large scale Arctic and Northern Hemisphere temperatures based on networks of temperate to sub-Arctic trees were being undertaken (e.g., Jacoby and D'Arrigo, 1989; D'Arrigo and Jacoby, 1993). Much recent attention has been focused on a multi-proxy reconstruction of Northern Hemisphere temperature by Mann et al (1998), which included tree ring series and showed the recent warming trend to be unmatched for the past 1,000 years. Esper et al. (2002) used networks of tree ring sites and novel standardization procedures (see *Dating, dendrochronology*) to produce a Northern Hemisphere temperature reconstruction that placed the recent warming within the scope of the natural variability of climate for the past 1,000 years, and suggested a MWP warming that rivaled the current temperature increase. D'Arrigo et al. (2006) provide a recent version of a Northern Hemisphere temperature reconstruction

that includes newly collected data and different methodologies from previous versions. While the scientific debate surrounding global warming goes on, tree rings remain among the most important proxies used for paleoclimate research.

DESERT VARNISH AS A PALEOCLIMATE PROXY

Desert varnish, a paper-thin accretion on rock surfaces (Figure D34), greatly alters the appearance of bare rock faces. Almost any lithology can host varnish, but the surface must remain stable for thousands of years in order to accumulate varnish in most desert environments. Rock varnish is the better term because this same rock coating forms on rocks in all environments, for example, alpine, Antarctic, Arctic, periglacial, stream, temperate, and tropical environments. The term desert varnish is most often used in arid regions (Dorn, 1998).

Environmental changes influence varnish. Lichens and many fungi, for example, secrete biological acids that destroy desert varnish by dissolving the manganese and iron oxides. Where rocks exist in a desert pavement or in other settings such as an opened rock crevice, local environmental conditions play the key role in varnish development. However, where rock surfaces are not greatly influenced by the local microenvironment, varnish layers, called visual microlaminations (VML), record changes in the aridity of an area. Varnishes seen in ultra thin sections (<5 μm) with a light microscope reveal orange-yellow and black layers.

In these boulder-top positions, wetter climates favor bacterial enhancement of manganese (Figure D35), producing the black layers. Drier climates with more alkaline dust foster development of orange-yellow (Mn-poor) layers that record arid periods (Dorn, 1990). In places where VMLs have been calibrated by radiometric dating methods, they can yield

correlated ages for rock surfaces (Liu, 2003, 2006), as revealed in a recent test: "... results of the blind test provide convincing evidence that varnish microstratigraphy is a valid dating tool to estimate surface exposure ages" (Marston, 2003, p. 197). Based on a decade of detailed analyses of over 10,000 microsedimentary basins, Liu (2003, 2006) found that black varnish layers correspond with Heinrich events, the Younger Dryas (Figure D36), and wet events during the Holocene.

The wet periods recorded in rock varnish, however, do vary in timing regionally. Cremaschi (1996), for example, found a mid-Holocene Mn-rich layer in Tunisian varnish correlating with a regional wet pulse in North Africa. When regionally calibrated, varnish microlaminations provide archaeologists and geomorphologists a powerful Quaternary tool (Liu and Broecker, 2008), because they reveal both climatic change and a time signal (Figure D37). The potential of VML extends beyond the Quaternary in circumstances where varnish is

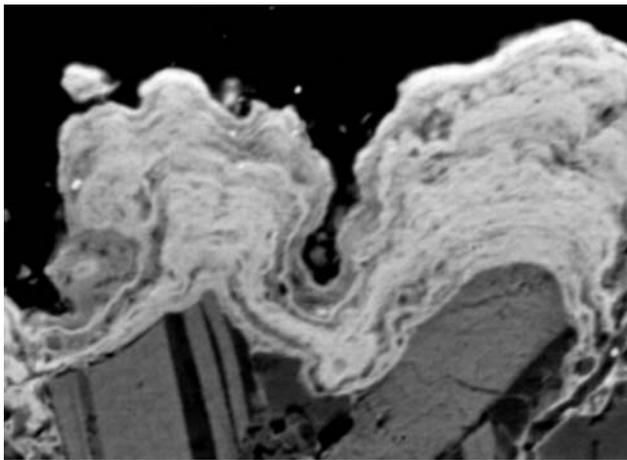

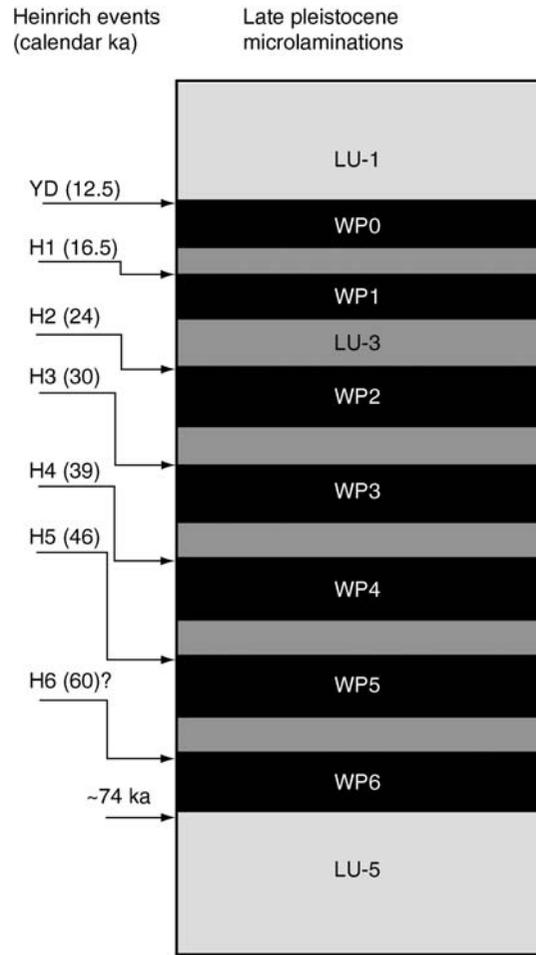

Figure D34 Backscattered electron microscope view of brighter rock varnish formed on granodiorite (feldspar and quartz minerals) at Kitt Peak, Arizona. The varnish is only about 0.05 mm thick. Note the distinct boundary between varnish and rock, indicating that varnish is an accretion.

Graph not drawn to scale

Figure D36 Calibration of varnish microlaminations from the basin and range of western North America (based on data in Liu, 2003), where ka is thousands of years.

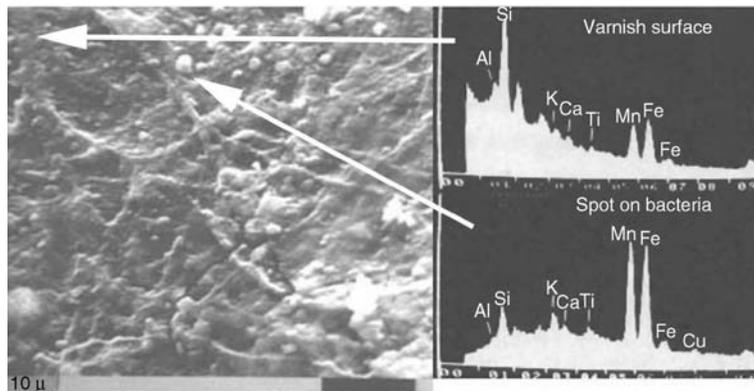

Figure D35 Budding bacteria concentrate manganese in rock varnish, as seen here through electron microscopy and energy dispersive chemical analyses of Negev Desert varnish.

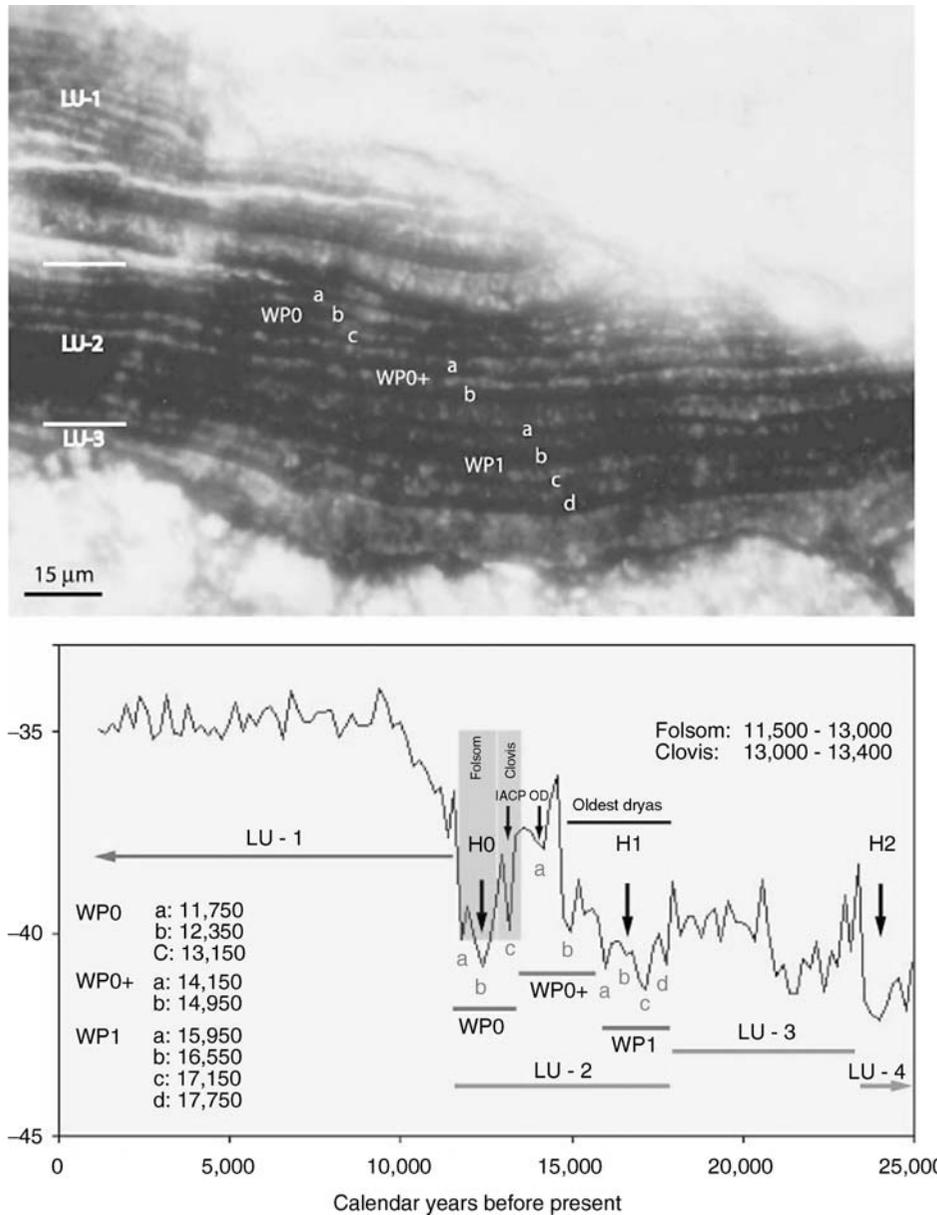

Figure D37 Rock varnish record of the latest Pleistocene wet events in Death Valley, California and its possible correlation with GISP2 $\delta^{18}\text{O}$ ice core record in Greenland (below), where the graphic is modified from Liu (2006). In fast accumulating varnishes, such as this sample from Death Valley, there are three wet phases in the Younger Dryas event (WPO), four wet phases in Heinrich event 1 (WP1), and two wet phases between them (WPO+) that can discriminate different events in the terminal Pleistocene.

preserved in sedimentary environments; investigators can infer from VML that the environment probably fluctuated between arid and less arid environments (Dorn and Dickinson, 1989).

There are other paleoclimatic indicators found in association with desert varnish. When other types of rock coatings (Dorn, 1998) alternate with desert varnish, the change in coating type often has implications for environmental change. Changes in the trace element geochemistry of varnish, for example, changes in carbon isotopes and lead (Dorn, 1998), also record environmental changes. Still other indicators include micromorphological changes in varnish layering that provide an indicator

of the dustiness of the depositional setting. Because desert varnish is a weathering feature, sensitive to climatic change, changes in its physical and chemical structure provides researchers opportunities to understand paleoclimatic changes in arid regions.

DEUTERIUM, DEUTERIUM EXCESS

Measurements

Deuterium is the heavy stable isotope of hydrogen, ^2H or D, with a natural occurrence on Earth ($^2\text{H}/^1\text{H}$ isotopic ratio, hereafter D/H) of $\sim 153 \times 10^{-6}$ (Lécuyer et al., 1998). For the purpose of reconstructing paleoenvironments, it is commonly measured in paleowaters (e.g., groundwaters, ice, fluid inclusions), organic matter (e.g., tree cellulose), and hydroxylated minerals (e.g., clays, hydroxides), in which the D/H ratio ranges between approximately 160×10^{-6} and 80×10^{-6} (Mook, 2001; Jouzel, 2003).

The D/H ratio of a sample is measured by mass spectrometry on H_2 (hydrogen gas), after either a total reduction of the water, or a catalytic equilibration with H_2 . Both techniques allow some automation, but the latter requires larger sample volume (few ml, compared with few μl for the former). A new laser spectrometric technique is achieving promising results (Kerstel et al., 1999). The isotopic composition is usually expressed relative to a standard, currently the Vienna Standard Mean Ocean Water (V-SMOW), defined in 1966 by the International Atomic Energy Agency (IAEA), with a D/H ratio close to 155.75×10^{-6} . The relative composition is expressed with the δ notation:

$$\delta D = [(D/H)_{\text{sample}} / (D/H)_{\text{V-SMOW}} - 1] (\times 1,000, \text{ per mil})$$

It is recommended that isotopic measurements be expressed with respect to V-SMOW, and normalized on a two-standard scale, V-SMOW and SLAP (Standard Light Antarctic Precipitation), assuming a value $\delta D = -428\text{‰}$ for SLAP (Coplen, 1995). The different measurement techniques achieve a precision usually better than 1‰, but with a lower accuracy, as shown by interlaboratory comparisons (Meijer, 1999).

Reconstruction of paleoenvironments

The deuterium composition δD allows similar reconstructions of paleohydrological and paleoclimatic conditions as can be

achieved with the $\delta^{18}\text{O}$, both quantities being related by the ratio of their fractionation factors. Because condensation of water occurs mainly at equilibrium in the atmosphere, and because the ratio of their equilibrium fractionation factors is more or less constant with temperature, the δD and $\delta^{18}\text{O}$ values of precipitation (and of most surface waters) are linearly related with a slope close to 8, the so-called “Meteoric Water Line” (Craig, 1961). In contrast, kinetic conditions prevailing at evaporation modify both the slope and the intercept of this line (Merlivat and Jouzel, 1979). To infer these kinetic conditions, a second order isotopic parameter, the deuterium excess d , has been defined as $d = \delta D - 8 \times \delta^{18}\text{O}$ (Dansgaard, 1964).

DIAMICTON

Diamicton is a general term used to describe a non-sorted or poorly sorted, sometimes non-calcareous, terrigenous or marine sediment containing a wide range of particle sizes derived from a broad provenance (Harland et al., 1966). Diamictons may have sorted and stratified subfacies, usually contain “floating” clasts of a wide provenance, and may have a fine-grained matrix (Dreimanis and Lundqvist, 1984). The term diamictite

is used to describe a lithified diamicton. The term, today, also carries with it the connotation of a glacial origin but diamictons can be deposited within a variety of geological settings.

The term, diamictite, and, from it diamicton, was first proposed by Flint et al. (1960) to replace the term symmictite. (Diamicton comes from the Greek, *diamognymi* – to mangle thoroughly.) Often synonymous with diamicton is the term “till” but not all diamictons are tills. The term “diamict” has been used occasionally as a separate term but has become an alternative to diamicton (Hambrey and Harland, 1981, p. 23).

Tills are, in general, poorly sorted glaciogenic sediments, with occasional sorted subfacies, that subdivide into lodgment, flow, and meltout (Dreimanis, 1988). As till research expanded, it became clear that tills form within terrestrial and marine environments but such origins are not always easily ascertained.

Diamictons can be, in general, classified as conglomerates or various forms of cataclastics that contain varying proportions of fine-grained matrix within which “floating” clasts of a range of sizes and shapes occur (Pettijohn, 1975; Allen, 1982). Some classifications use different terms depending on the percentage of clasts or the degree of fine-grained matrix present (Folk, 1954; Schermerhorn, 1966; Pettijohn, 1975); however, essentially all of these types are diamictons as defined above. As such, diamictons can be derived from three dominant sources: glacial, mass movement, or endogenic. All three types can also be formed in terrestrial and subaqueous environments and in many instances appear remarkably similar in hand-specimen. One distinguishing characteristic of glacial diamictons may be the presence of striations on the surfaces of clasts, but caution must be exercised in using this diagnostic criterion (Gravenor et al., 1984; Iverson, 1991).

Glacial diamictons represent the largest group of diamictons both on land and on the ocean floor. Although the three classes of tills, as noted above, have become accepted, newer research suggests that all tills are formed under stress conditions such that it may be more appropriate to group lodgment and flow tills as part of a spectrum of glacial mélange (Ruszczynska-Szenajch, 1983; Menzies, 1990). Meltout tills are a special group of diamictons that deposit under relatively low stress conditions such that deformation is limited (Lawson, 1981); their global extent, however, is limited (Rappol, 1987; Paul and Eyles, 1990). In using micromorphology, it is apparent that the dominant three till (diamicton) types need to be revisited since most glacial diamictons are products of various ductile and brittle deformation processes of deposition or emplacement (Hiemstra and Meer, 1997; Meer van der, 1997). It has been proposed that these glacial diamictons be renamed “tectomicts,” indicative of the deformation history undergone in the processes of deposition (Meer et al., 2003).

DIATOMS

Diatoms, a type of unicellular algae, are one of the most abundant groups of phytoplankton and are an essential component of the oceanic food web. As autotrophs, their primary requirements for survival are adequate light and nutrients. Their primary photosynthetic pigments are chlorophyll a and c, xanthophylls and fucoxanthin. They are widely distributed in a variety of marine and freshwater environments, including open ocean and lake waters, shallow marine and lake sediments, sea ice, soils and even aerial habitats (such as wet rocks and bark). Diatoms can exist in a free-floating or planktonic form, or can be attached to a substrate, including rocks, other algae or sea ice. Species live both as solitary cells and colonially. One of their most important distinguishing characteristics is that their cell walls are impregnated with opaline silica. These paired silica valves fit together much like a box, with the larger epitheca fitting on top of the smaller hypotheca. They are held together with overlapping connecting bands, collectively termed the girdle and, together, these components comprise a frustule. These tests, which are intricately

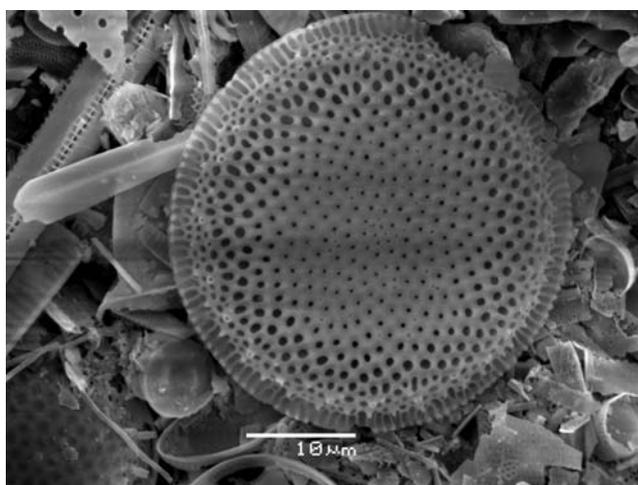

Figure D39 *Thalassiosira antarctica*, Southern Ocean, west of the Antarctic Peninsula, core NBP0107 KC8.

ornamented and taxonomically diagnostic, are often well-preserved in the fossil record, hence their use in paleoecologic and stratigraphic studies. They generally range in size from a few microns to a few hundred or even thousand microns, though most are around tens of microns in size (see [Figures D38–D40](#)).

Taxonomically, diatoms are placed in the class Bacillariophyceae, and are grouped with the Chrysophyceae (includes silicoflagellates and calcareous nannofossils) and Xanthophyceae in the phylum Chrysophyta. Two orders are distinguished, the Centrales, with radial symmetry, and the Pennales, which have bilateral symmetry. Over 100,000 different species (extinct and extant) have been described but perhaps only 15,000 of these are valid species, since many of the taxa described are now known to be variations of a single species. For example, through culturing work, workers have documented morphologic variability at different life cycle stages. A sparse fossil record of marine diatoms might date as far back as the Jurassic; however, these reports of Jurassic diatoms are not universally accepted. Certainly, a diverse flora of marine diatoms extends back to the

lower Cretaceous, suggesting their previous evolution. Lower Cretaceous diatoms are known from California, Russia, Antarctica and the southwest Pacific and Indian Oceans. Freshwater diatoms are known only as far back as the Paleocene.

Data on past and present abundance and distribution of diatom assemblages are used to reconstruct and document changes in environment, including those occurring today, for example, in the acidification and eutrophication of lakes, and pollution of freshwater and marine systems. Diatoms are particularly sensitive to a number of different environmental parameters, such as temperature, salinity, water chemistry (pH, alkalinity, nutrient concentration) and light levels, so analysis of assemblages over time is used as a proxy for these factors. The rapid regeneration rate of diatoms allows them to respond quickly to environmental change; their siliceous tests provide long-term documentation of these changes. Diatom data also provide important biostratigraphic information and have been used extensively as a correlation tool. Finally, diatoms have proven useful in a variety of other settings, such as archeological work, forensic studies and industrial use of diatomite (sedimentary rock formed by the accumulation and lithification of diatomaceous deposits), primarily for filtration.

DINOFLAGELLATES

The ecology of dinoflagellates

Dinoflagellates are microscopic unicellular organisms or protists belonging to the division of Dinoflagellata (Fensome et al., 1993). They inhabit most types of aquatic environments, from lakes to open ocean, and from equatorial to arctic settings.

When blooming, dinoflagellates can be responsible for “red tides”, so called because the very large number of cells in the surface water induces a color change. A few dinoflagellate species produce neurotoxins that may be bioconcentrated by filtering organisms, notably shellfishes, which then become poisonous and dangerous for the health of animals feeding on them.

Living dinoflagellates are characterized by two flagella, which permit swimming motion. Many dinoflagellates are phototrophic (i.e., undergoing photosynthesis) and form an important part of the planktonic primary production in lakes and oceans. Some dinoflagellates are heterotrophic (i.e., feeding on other organisms), and others are symbionts of marine invertebrates such as corals, in which they are known as zooxanthellae.

The life cycle of dinoflagellates and the cyst stage

Most dinoflagellates have a complex life cycle involving several stages, asexual and sexual, motile and non-motile (see Figure D41). During the course of sexual reproduction, some species form a diploid cell (i.e., with $2n$ chromosomes following the fusion of the gametes) that is protected within a cyst, permitting survival of the organism during a dormancy period of variable length (Fensome et al., 1993).

The motile and cyst stages are characterized by distinct morphologies. The cell wall or theca of many motile dinoflagellates is armored and consists of cellulose plates that form a distinctive geometry or tabulation, whereas the cysts only bear traces of the theca tabulation.

The organic-walled dinoflagellate cysts or dinocysts

Many species of dinoflagellates produce fossilizable cysts that are composed of highly resistant organic matter, similar in composition to the sporopollenin of pollen grains. The

organic-walled cysts, also known as “dinocysts” and previously called “hystrichospheres” by paleontologists, are usually well preserved in sediment. The dinocysts are typically 15–100 μm in diameter, and are observed in palynological slides prepared by standard laboratory procedures used for the study of pollen and spores, which involve treatments with hydrofluoric and hydrochloric acids. The study of dinocysts is thus considered a sub-discipline of palynology.

Dinocysts in paleoecology, paleoceanography and paleoclimatology

Fossil dinocysts are mainly known from marine sediments. They appear to be particularly abundant along continental margins (estuaries, continental shelves and slopes, epicontinental seas). Dinocysts were widely used in biostratigraphy and paleoecology of the Mesozoic and Cenozoic. In the field of Quaternary paleoceanography and paleoecology, the study of dinocysts is of growing interest. Because they are very resistant, dinocysts are generally well preserved in sediment despite dissolution that may affect calcareous or siliceous biological remains. Moreover, the development of reference databases from surface sediment samples (Dale, 1996; Rochon et al., 1999; Matthiessen and de Vernal, 2001; Zonneveld and Marret, 2003) has led to the documentation of strong relationships between the distribution of dinocyst assemblages and sea-surface parameters, including productivity and hydrographical conditions. Transfer functions derived from these databases have permitted the quantitative reconstruction of temperature, salinity, and sea-ice cover extent. For example, hydrographical maps of the northern North Atlantic during the Last Glacial Maximum (21 ka) were established using dinocyst data (de Vernal et al., 2000), and many regional reconstructions are currently being developed.

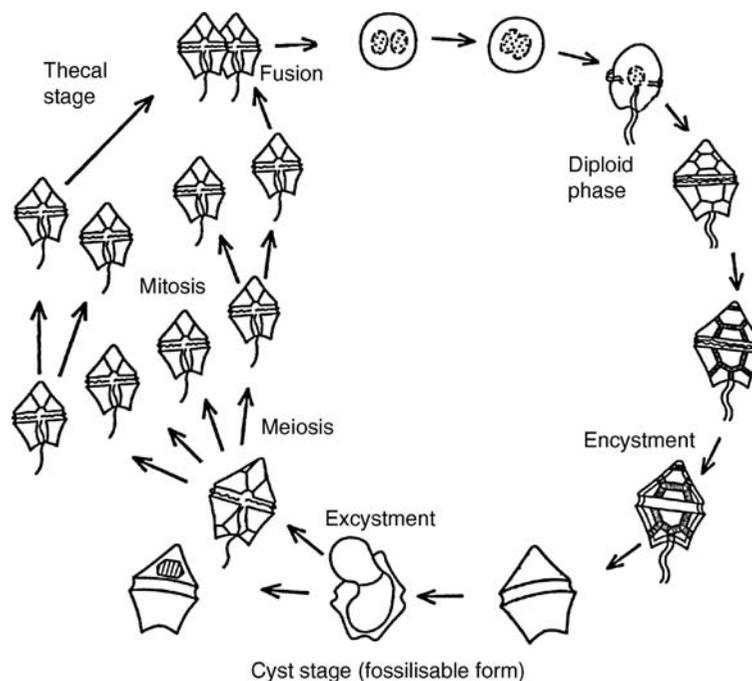

Figure D41 Schematic illustration of idealized dinoflagellate life-cycle (adapted from Fensome et al., 1993).

The calcareous dinoflagellates

In addition to organic-walled cysts or dinocysts, some dinoflagellate taxa yield calcareous microfossils generally associated with the cyst stage (Vink et al., 2000). Calcareous dinoflagellates appear to be abundant in oceanic sediments at middle to low latitudes, where they can be used as tracers of hydrographic conditions in the upper water column.

DOLE EFFECT

In 1935–1936, Dole (Dole, 1935) and Morita (Morita and Titani, 1936) discovered independently that the isotopic composition of atmospheric oxygen ($^{18}\text{O}/^{16}\text{O}$) is enriched relative to oceanic water. This isotopic enrichment of molecular oxygen in the heavier ^{18}O was named the Morita-Dole effect or just the Dole effect (DE in the following). The exact value of the enrichment was badly constrained for a long time after the discovery of the DE. It was not until 1972 that Kroopnick and Craig (Kroopnick, 1987) determined the DE with sufficient precision. Expressed relative to the Vienna Standard of Mean Ocean Water (V-SMOW) (Craig, 1961), they identified a value for the modern DE of

$$\begin{aligned}\delta^{18}\text{O}_{\text{Atm}} &= (^{18}\text{O}/^{16}\text{O})_{\text{Atm}} / (^{18}\text{O}/^{16}\text{O})_{\text{V-SMOW}} - 1 \\ &= 23.5 \pm 0.1\text{‰}.\end{aligned}$$

However, the reasons for this relatively strong enrichment of 23.5‰ were not clear for a long time and still are disputed to some extent. The first assumption was that photosynthesis produces an enriched O_2 flux; however, measurements did not confirm this hypothesis (Ruben et al., 1941; Dole and Jenks, 1944). Subsequently, various other hypotheses have been formulated: photochemical isotopic exchange between O_2 and H_2O (Roake and Dole, 1950) or between O_2 and CO_2 in the stratosphere (Dole et al., 1954), or, alternatively, preferred consumption of the light ^{16}O of dissolved oxygen by marine organisms (Rakestraw et al., 1951) or by soil bacteria during respiration processes (Dole et al., 1947). In each case, the measured enrichment due to the different processes could not confirm the corresponding hypothesis. Lane and Dole (1956) demonstrated convincingly that respiration processes in the ocean are indeed at least one important contribution to the DE. They measured a progressive isotopic enrichment of dissolved oxygen in oceanic water samples due to remineralization of organic material and demonstrated therewith that the biochemistry of plants must be studied to determine the origin of the DE.

Bender et al. (1994a) gave a detailed overview of current knowledge of processes contributing to the DE (see Figure D42 for a scheme of the global ^{18}O budget). Photosynthesis and respiration are the principal global O_2 fluxes. Photosynthetic production of O_2 tags the outgoing O_2 flux with the isotope signal of ambient water without any further fractionation (Guy et al., 1993). In the marine biosphere, the water of the euphotic surface layer has an isotopic composition of approximately 0‰ globally. In the terrestrial biosphere, the isotopic signature of water adjacent to photosynthetic production is characterized by large geographical and temporal variability. Following Farquhar et al. (1993), Bender et al. (1994a) opted for a global value of 4.4‰. This isotope signal of ambient water in leaves is significantly enriched as compared to oceanic surface waters and is mainly responsible for the different contribution to the DE by the terrestrial and the marine biosphere.

The most important contribution to the high value of the DE takes place during autotrophic and heterotrophic respiration. Various respirative O_2 fluxes (photorespiration, Mehler reaction, cyanide-sensitive and cyanide-insensitive pathways in dark respiration) fractionate ^{16}O against ^{18}O differently, but the mean fractionation is close to 20‰ in both the terrestrial and the marine environment. In the ocean, part of the respiration takes place in the deep ocean, isolated from the atmospheric oxygen reservoir. This slightly reduces the overall marine contribution to the DE due to a fraction of oxygen that fractionates against an already enriched oxygen pool.

Furthermore, there is a small temperature dependent fractionation during the dissolution of O_2 in water ($\sim 0.7\text{‰}$) (Benson and Krause, 1984). Equally, a small fractionation (0.4‰) takes place in the stratosphere during the photochemical exchange between CO_2 and O_2 . When adding up all these different fractionations, weighted with the corresponding fluxes, Bender et al. (1994a) computed a global equilibrium of $\delta^{18}\text{O}_{\text{Atm}} = 20.8\text{‰}$, underestimating by approximately 3‰ relative to the observed value. Besides a number of uncertainties in the considered processes, there might also be some processes neglected in this global budget such as fractionation during the diffusive mixing of O_2 in the upper soil column (Angert et al., 2001).

There are a number of applications of the DE (or of the $\delta^{18}\text{O}_{\text{Atm}}$ signal respectively) in paleoclimate studies. Past $\delta^{18}\text{O}_{\text{Atm}}$ can be reconstructed by analyzing the isotopic composition of air bubbles enclosed in the deep ice from Greenland

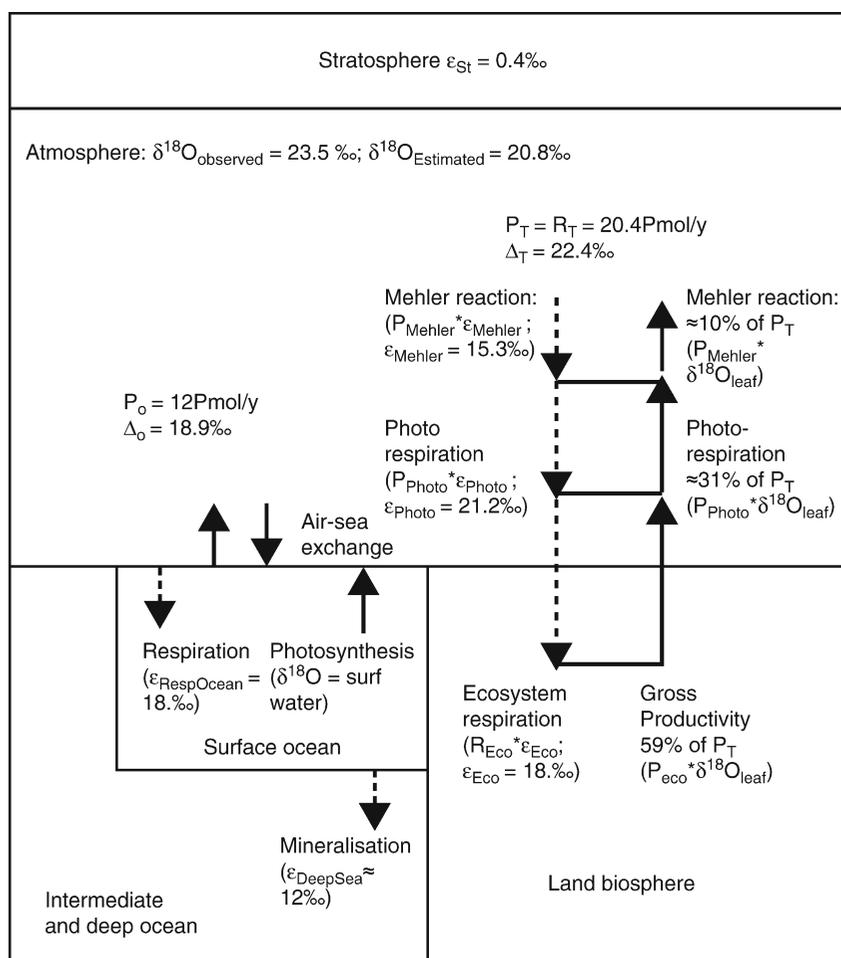

Figure D42 Scheme of the modern Dole effect according to Bender et al. (1994b). Three different oxygen consuming respirative fluxes (dark respiration, photorespiration, Mehler reaction) contribute to the total ecosystem respiration, R_{eco} , each with a different specific fractionation ϵ . This oxygen consuming process is exactly balanced by oxygen production during photosynthesis tagged isotopically with the isotopic composition of leaf water $\delta^{18}O_{leaf}$. The total terrestrial DE is 22.4‰ with a terrestrial O_2 flux of 20.4 Pmol yr^{-1} . Respirative fractionation in the ocean is slightly smaller than on land mainly due to respiration of already enriched oxygen in the deep and intermediate ocean. The photosynthetically produced O_2 flux has an isotopic signal of approximately 0‰ resulting in an oceanic contribution to the DE of 18.9‰ with an oceanic productivity of 12 Pmol yr^{-1} . The steady state solution of this best estimate is 20.8‰ compared to an observed DE of 23.5‰.

and Antarctica. The $\delta^{18}O_{Atm}$ signal is globally uniform within today's instrumental precision. Its variations in the past can therefore be used to synchronize ice cores from the Northern and Southern Hemisphere (Sowers et al., 1991; Bender et al., 1994b). Furthermore, the $\delta^{18}O_{Atm}$ signal was shown to be remarkably in phase with precessional insolation variations during the last four glacial/interglacial cycles (Petit et al., 1999). This observation was used to establish a more precise dating of polar ice cores (Parrenin et al., 2000; Shackleton, 2000). Modeling the DE also offers the potential of quantitatively constraining marine and terrestrial productivity in the past (Leuenberger, 1997; Hoffmann et al., 2003).

DRUMLINS

A drumlin is a subglacial landform that appears as a distinctive streamlined hill of sediment in the postglacial landscape. The term is derived from a Gaelic word meaning a mound or rounded hill. Drumlins vary significantly in size, shape and composition, and their origins remain controversial.

Drumlins are streamlined in the direction of ice movement, with a degree of elongation typically about 3:1 but sometimes as much as 60:1. At higher elongations drumlins grade into megaflutes. The up-glacier (stoss) end is typically the steeper and blunter while the downstream (lee) face is more gently sloping and more sharply pointed in plan form. Drumlins may occur singly or in “swarms” containing hundreds or thousands of hills. The largest drumlins reach 50 m in height and may be 20 km long, while the smallest examples are only 10 m long and grade

into other classes of smaller streamlined features such as flutes. Small drumlins can be superimposed on larger ones.

The composition of drumlins is variable but typically dominated by massive diamicton usually interpreted as till. Some drumlins contain a rock core and many include coarse stratified glaciofluvial deposits. The material is often highly deformed.

Several different origins for drumlins have been proposed and it is likely that different drumlins are formed in different ways. Some models suggest that drumlins are remnants of subglacial erosion of previously deposited sediments. It has been suggested that erosion was accomplished by huge subglacial “megafloods.” Other models suggest that drumlins are depositional features reflecting either subglacial lodgment or meltout. Many theories propose that the key processes are deformational. A widely accepted model is that drumlins are created by differential movement of material within a deforming subglacial sediment layer. The drumlins reflect areas of less mobile sediment while intervening areas reflect more rapidly moving material. Stratified sediments in some drumlins have been interpreted as lee side stratification sequences in water-filled cavities on the downstream end of drumlins. The flow of water through subglacial sediment under varying pressures, and the deformation of material in response to both glacial and water pressure are central to much current thinking about drumlins.

It has been suggested that drumlins form in a narrow belt only 20–30 km wide close to an ice-sheet margin. As the margin retreats, the zone migrates, and extensive fields of drumlins can be created in a time-transgressive sequence. It has also been suggested that drumlin fields mark the positions of former ice streams. Although drumlins are possibly the most intensively studied glacial landform, our understanding of them remains incomplete. However, it is clear that they have the potential to provide important information about former ice sheets both through their geographic distribution and through their sedimentology. Useful reviews are provided by Benn and Evans (1996), Bennett and Glasser (1996) and Hambrey (1994).

DURICRUSTS

Duricrusts are near-surface geochemical crusts formed as a result of low-temperature physicochemical processes operating within the zone of weathering that lead to the absolute or relative accumulation of minerals through the replacement

Figure D43 A 10 m thick exposure of silcrete and calcrete in the flanks of the Auob Valley at Kalkheuvall, Namibia (photograph: David J. Nash).

and/or cementation of pre-existing soil, sediment, bedrock, or weathered material. They can vary in hardness from powdery to highly indurated, and may reach thicknesses of >50 m although 1–10 m is more common (Goudie, 1973). Calcrete or caliche (cemented by calcium carbonate) is the most widespread form and is estimated to underlie >13% of the Earth's land surface (Wright and Tucker, 1991). Iron- and aluminum-rich ferricretes and alcretes are the next most common, and occur over large areas of west, central and east Africa, Australia, and India. Silica-rich silcrete is less widespread but is locally important in southern Africa, Australia, and Europe (Watson and Nash, 1997). Other accumulations such as calcium sulfate-cemented gypcrete are sometimes defined as duricrusts but are less likely to persist within the landscape. In contrast, durable duricrust varieties such as ferricrete and silcrete can act as important controls upon landscape evolution once exposed since they may form resistant caprocks (Figure D43).

There is no single model to explain the formation of all duricrusts. Ferricretes and alcretes commonly form by the relative accumulation of iron and aluminum oxides and hydroxides in seasonally-wet humid to sub-humid tropical environments as other more mobile elements are leached from weathering profiles. Absolute accumulation may also occur where iron and aluminum are transported downslope mechanically or in solution, or are mobilized within the weathering mantle. Silcretes and calcretes usually develop through the absolute accumulation of silica and calcium carbonate derived from rock weathering, dust, rainfall, surface- and groundwater, or biogenic sources. The translocation of solid or dissolved materials to sites of accumulation can be achieved via lateral movement of solutions through fluvial, lacustrine, or groundwater systems, and/or by vertical transfer mechanisms such as percolation and capillary rise (often in association with pedogenesis). Once at a site of accumulation, silica and calcium carbonate precipitation can be triggered by evaporation, pH changes, reactions with other cations, and organic activity.

Duricrusts may act as important paleoenvironmental indicators, particularly when found beyond their zone of contemporary formation or within the geological record. However, it is vital that the factors controlling formation are understood prior

to their use as such indicators. Low relative relief appears to be a requirement for the development of all varieties since the rate of formation must exceed that of removal of material by erosion. Topography may also influence the ability of a host material to retain moisture or permit leaching. The availability of a source material is critical in determining the degree and rate of formation. There is less agreement about the climatic requirements for duricrust formation. Calcretes are known to be forming today in dryland regions with rainfall in the range 200–600 mm (Goudie, 1973), and may, therefore, be a useful indicator of semi-arid climates. The environment of silcrete formation is more complex, with pedogenic varieties thought to develop under humid tropical climates and non-pedogenic silcretes under arid tropical conditions. However, as silcretes are only forming in one location today (through fixation by cyanobacteria in the highly alkaline Sua Pan, Botswana), it is difficult to identify representative modern analogs. The requirement of intensive leaching for ferricrete and alcrete development makes them a potentially useful indicator of humid tropical climates, with alcretes more prevalent where contemporary rainfall levels are particularly high.

DUST TRANSPORT, QUATERNARY

The atmospheric cycle of soil-derived dust aerosol is expected to respond to changes in global climate conditions, such as the overall intensity of winds that entrain dust, and changes of the hydrological cycle that can affect the extent and dryness of source areas as well as the length of time that dust remains in the atmosphere. At the same time, dust can potentially impact global and regional climate conditions in several ways, by impacting the radiative balance of the atmosphere or by providing micronutrient fertilizers to marine and terrestrial plants, thereby modulating atmospheric CO₂ concentrations. Major dust source regions today are the Saharan desert, Arabia, the Asian deserts, Australia, and North America. The majority of atmospheric dust comes out of North Africa (50–70%) and Asia (10–25%).

Dust is particularly important within the context of the Quaternary because large fluctuations and overall increases in atmospheric dust concentrations coincided with the onset of Northern Hemisphere glacial cycles, approximately 2.8 Ma. The longest land records suggest that relatively continuous atmospheric dust deposition occurred on the Chinese Loess Plateau since about 7 Ma (Ding et al., 1999). These records, along with marine records from the North Pacific (Rea et al., 1998), suggest that dust deposition was enhanced following a geologically more recent phase of uplift of the Tibetan Plateau (approximately 3.6 Ma). This uplift blocked Indian moisture sources from reaching East Asia and created conditions favorable for the development of the East Asian monsoon, which modulates the southward flow of cold dry air masses across the East Asian continent in winter. As glacial cycles intensified, they enhanced conditions of stronger winds and higher aridity that favor dust emission during cold periods.

Marine sediment records of dust from around Africa also suggest a shift from a predominantly monsoon-driven climate before 2.8 Ma towards more arid conditions modulated by the periodicity of Northern Hemisphere glaciations after 2.8 Ma (deMenocal, 1995). The intensification of Northern Hemisphere glaciations resulted in cooler North Atlantic surface ocean temperatures that inhibited the expansion of the North African summer monsoon into the African continent, thereby increasing Saharan and Sahelian aridity.

Dust deposited over land, ocean or ice surfaces can be preserved in the geologic record and serve as archives of periods of past dustiness. Determining exact changes in deposition rates between different time periods is limited by the many different techniques used to measure dust, as well as the limited number of precise dates generated on these different sediment types. Nevertheless, significant efforts have been made to quantify changes in dust deposition through time, and the best-documented period of intensified dustiness in the Quaternary is the Last Glacial Maximum (approximately 17–23 ka). From these records, we know that dust was about 2–3 times increased globally during glacial periods compared with interglacial periods (Figure D44). During the last glacial period, North Africa remained the most important source of dust, but both data and models suggest an additional expansion of Asian, Australian, and South American dust sources during this time.

Loess deposits

During the last glacial period, loess deposition was greatly expanded, mostly in periglacial regions such as North America,

the Eurasian continent, and the South American Pampas region. The source of dust forming loess deposits is largely material that has been ground by glaciers and subsequently becomes available following fluvial transport to arid, non-vegetated source regions. Loess deposits are indicators of changes in both the extent and activity of dust sources, but also strongly depend on local conditions like terrain forms. For example, flat basins are relatively stable sites of continuous deposition. River terraces very near sources frequently show amplified deposition rates and are more likely to contain erosional discontinuities. Dust particles deposited in loess regions consist of relatively coarse particles (10–63 μm size) that have not been transported over large distances. As a result, deposition rates in loess deposits have been measured to be as high as 20,000 g m⁻² yr⁻¹ in the mid-continental USA (Roberts et al., 2003), while much of the loess deposited on the Chinese Loess Plateau falls in the range of 300–500 g m⁻² yr⁻¹.

Patterns of thickness and loess grain size can provide information about surface transport trajectories of loess. For example, in the mid-continental USA, thickness trends in the last glacial loess indicate that predominant surface winds came from the west and northwest (Figure D45). Loess thicknesses are greatest near dust sources along rivers, at the southern edge of the North American ice sheet, and directly downwind of the Rocky Mountains, and rapidly decrease to the east of these source regions.

Marine sediments

In order to examine dust records in marine sediments, one must first isolate the terrigenous material within marine sediments, and then avoid contamination by non-eolian terrigenous material such as turbidites, river plumes, ice bergs, and deep currents ice-rafted detritus. Once these complications are circumvented, marine sediment records can be good indicators for intermediate and long-distance transport of dust particles. Mean grain sizes in marine sediments are usually much less than 10 μm, although larger grains are found in sediments close to continental source areas. Accumulation rates in marine sediments can be as high as 100 g m⁻² yr⁻¹, but are usually in the order of 1–10 g m⁻² yr⁻¹.

Overall, marine sediments suggest about a 2-fold increase in glacial compared with interglacial dust deposition in the tropics and mid-latitudes, where the records are reliable. Different regions experienced different changes in dust deposition during glacial-interglacial cycles. Marine sediments in the North Pacific region suggest a 1–3-fold increase in dust deposition at the LGM compared to the late Holocene period, deposition off Africa increased by approximate 2–5 times, and deposition to the southeast of Australia shows 2–9-fold increases in dust deposition during glacial periods. In contrast, although the absolute magnitude of dust entering the Arabian Sea is high, increases in glacial dust deposition over the Arabian Sea are relatively small (60–80% increase at the LGM compared to today). In general, the spatial patterns of where dust was deposited did not undergo major changes, suggesting that the actual transport pathways of dust did not shift significantly between glacial and interglacial periods for most parts of the world.

Ice cores

Ice cores provide a record of long-distance transport of dust that reflects combined changes in source strengths, transport, and deposition through time. Grain sizes of dust found in ice cores are almost always smaller than 5 μm in diameter. Glacial increases in dust fluxes are highest in the Antarctic ice cores, with an approximately 10-fold increase in the Vostok Ice Core

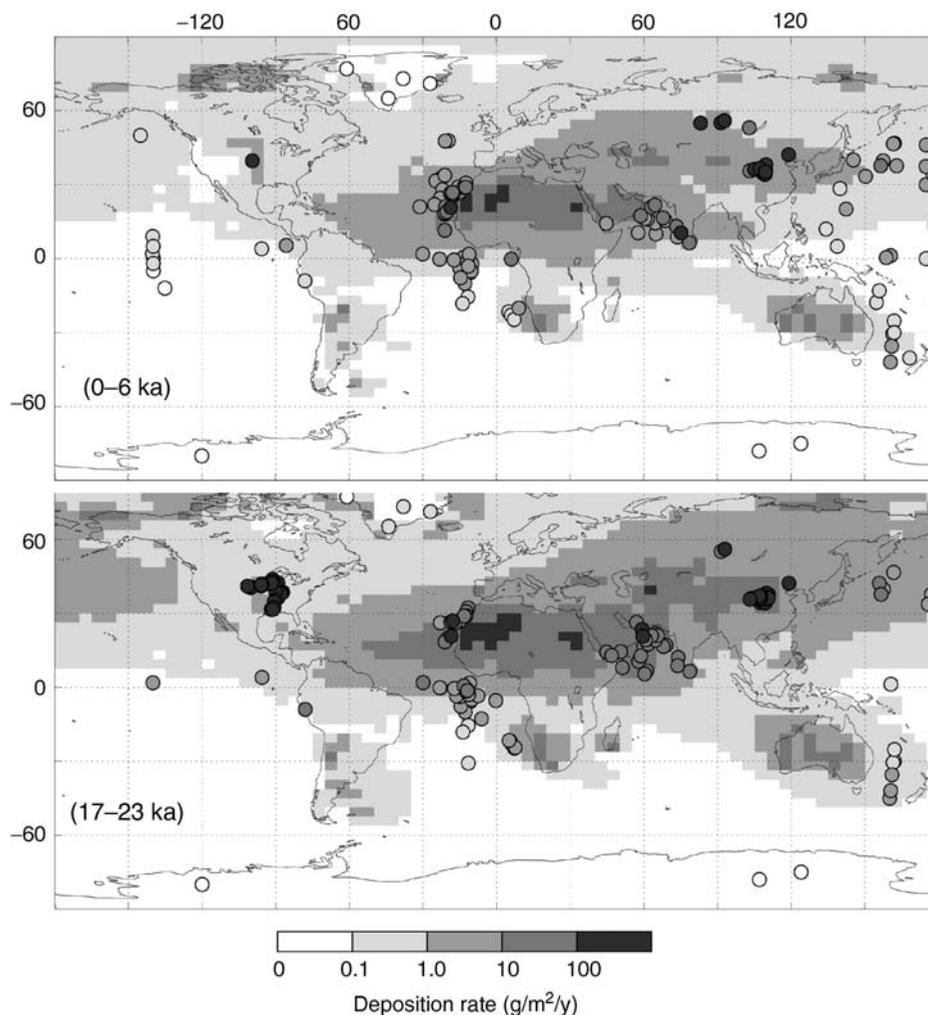

Figure D44 Simulated and observed glacial-interglacial changes in dust deposition between the late Holocene (0–6 ka) and the last glacial period (17–23 ka). Geological data are represented by circles taken from the Dust Indicators and Records of Terrestrial and Marine Paleoenvironments (DIRTMAP) database (Kohfeld and Harrison, 2001) superimposed on model results of Werner et al. (2003).

(Petit et al., 1999). While the changes in dust fluxes at these locations are very high, the actual fluxes are low (on the order of $0.0001\text{--}0.01\text{ g m}^{-2}\text{ yr}^{-1}$).

Mineralogical and isotope studies of the dust from ice cores in both Greenland and Antarctica have been used to constrain the polar transport and origins of dust. Current studies indicate that glacial dust arriving at Antarctica originates in southern South America (which is the dominant source), with lesser amounts possibly derived from northern New Zealand and the Antarctic dry valleys (Delmonte et al., 2002). Dust arriving in Greenland originates in the Asian deserts. Ice-core dust concentrations during interglacial periods are generally so low that their source regions cannot be pinpointed. However, studies on snow pits near the Greenland ice cores suggest that modern dust is still derived from Asian deserts (specifically the Takla Makan and Inner Mongolian deserts of northern China (Bory et al., 2002).

Ice core data from Vostok have also revealed the relative timing of changes in dust fluxes compared with other environmental parameters such as temperature and CO_2 (Figure D46).

In these records, dust increased well after the onset of glacial cooling and lowering of atmospheric CO_2 , with peak dust fluxes occurring only during peak glacial periods. This timing may provide insights into the causes of increased dustiness, as well as feedbacks of dust on climate parameters such as temperature, precipitation, and radiative balance.

Causes of increased glacial dustiness

Possible causes for increased dust emissions in glacial periods are stronger surface wind speeds that could lift higher amounts of dust aerosols from surfaces compared to modern conditions; increased aridity, which would expand the areas with drier soils and reduced vegetation where soil deflation by wind is possible; and increased availability of fine sediments that could easily be picked up by surface winds. Atmospheric loading of dust particles could also be increased under cold climate conditions as a consequence of the weakened hydrological cycle. (This can be deduced from the Clausius-Clapeyron relationship, which predicts lower atmospheric water content at lower temperatures.) The decrease in atmospheric water content leads

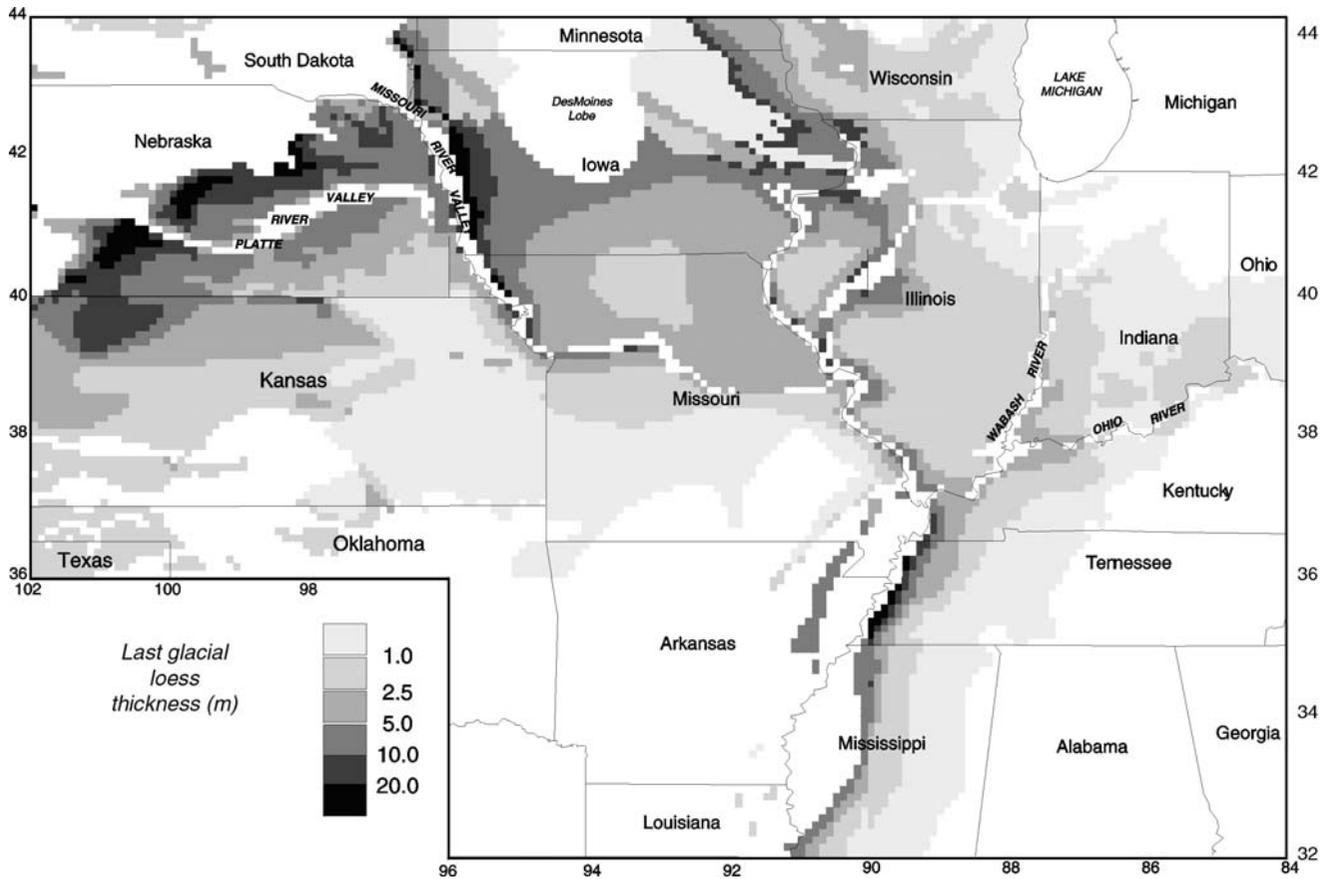

Figure D45 Thickness of last glacial loess from the midcontinental USA (Kohfeld and Harrison, 2001).

to decreased precipitation, reducing the washout of atmospheric dust particles and thus leading to longer atmospheric lifetimes.

The Last Glacial Maximum (LGM) has been a major focus of dust cycle modeling (e.g., Joussaume, 1993; Andersen et al., 1998; Mahowald et al., 1999; Reader et al., 1999; Lunt and Valdes, 2002; Werner et al., 2003), partly because dust deposition rates were high and well-documented for comparison (e.g., DIRTMAP, Kohfeld and Harrison, 2001), and partly because the changes in boundary conditions (e.g., ice sheet extent, atmospheric composition) are relatively well known.

Global dust models can only reproduce the increase in glacial dust deposition observed at high latitudes when the combined impact of increased wind speeds, reduced intensity of the hydrological cycle, and vegetation changes are included together. Neither increase in surface wind speeds and decrease in soil moisture alone (Joussaume, 1993; Andersen et al., 1998; Reader et al., 1999), nor additional increase in dust source areas caused by exposure of continental shelves can explain the observed increased high latitude dust (Andersen et al., 1998; Reader et al., 1999). Incorporating increases in dust source areas from changes in vegetation cover (Mahowald et al., 1999; Lunt and Valdes, 2002) produces a 20-fold increase in atmospheric dust loads at high latitudes, which is consistent with the high dust fluxes observed in polar ice cores. An LGM simulation using a full seasonal cycle of vegetation cover as a mask for dust emissions, as well as dried lake-beds as preferential dust emission regions, shows a more moderate increase in dust emissions, of a factor

of 2–3 during the LGM, in agreement with the available marine sediment and ice core data (Werner et al., 2003). The potentially large effect of dust supplied by glacial outwash, and increase in dry lake-beds at the LGM has not yet been evaluated by such global dust cycle models.

Effects of increased glacial dust

Dust may impact the climate by its direct radiative effect, i.e., it may either decrease or increase surface temperatures and modify atmospheric circulation depending on its optical properties and the albedo of the surface underlying the dust cloud. Overpeck et al. (1996) hypothesized that absorption of solar radiation over bright, ice covered surfaces in the Northern Hemisphere could cause warmer temperatures compared with those that would have occurred without increased dustiness at the LGM. In contrast, Claquin et al. (2003) showed that warming by dust would have a negligible effect at high latitudes when compared to the cooling impact of increased albedo due to the tremendous ice sheet expansion at the LGM. On the other hand, Claquin et al. (2003) estimated that the albedo feedback due to increased glacial atmospheric dust could reduce the incoming radiation in the tropics by as much as 2 W m^{-2} , which is the same order of magnitude as the decrease in greenhouse forcing due to reduced atmospheric CO_2 . This decrease in solar radiation at the surface might have caused additional cooling at low latitudes during the LGM. So far, no estimates regarding the impact of increased glacial dust on cloud

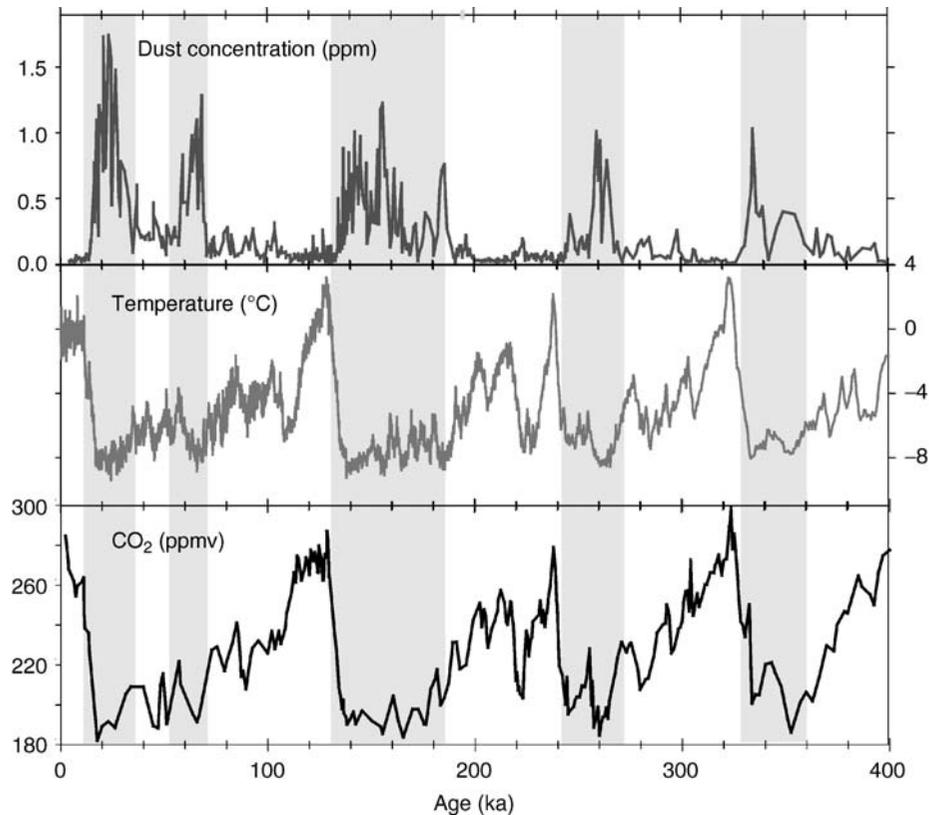

Figure D46 Records of temperature, carbon dioxide, and dust concentrations taken from the Vostok Ice Core, Vostok, Antarctica (Petit et al., 1999).

properties exist, but it is suspected that the presence of dust particles could have a significant impact on the brightness of clouds and precipitation formation (Rosenfeld et al., 2001).

In addition to the radiative effects of dust, the addition of iron from the increased dust deposited over the ocean could have fertilized the oceanic biosphere and subsequently enhanced the drawdown of atmospheric CO₂. This effect has been estimated to lie between 10 and 40 ppm of the observed glacial-interglacial atmospheric CO₂ change (Archer et al., 2000; Watson et al., 2000; Bopp et al., 2003). However, these estimates still incorporate large uncertainties, ranging from the estimation of Fe solubility to the exact role of Fe within marine ecosystems.

E

EARLY PALEOZOIC CLIMATES (CAMBRIAN-DEVONIAN)

Introduction

Early Paleozoic climates obviously cannot be studied directly. Proxies for climate must be employed as a substitute for direct observations. These proxies include lithological indicators, such as evaporites, calcretes, tillites, coals, kaolins, and bauxites. Evaporites, marine and nonmarine, are evidence of climatic conditions adequate to permit precipitation of salts from concentrated seawater or freshwater, i.e., arid climates. Marine evaporites are formed only in shoreline regions and not in the open ocean or in estuarine, lagoonal, or other situations where seawater is subject to enough evaporation to permit precipitation of its load of dissolved salts. This is also the case with nonmarine evaporites formed in permanent (lakes) or temporary (playa) environments. The evaporate minerals commonly preserved in the geological record are calcium carbonate (most commonly calcite), sodium chloride (halite), and calcium sulfate (anhydrite [anhydrous] or gypsum [hydrated]). Evaporites are overwhelmingly representative of arid, desert type environments. Calcretes are lumps (nodules) or layers (limestones) of calcium carbonate precipitated in the lower layers of ancient soil profiles under semiarid conditions. Tillites are lithified glacial deposits, and may also include glaciomarine deposits. Coals are chiefly lithified higher land plant materials, representing overall humid conditions, warm to cold, that first appeared in the Late Devonian when woody plants became widely preserved in what were peats in swamp or bog environments. Kaolins are clay deposits dominated by the hydrated aluminum silicate kaolin, or transported grains of the mineral derived from nonmarine clay deposits, formed under at least annually warm, humid weathering conditions. Bauxite is a lateritic product formed under tropical-subtropical, annually humid weathering conditions. Note that all of these materials are basically nonmarine in origin, although their salts are of marine origin. "Marine" evaporites occur in the shoreline region, although they commonly mix with nonmarine evaporitic materials in the landward direction. An extended discussion of these items is

provided by Boucot et al. (in press). Other potential climatic proxies, such as oolitic sedimentary iron ores and sedimentary phosphate deposits, are still too poorly understood in this context to be employed.

Additionally, there is an important suite of sedimentary rocks and associated cool/cold climate faunas in the Cambrian through the early half of the Middle Devonian that provide evidence about very high southern latitude conditions, the so-called Malvinokaffric and Atlantic realms (see Boucot and Blodgett, 2001, for an example).

Geographically, it is important to understand that the present distribution of these climatic proxy materials commonly does not correspond to their original geographic position owing to subsequent movements of varied crustal blocks following the Early Paleozoic, as well movements that occurred during the lengthy Cambrian-Devonian. With this in mind, the Cambrian-Devonian climatic proxy distributions may, in principle, be used to estimate the changing positions of Cambrian-Devonian climatic belts. However, owing to the somewhat limited known record of Cambrian-Devonian climatic proxy materials, there are limitations imposed on these climatic reconstruction possibilities. For example, there are no known Silurian bauxites, with very few in the Ordovician and none in the Cambrian, although a few that are present in the very late Precambrian permit estimation of where bauxite-forming environments might have been located in the Cambrian.

It has been concluded that there were several significant changes in the global climatic gradient during the Cambrian-Devonian (i.e., the Equator to polar temperature gradients, which are high during times of polar glaciation and low during times of polar warm temperate conditions), from moderately high in the Cambrian through earlier Middle Ordovician, very high during the later Middle to Late Ordovician, back to moderately high in the Silurian through earlier Middle Devonian, followed by a globally lower later Middle Devonian, a relatively low Late Devonian, and terminating in a relatively high gradient in the very latest Late Devonian.

Atmospheric and oceanic composition

There is no direct information about Cambrian-Devonian atmospheric or oceanic composition(s). Boucot and Gray (2001)

summarized current information about atmospheric carbon dioxide tenor that discounts earlier modeling attempts by others. [Figure E1](#) provides a summary of changing Cambrian-Devonian global climatic gradients. If atmospheric carbon dioxide concentrations are a direct function of global climatic gradient (i.e., global mean temperature with carbon dioxide assumed to be the major greenhouse gas), the Cambrian through earlier Middle Devonian concentrations were probably not much higher than today, but were significantly higher for the much lower global climatic gradients of the later Middle Devonian through much of the Late Devonian.

Oceanic composition, i.e., major and trace element ionic composition and concentration, cannot be directly measured. However, when one the physiological requirements of marine organisms, chiefly megascopic, are considered, it can be concluded that it is unlikely that oceanic composition has changed significantly from the Cambrian to the present unless there have been varied evolutionary changes affecting their physiologies, which is unsupported by available data.

Global climatic gradients

Boucot and Gray (2001) summarized Phanerozoic global climatic gradients ([Figure E1](#)). It is clear from the evidence that average global mean annual temperatures have changed back and forth over time. High global climatic gradients featuring continental glaciation are present only in the later Ordovician (part of the Caradocian plus the Ashgillian epochs) where a large Southern Hemisphere region, including at least Africa, the southern two-thirds of South America, and glaciomarine conditions extending into Central Europe, are involved. The later Devonian is characterized by a far lower global climatic gradient than at present.

Cambrian climatic evidence

The Cambrian features the beginning of high latitude Southern Hemisphere cool/cold regions that include Africa; South America, except for the Argentine Precordillera, where evaporites and calcrete are recognized; parts of easternmost North America; and most of Europe, except for Sardinia, where local evaporites are known. Arid conditions are indicated for a widespread, lower latitude Southern Hemisphere belt to the north of the cool/cold climate belt, which includes North America, the Near East and Arabia, northwestern peninsular India, North and South China, southern Siberia, and Australia. There is no evidence for a tropical-subtropical belt owing to the nonrecognition of bauxites, but such a belt is inferred by extrapolating from the prior late Precambrian and subsequent Ordovician situations.

Early Ordovician

The known Early Ordovician climatic distribution data are similar to that for the Cambrian. Cool/cold, high southern latitude rocks and faunas are known from parts of South America and North Africa as well as most of Southern and Central Europe. To the north of these, there is widespread evidence of arid conditions at lower latitudes, with widespread evaporites in North America, the Argentine Precordillera, North China, Australia, southern parts of the Siberian Platform, and southern Thailand (the Shan-Thai Terrane), together with an occurrence in Northern India. Again, there are no known bauxites but evidence extrapolated from the overlying Middle Ordovician suggests the presence of a warm, humid tropical-subtropical belt. Climatic evidence is lacking for Antarctica, Northern Europe, and Central Asia.

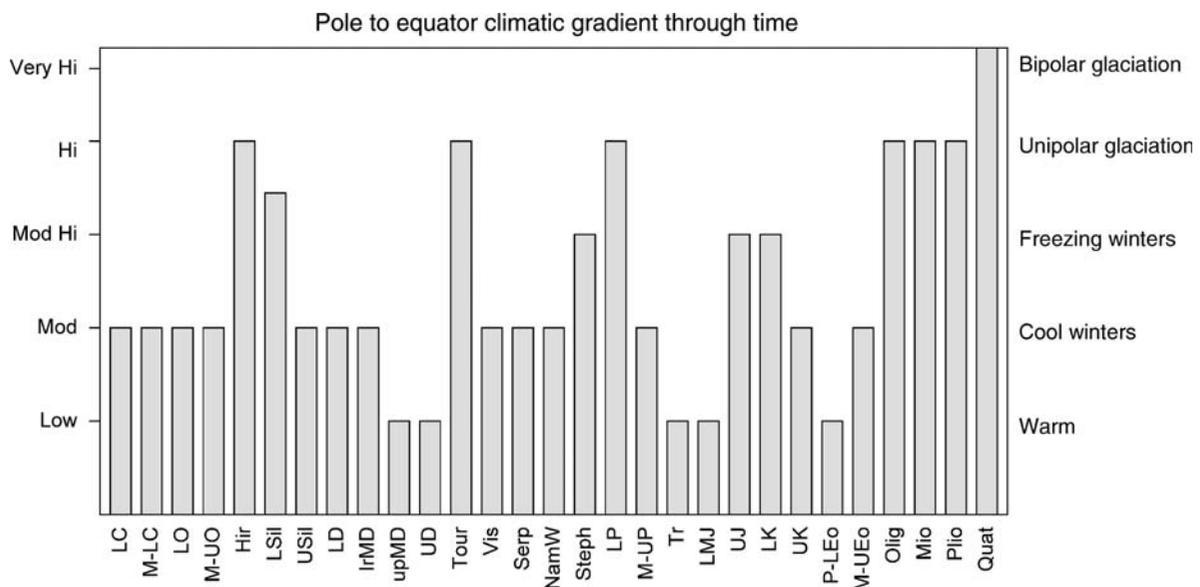

Figure E1 Periods when warm temperature indicators are present at high latitudes are taken as representative of intervals of low climatic gradient. Periods of temperate indicators at high latitudes display moderate climatic gradients, while times of cool to cold climate indicators near the poles suggest freezing winters, indicating “moderately high” climatic gradients. Continental glaciation at one pole represents an interval of high climatic gradient. Continental glaciation at both poles (i.e., the Quaternary), represents a period of “very high” climatic gradient (based on data from Boucot et al., in press).

Middle through end Ordovician

The middle to end Ordovician features later Ordovician evidence of global heightening of the climatic gradient, culminating in widespread latest Ordovician, Southern Hemisphere, high latitude, continental glaciation. Prior to this glaciation, there is evidence for cooler climates occurring earlier in the later-Ordovician, indicated by dropstones in North Africa and tillites in South Africa that are earlier in time than the latest Ordovician continental glaciation. Evidence of the latest Ordovician includes widespread sites in North Africa and Arabia, scattered localities in South America from southern Peru south, and widespread dropstones in central and Southern Europe, all of which probably reflect freezing winters at the very least, if not actual glaciation. Throughout this interval in the Southern Hemisphere, there is faunal and lithological evidence for cool/cold water conditions at higher latitudes. At lower southern latitudes, there is widespread evidence of an arid belt with widespread evaporites and calcretes in North America, and evaporites in Northern Europe (Baltic region and northern Russia), North and South China, Australia, and southern Siberia. Evidence for a humid tropical-subtropical belt is provided by Middle Ordovician bauxites in southeastern Kazakhstan and on part of the Siberian Platform. A Northern Hemisphere arid belt is indicated by the presence of evaporites in southern Siberia. The presence of kaolins in the same region as evaporites, in North America for example, is most easily explained by at least annually humid intervals at higher elevations with overall arid conditions widespread at lower elevations.

The presence of later Ordovician bauxites in northwestern Sudan is supportive of a brief incursion of warm climate conditions during the later Ordovician featuring warm water fauna and limestone in Central and Southern Europe and North Africa.

Silurian

There is widespread, high southern latitude lithological and faunal evidence for cool/cold climate conditions, with associated tillites, in the earlier Silurian at scattered Brazilian localities and dropstones at several North African localities. At lower southern latitudes, there is widespread evidence, including both calcretes and evaporites, from North America, Europe, Iran, northern India, and Australia that is indicative of a Southern Hemisphere arid belt. Evaporites in southern Siberia are consistent with the presence of a Northern Hemisphere arid belt. No bauxites are presently recognized in the Silurian, but a tropical-subtropical belt is extrapolated from later Ordovician and Devonian data.

Early Devonian

Climatically useful data for the Early Devonian indicates the presence of a high southern latitude cool/cold climate region, consistent with both faunal and lithological evidence. A lower latitude Southern Hemisphere arid belt is indicated by North American evaporates; calcretes and evaporites in Europe; evaporites in Iran, Libya, and northwestern Arabia; calcretes and evaporites in North and South China and Tarim; and evaporites in Australia. A Northern Hemisphere evaporate belt is suggested by widespread evaporites in Southern Siberia. Tropical-subtropical belt evidence is restricted to bauxite occurrences in the northern part of the eastern Urals and the Salair.

Middle Devonian

The Middle Devonian features the presence of the same cool/cold climate high southern latitude region indicated both faunally and lithologically for the earlier half of the Middle Devonian, followed by a lowering of the global climatic gradient consistent with the disappearance of this cool/cold climate region in the latter half of the interval. A warm temperate, mid southern latitude belt is consistent with North African coal at a single locality, more widespread kaolins in northern South America and North Africa, and coal in Libya. At still lower southern latitudes, there are widespread evaporites and calcretes in North America and Europe, evaporites in Australia, and calcrete in the later Middle Devonian of Antarctica. Evaporites in southern Siberia are consistent with a Northern Hemisphere arid belt. A tropical-subtropical belt is consistent with bauxites in southern Siberia, southeastern Kazakhstan, and northeastern Russia as well as coal from Central Asian and South China. In the later Middle Devonian, coals overlying earlier Middle Devonian evaporites in Arctic North America indicate movement into the tropical-subtropical belt.

Upper Devonian

The Upper Devonian features a latest Devonian restricted region of continental glaciation in the region from Bolivia through the Amazon and Parnaíba Basins, plus possible occurrences in Chad. A lower latitude Southern Hemisphere arid belt is represented by widespread North American calcretes and evaporites (except for northernmost coals), European and Australian evaporites and calcretes, plus evaporates and calcretes in localities in northern India, Asiatic Russia, Kazakhstan, Iran, and Turkey, and calcretes in Vietnam. Northern Hemisphere arid conditions are represented by Siberian Platform evaporites. The tropical-subtropical belt is represented by coals in South China, Bear Island and Svalbard; and bauxites in South China, the Salair and southern Siberia, the Urals, southeastern Kazakhstan, and the Russian Tien Shan and Timan.

EARTH LAWS AND PALEOCLIMATOLOGY

Introduction

Paleoclimatology, as one of the Earth Sciences, is subject to the laws of physics, chemistry and biology. Specifically, five “Earth laws” apply to this planet. Four of these, with limitations, also apply to other celestial bodies in the Solar System (Shirley and Fairbridge, 1997). Paleoclimatology falls within the scope of all five Earth laws.

The five laws, proposed here, are modified from earlier writings (Fairbridge, 1980). They are summarized as follows but discussed in some more detail (with selected references) later in this entry.

- *First Earth law: Stellar evolution and history of the Sun.* The Solar System has a finite existence that depends upon the evolution of the Sun, which behaves as a “main-sequence” star, burning hydrogen into helium, with nuclear fusion as its primary source of energy. The Sun’s energy is in part gravitational, relating to the inertial effects of its angular momentum developed by its rotation (axial spin), and to its orbital motions, which are accelerated by those of the planets (and cumulative). In addition, there are two types of solar emissions: electromagnetic radiation (dominated by optical wavelengths, e.g., 400–750 nm) and ionized, magnetic particles in the solar wind. Of importance to Earth history and climate is the long-term stability of the Solar System due to the Sun’s estimated 10 billion-year lifespan, thus enabling evolution to progress to more advanced forms of life.
- *Second Earth law: Galactic cycles.* As components of the Milky Way Galaxy, the Sun and Solar System are subject to its motions and history, following an inertial orbit from *perigalacticum* (closest approach to the center, a “black hole”) to *apogalacticum*, the farthest, with the cycle lasting about 240 Myr. On Earth, the ice ages, long-term geomagnetic reversals, and organic evolution may be modulated by it.
- *Third Earth law: Physical evolution of the Earth and Moon.* The physical evolution of the planet Earth, through 4.6 billion years, involves the gravitational ordering of its successive spheres – core, mantle, lithosphere, hydrosphere and atmosphere – a process known as differentiation, which occurred early in Earth history. This evolution has subsequently been modulated by the motions and tides of the Earth’s only natural satellite, the Moon, which has a revolution closely locked into its own 365.25 d period. Earth’s history and climate have also been influenced by secular changes in the obliquity of its spin axis.

Changes in the state of the Earth over time are recorded in the rock strata. Cutler (2003), in a recent biography of Nicolaus Steno (1638–1686), a Danish priest and early geologist, points out Steno’s fundamental observation that sedimentary rocks were laid down in water sequentially, establishing the geological “law of superposition.” It was based on exhaustive field work and proved conclusively the principle of physical evolution. It also provided evidence for the immensity of geological time. This latter inference remained to be demonstrated some two centuries later when applied to biological evolution.

- *Fourth Earth law: The organic or biological evolution of the Earth.* This has proceeded without interruption following

the first appearance of self-reproducing organisms at a very early stage in its history (“Hadean”). A certain degree of planetary stability is implied by the continual existence of life on Earth for over 3 billion years. During this time, the Earth has not undergone a runaway greenhouse effect, as on Venus (see *Atmospheric evolution, Venus*, this volume), nor has it frozen entirely (placing constraints on the concept of “Snowball Earth,” Hyde et al., 2000; Hoffman and Schrag, 2000; *Snowball Earth hypothesis* – this volume). Increases in species and speciation (as shown by stratigraphic paleontology) have accelerated through time, in spite of periodic mass extinctions that appear to be due to asteroid impacts, volcanism, ice ages and plate-tectonically forced isolation. Each mass extinction creates an ecologic “vacuum” that leads to an abruptly accelerated new speciation. Classical biological evolution *per se* through mutations (such as shown by embryology or DNA) or natural selection are of secondary significance compared with the dramatic speciation demonstrated by the paleontological/stratigraphic sequence following such extinction events. The “biosphere” (habitable region of the planet) interacts closely with the atmosphere, hydrosphere and superficial lithosphere (“pedosphere”), with mainly biogeochemical changes through time.

- *Fifth Earth law: Principle of Homeostasis.* The fifth law refers to dynamic equilibrium, a multi-feedback mechanism that tends to keep all natural systems in relative balance. On the planetary scale, that balance is represented by the “invariable plane” of the Solar System – the ecliptic. Passage through it affects the physics of every planet and their satellites. The 88-day highly elliptical orbit of Mercury (reflected in the Sun’s radiation spectrum) contrasts with the ecliptic-crossing orbits of Neptune and Pluto (with a revolution of 248 years). The Earth’s lunar orbit crosses this plane in an orbit of about 25,500 years ($1,370 \times 18.6134$ year, the Moon’s nodal cycle). During ice ages, Earth’s spin rate increases with near-axial ice loading, and the lunar orbit becomes shorter. During deglaciation the spin and orbit changes are opposite, but with distinct lags.

This law also applies to such terrestrial processes as *isostasy*, which determines how a crustal uplift or downwarp will be compensated in various ways (exhibited by gravitational “anomalies”). “Glacio-isostasy” applies to ice loading or melting on land and “hydro-isostasy” concerns the effect of adding glacial meltwater to the ocean, both processes affect global sea level. Another aspect of the equilibrium law is shown in orogeny, where mountain-building uplift leads to accelerated erosion, transport and sedimentation. This erosion in turn leads to renewed uplift due to isostatic rebound. The “penepplain” represents a long pause in crustal movements and is the theoretical end-phase of this equilibrium.

Earth laws: discussion and some climatological consequences

External influences on climate

The Sun

The Sun is a spinning body, tilted at about 5° from the mean plane of the planetary orbits. Its internal spin rate is about 25 days, while the photosphere’s rotation is slower, about 26–28 days, varying with solar latitude and time. The Sun also undergoes an inertial orbital revolution around the barycenter of the entire solar system. These patterns repeat sequentially but unevenly over about 178 years (Fairbridge and Sanders,

1987; Charvátová, 1995; Windelius and Carlborg, 1995). Long-term climate proxy data also disclose 178 year cycles (Windelius and Carlborg, 1995).

Inasmuch as planetary orbits are elliptical, their effects are variable, generally calculated by the beat frequencies of adjacent pairs. They are strongly cyclical. The “heartbeat” of the Solar System is approximately 19.859 years, the beat frequency of the two largest planets, Jupiter and Saturn.

The astronomic alignments of planets on one side of the Sun sets up an inertial momentum that develops a looping solar orbit around the solar system’s center of mass (the “barycenter”), as specified in the First Earth Law. Its 9.8 year cycle, generated by Jupiter, is amplified to a 19.859 year periodicity when Saturn is added, the resultant double loop being an epistrochoid with a heliocenter-barycenter distance that may sometimes exceed 1.5 million km (see Fairbridge and Sanders, 1987, fig. 26–6).

Solar energy is expressed in part gravitationally with respect to the planetary orbits, and in part by radiations that are intercepted by the surfaces of the planets. The gravitational relationship is not tidal but expressed by a torque applied both to the photosphere and to the orbiting and spinning planets, as shown by changes in their angular orbital momentum ($M \times D \times V$; mass, distance and velocity, with only mass being constant).

Solar radiations are of two types. One is essentially electromagnetic (over a wide spectrum, but dominantly in the optical range), and the other consists of ionized, magnetized particles (in the plasma of the solar wind). The first is felt primarily in the equatorial plane of the Earth (traveling at the speed of light), and fluctuates with the 11/22 year sunspot cycle. The second is highly variable in travel time, from hours to days, but the particles tend to be funneled into the Earth within the auroral oval of the magnetic poles; high-energy events often have a climatic impact. Although of low energy, the UV radiation is responsible for stratospheric ozone, which is important in climate modulation.

The Solar System is presently located about 3.6 million light-years above the mean plane of the galactic disk, a multi-arm spiral structure. Viewed from galactic “north,” this disk rotates clockwise at 160–220 km s⁻¹. However, relative to a given point on it, the Solar System moves counter-clockwise in a quasi-elliptical orbit around the galactic center, a “black hole” (Weissman, 1999). The closest approach of the Sun to the center of the galaxy, or “periglacticum,” is expected in a few thousand years, in contrast to its last “epogalacticum,” which would have been during the early Cretaceous. A complete cycle around the galaxy takes ~240 million years (see Second Earth Law). The trajectory also undulates in a vertical sense above and below the galactic plane with a period of 52–74 million years. Its last passage in an upward or “northerly” direction was about 2–3 million years ago (the beginning of the Pleistocene). Galaxies vary in structure but the Milky Way galaxy may be compared with the classical M-81, which has two very distinctive spiral arms. The passage of the Solar System through such an arm would subject the Earth to an accelerated infall of dust and comets. Such events tend to “punctuate” the planetary climate history!

“Icehouse” climates or major cooling intervals during the Earth’s history may be in part correlated with the galactic cycle, when passage of the Solar System through the galactic arms would increase the rain of cometary and possibly extra-galactic objects, which could affect terrestrial climates (e.g., cooling). Global cooling would coincide with a fall in atmospheric

CO₂, reflecting decreased land vegetation (extensive deserts), and colder seawater (reduced evaporation and lower pH). The cooling from impacts (nuclear winter scenario) would be counteracted to a small extent by warming due to CO₂ and CH₄ increase from burning wildfires, decaying organic matter, etc. (see *Bolide impacts and climate*, this volume). Alternatively, global cooling could be attributed to reduced levels of volcanism or to solar weakening.

A geologic “icehouse” may recur at intervals of about 120 Myr as the Solar System passes through the galactic arms, and may be amplified during the 240 Myr return of the perigalactic geometry, but nevertheless is always subject to a favorable paleogeography (“Susceptibility” or “Eiszeitvorbereitung” of Schwarzbach, 1963). The absence of glaciation at the Jurassic-Cretaceous boundary (expected in a 120 Myr cyclicity) has long been a point of discussion. In neritic (shallow, near-shore marine) regions it was certainly marked by a major eustatic withdrawal, but the principal factor was the global paleogeography dominated by Tethys, which maintained a warming effect on the world ocean.

While the passage of the Solar System through the galactic arms could possibly lead to cooling of the Earth, it is clear that not every such event result has resulted in an ice age. The explanation appears to lie in the unfavorable distribution of land masses and the related oceanographic circulation, as outlined below. Such periods constitute the inverse to Schwarzbach’s “susceptibility” or “preparation” rule. Thus, besides the ice ages, as climaxed in long-term “icehouse” climates, long-term (30–50 Myr) high susceptibility intervals have alternated with long-term low susceptibility “hothouse” or “greenhouse” conditions when, for example in the late Cretaceous, warm ocean temperatures extended to polar latitudes.

Milankovitch orbital cycles

Within a given ice age, there is an alternation between glacial and interglacial conditions, which are forced by Milankovitch orbital cycles of the Earth-Moon-Sun. The 90,000–100,000 year eccentricity cycle – dominant over the last 800,000 years – also has peaks at about 413,000 year. Secondary modulations are provided by the 40,036 obliquity period and two axial precessional cycles of around 19,000 or 23,000 years.

The sequence of glacial to interglacial states tends to follow a saw-tooth pattern, asymmetrically skewed toward the deglaciation phases. This is because of the latent heat of the ocean, which has a great heat-conserving potential and therefore cools slowly. When deglaciation starts, there is a tendency for run-away warming, aided by the feedback from eustatic rise of sea level, increasing global oceanicity and precipitation, spread of vegetation to semi-arid regions, and drop in albedo, due to shrinkage of ice sheets. The flood of freshwater from melting glaciers also affects ocean circulation, and produces important hydroisostatic effects. An interglacial is generally limited to about three warm pulses of only a few thousand years in an overall interval of about 20,000 years.

QBO and sunspot cycles

The most universal climate cycle over 12 months is the Quasi-biennial Oscillation (QBO) at 2.172 year, which Lamb (1977) recognized as a world-wide terrestrial phenomenon. With improved solar emission monitoring, it is now also recognized as extraterrestrial (Coughlin and Tung, 2004). Although the QBO is equatorial in its initial focus, it even reaches to the North Pole in the stratosphere (Kodera, 1993).

Spectrum analyses of all climatic and proxy time series discloses powerful spikes clustering about certain intervals. Comparison between different series at less than 22–23 years is sometimes confusing because of two factors (a) the 12-month seasonality, and (b) the ± 6 year variability of the sunspot cycle (Haigh, 2002). A great deal depends upon the source material and the length of the series. To overcome such barriers it is customary to select long series beginning at over the 22–23 years hurdle, for example the 2,600 year series of sunspots and auroras combined by Schove (1983) and analyzed by Jelbring (1995). Those peaks were identified by letters: A – 200 year, B – 133 year, C – 79 year, D – 50 year, E – 42 year, F – 33 year and G – 29 year. By selecting segments of the Schove series and analyzing them separately, Jelbring was able to (a) confirm the consistency of the Schove series, and (b) identify the major long-term peaks. Using the more precise data of the last century or so (since 1854) a 2.17 year QBO peak stood out clearly (Currie, 1995), with the same pattern occurring when the analysis was extended back to 1749.

Sea level-lunar modulation and meridional heat transport

Solar and lunar cycles appear to play a role in Earth's climate (e.g., Landscheidt, 1988; Charvátová, 1995; Hoyt and Schatten, 1997; Bond et al., 2001; Haigh, 2002; *Sun-climate connections*, this volume). A large number of regional climatic time series analyses (e.g., Currie, 1995) showed the universal presence of solar (11–22 year) and lunar (18.6134 year) forcing. The latter is further complicated by the principal oceanic tide at 18.03 year (“Saros” of the Babylonians), which in long-term records can be in or out of phase from time to time. Use of an 11-year average may be simple and straightforward, but is often wrong. Seasonality is often critical, as in the timing of El Niño before or after perihelion (around January 1–3 in the Northern Hemisphere, at present). In addition, the North Magnetic Polar oval and geographic latitude affect the concentration of the electromagnetic and particulate (solar wind) forcing. Nevertheless, it is apparent from Currie's pioneer labors that these two world-wide and astronomically predictable forcing functions (i.e., solar and lunar) should be included in all climatic studies.

The North Atlantic provides the sole significant oceanic connection with the Arctic Ocean and thus has a major effect on its circulation. The Bering Strait link plays only a minor role. The North Atlantic is modulated by the lunar tidal influence on its principal geostrophic current, the Gulf Stream. This is mediated by the zenith shift of the Moon (by over 1,100 km) every 9 years in its nodal cycle (18.6134 year). This acceleration and warming pulse is recognized not only by tide gauges and ocean temperatures but also by fishery statistics and sea-ice as far north as the Murmansk Current in the Barents Sea (Lamb, 1977, 1979). Increased evaporation in the westerly system occurs during the warming phase, raising winter snowfall in Scandinavia (small glacier advances) and increasing albedo all across central Asia (Kukla, 1981). Inasmuch as increased snowfall in the Himalayas and other Asiatic mountain systems leads to a retardation of the summer monsoon, sometimes there are droughts and famine in India, as was noted nearly a century ago by Sir Gilbert Walker. A giant feedback loop is thus created that further modulates the Indonesian wind reversal and the climate of northern Australia.

In the North Pacific, the Kuroshio is a geostrophic current analogous to the Gulf Stream, but it is mainly deflected south of the

Aleutian Islands to form the south-moving California Current off the west coast of North America. Although in its north-setting phase it has warming effects, it is cooled along the Aleutians and provides a cool pulse to North America in contrast to the warm pulse delivered by the Gulf Stream in Europe.

Tide gauge data disclose that when geostrophic currents accelerate worldwide, mean sea level responds, even in opposite hemispheres, because of the Coriolis effect. An accelerating current heading north off North America causes a fall in mean sea level near the coast, while the same trend in the Canaries Current heading south will also lower sea level off Africa. The twentieth century global rise of sea level (from about 1–2 mm yr⁻¹; Houghton et al., 2001), suggests, however, not only a sterically warmer ocean but also a more sluggish overall circulation. Climatologically, this is to be expected because the thermal gradient from the North Pole to the Equator is being reduced. Although Arctic and high latitude temperatures rise, equatorial sea-surface temperatures (SSTs) remain almost constant. The less the temperature contrast, the flatter the gradient, therefore mean sea level (MSL) rises on all continental coasts (Holgate and Woodworth, 2004). On the other hand, in mid-ocean situations (e.g., Turk Atoll in the mid-Pacific) there is remarkably little change.

Plate tectonics and paleogeography

A second very important factor in climate change and ice ages is the plate tectonic control of planetary paleogeography, specifically the relative patterns of land and sea (see *Plate tectonics and climate change*, this volume). A land-mass clustering (e.g., Pangaea) favors continentality and climatic extremes. An equatorial seaway, such as “Tethys,” on the other hand, would bring warm currents to all low- and mid-latitude land masses, incompatible with an ice age (Schwartzbach, 1963). Closure of seaways, for example at the Isthmus of Panama, the Strait of Gibraltar and the Sinai-Red Sea link, had the effect of isolating regional water bodies such as the North Atlantic and Mediterranean, and thus blocking the equalizing effect of marine circulation. The warm, open seaway of the Cretaceous Tethys therefore contrasts with the progressive blockages of Tethys that began in the early Tertiary and presaged the eventual Quaternary ice age (Fairbridge, 1961, 1967).

During the nineteenth century, it was recognized that the Earth's crust was subject to orogenic folding and faulting, but continents and oceans were taken to be permanent (“fixism”). Early in the twentieth century came “mobilism” and Wegener's theory of continental drift. With improved technology and marine geophysics in the late twentieth century, drift evolved into the plate-tectonic paradigm, which introduced crustal fracturing, sea-floor spreading, subduction and the systematic rearrangement of crustal blocks. Recently, global reconstructions became feasible.

Major break-ups of crustal plates, termed “*taphrogenesis*” (Fairbridge, 1982), once initiated, were followed by progressive dismemberment of former megacontinental blocks. Major changes in paleogeography and re-organization of continental plates can cause fundamental changes in the Earth's climate. Actualistic examples are the late Cenozoic opening of the Red Sea and the East African rifts with their major lakes. Climatologically, such taphrogenesis may introduce major moderating systems into an arid high-pressure region. In contrast, subduction and plate collisions can lead to major plateau uplift, as in Tibet, which can affect global climate (Ruddiman and Kutzbach, 1990,

1991; Raymo and Ruddiman, 1992). In a low-latitude maritime setting, numerous volcanic cones such as in the Caribbean or the Indonesian Archipelago favor micro-climates of highly varied nature. Paleogeographic reconstructions can therefore help to map out paleoclimates.

Thanks to its pre-existing physiographic irregularities, the present-day Earth is subject to a wide range of climatic variables (Oliver and Fairbridge, 1986; Hewitt and Jackson, 2003). Global average climate, however, can conceal opposing trends of temperature, pressure and precipitation, which in effect are often not only contradictory but often appear to generate spurious, random products. The search for regionally coherent patterns has proven to be much more rewarding, as was pioneered a century ago by Sir Gilbert Walker for the meteorological service of India. Notably, the most successful example has been the SOI, *Southern Oscillation Index*, which is based on regional data from the southeast Pacific (El Niño history), seawater temperatures and atmospheric pressure from the Pacific in general, and likewise from the northeast Indian Ocean. A more complex example is the *North Atlantic Oscillation* (NAO), based on the pressure difference between Iceland and the Azores, but it is susceptible to modulations of the Northern Hemisphere jet streams. These, in turn, are often subject to the influence of the North Magnetic Pole on incoming magnetized particles in the solar wind and on the locus of the Polar Vortex (see for example Boberg and Lundstedt, 2002; Thejll et al., 2003).

Global climatic asymmetry

The base of the atmosphere is the Earth's surface, two thirds of which is ocean and one third composed of rock, soil and vegetation. The land interface is subject to extreme seasonality and vegetation changes, instantly visible by satellite monitoring, and measurable most importantly in terms of *albedo*. In each hemisphere this value rises dramatically in winter over the high-latitude oceans, due to snow covered sea-ice, and over land with snow cover. However, this occurs mainly in the Northern Hemisphere because of the distribution of the continents, such that a gross *climatic asymmetry* is created in the annual heat budget. An additional albedo factor (also asymmetric) is created by the intertropical deserts (mainly Northern Hemisphere) and summer expansion of semi-arid Mediterranean lands. Global asymmetries produce non-linear responses and fluctuations in cyclic processes.

Climatologically, the Earth is not a perfect sphere but is subject to its physiography, which has a great influence on its annual heat budget. Its principal physiographic features are:

- The threefold equatorial inequality, consisting of two rainforest basins (Amazon and Congo, marked by endogenetic hydrologic systems) and the Indonesian Volcanic Archipelago (marked by about 10,000 micro-climates). Of the three, the latter constitutes the most important "center of action" on the globe. Satellite monitoring for more than a decade has shown its dominating role, with towering cumulus rising more than 15 km. The region is also unique oceanographically, straddling the two largest continental shelves in the world (the Sunda and Sahul Shelves, each more than 1.5 million km²), with the warmest ocean waters in the world. The surface water flow is always from east to west, partly tidal and partly the return phase of the "conveyor" thermohaline circulation. The resultant currents are quite powerful. They are subject to a strong lunar

cyclicality because the cold offshore water brought in over the shelf at high spring tides leads to thermal exchange with the atmosphere.

- The global continent/ocean asymmetry leads to a dominance of water in the Southern Hemisphere and land in the Northern Hemisphere. In contrast, the polar areas of the Southern Hemisphere are land, versus those of the North, which are water. The high elevation (ca. 3,000 m) of the former is distinctive. Both poles are largely covered by ice and snow, so that the albedo is always high but is variable perennially. North/south contrasts are most important at mid-latitudes. In the Southern Hemisphere, continents alternate with oceans, whereas in the Northern Hemisphere, the amalgamation of Eurasia and North Africa is not balanced by North America. Climatologically, this imbalance generates powerful fluctuations between zonal (westerly) and meridional (south-north) modes of circulation. "Oceanicity," or maritime air flow, alternates with "continentality," or turbulent and meridional air flow. In the Southern Hemisphere, the greater dominance of oceans means that strong continent/ocean contrasts are absent. Global climate systems are therefore dominated by the Northern Hemisphere, given the present continental configuration. Therefore, the Northern Hemisphere will dictate global periodicities during Ice Age fluctuations between glacial and interglacial states.

Geomagnetic reversals

The geomagnetic history of planet Earth demonstrates periodic polarity reversals of both brief and extended intervals (Lowrie, 1997). The explanation of the brief reversals could lie in reversals of flow within the molten iron core or possibly changes in mass loading, for example the growth of ice caps asymmetric to the Earth's spin axis, which would introduce a major wobble in the rotation that could be repeated during the melt phases. Another form of mass loading is by volcanic plateau eruptions, and yet another is the erosional unloading of mountains and the sediment filling of adjacent basins.

Long-term geomagnetic reversals may possibly coincide with perigalactic and apogalactic phases of Solar System history. Even more speculatively, the reversal process could influence rates of organic evolution as well as stratigraphic and climatologic history (McCrae, 1981). Links between reversals and galactic motions have been suggested by Negi and Tiwari (1983), as have links with mass extinctions (Raup and Sepkoski, 1984). The periodicity of the geomagnetic reversals has been analyzed by Stothers (1986), and locked into planetary and solar motions (Tsurutani et al., 1990).

Asymmetry of North Magnetic Pole – consequences

The North Magnetic Pole is not fixed but shifts from year to year. At present, it is west of Greenland, moving northwards. During the seventeenth century, when it was first measured, it lay east of Greenland, and the declination measured in London and Paris pointed east of Greenwich.

The charged particles of the solar wind are largely shielded from the Earth by the magnetosphere. The latter, however, is a toroid (doughnut shaped) and some of the particles are funneled into the Earth at the magnetic poles. Collisions with atmospheric atoms result in isotopic "spalling" and the creation of larger and denser atmospheric components. The periodic solar flares and magnetic storms set up strong atmospheric

turbulence (Bucha, 1976, 1984, 1988). From time to time, this could lead to a great outburst of cold anticyclonic polar air (Leroux, 1996); over North America such outbreaks can at times reach as far as the Canary Islands and the western Sahara. Short-term averages of the solar flares are about 0.417 year, but longer mean values of 13.4 years may correspond to the alignment frequencies of Jupiter and Uranus with the system bary-center (Landscheidt, 1988). Planetary triggering of dynamic events on the Sun is believed to operate through exchanges of spin and revolutionary torque. Sunspots tend to develop on the near side of the Sun and die out on the far side (with respect to the Earth).

Just as the Indonesian mega-center of action provides an equatorial climatic node in the Earth's dynamic systems, so the North Magnetic Pole provides a second, but much weaker node, asymmetrically located in the Northern Hemisphere, centered on about 70° west longitude. While the north geographic pole provides a normal center for the polar anticyclonic vortex, its locus shifts from time to time into the western hemisphere, thus modulating the pattern of the mean jet stream. This could influence the decadal to bi-decadal NAO (Lamb, 1977; see also Boberg and Lundstedt, 2002; Thejll et al., 2003).

Threshold effects

Following the Fifth Earth Law (Principle of Homeostasis), each phase of an ice age, glacial or interglacial, tends to maintain a *steady state* until a certain *threshold tolerance* is exceeded, whereupon a rapid (“runaway”) shift takes place in all parameters – including temperature, precipitation, current velocities, mean sea level, aerosols, trace gases, etc. This bimodal alternation within an ice age is mimicked by the icehouse/hot-house bimodality of long-term geologic history, but on much shorter timescales.

A critical threshold for the onset of glaciation is summer snow-melt. Once melting fails for several decades, a snow patch will increase in size and build its load to the point where old snow is converted to ice. Albedo increases and the snow patch expands. This condition tends to develop first in highland areas, leading to mountain (“valley”) glaciers, which eventually merge into an ice cap. The site of continental ice sheets is determined by the gross asymmetry of the two Northern Hemisphere landmasses, most importantly North America (fed by moisture from two sides) and secondly Northern Europe (fed only on one side). The Antarctic ice sheet, fed from all sides and symmetrical to the South Pole, is too large and too stable to melt in less than 100,000 yr. Consequently, it will remain more or less as a quasi-stable entity until the entire ice age ends.

Retardation, or delayed response to solar radiation forcing

A cooling cycle is signaled by the expansion of sea-ice. As its area increases, so does the albedo, leading to a positive feedback that accelerates the cooling. The season of snow-cover on land consequently increases. However, critical limits exist. During a warming cycle, the enormous heat capacity of the ocean retards its response to rising insolation. Therefore, both global cooling and post-glacial warming are out-of-phase with the actual glaciation and its related glacio-eustasy. There is evidence of ice-floes and ice-transport of large boulders in the English Channel (Fairbridge, 1971) near the beginning of the last (Weichselian) glaciation, up to 10,000 years before the general fall of sea level.

Likewise, during deglaciation there is a “retardation” effect of the same order, such as when, for example, the Virginia oyster (*Crassostrea virginica*) and other warming indicators appeared in the Canadian Maritime provinces up to 6,000 year before world sea level reached its peak (Fairbridge, 1961). Recent paleoclimate proxy records from both deep sea and polar ice cores confirm that during deglaciation, the retreat of ice sheets lags several thousand years behind insolation, temperature rises, and changes in atmospheric greenhouse gases (Petit et al., 1999; Raynaud et al., 2000).

Glacial environments

Periglacial environments develop on land areas during a glacial phase, in a broad marginal belt south of the ice sheets. In many regions, this belt is marked by extreme aridity, associated with high winds and dust storms that generate loess deposits. Dating from the numerous glacial cycles of the Pleistocene, these deposits have weathered, rich loamy soils and can now be traced all the way from the Atlantic coasts of Western Europe to the Pacific shores of China, as well as being found in North America, Australia and New Zealand.

In mountainous terrain the summer ice melt is likely to develop so-called “refugia,” in the form of humid oases and “pluvial” lakes (as in the Rocky Mountain region). A vast increase in desert areas, however, is the normal condition during a glacial period, such as is seen in Africa, India and Australia. Without adequate dating, when early explorers during the first half of the twentieth century found former lakes and riverbeds in desert regions, they tended to equate “glacial” with “pluvial” conditions, even in the total absence of evidence for former glaciers. Now, with radiogenic isotopic dating, Rocky Mountain pluvials have been correlated with displaced jet streams during glaciation and periodic glacier-melt conditions, whereas Saharan pluvials, in contrast, correlate with interglacial monsoon maxima. Based on climate modeling, the colder ocean surfaces of glacial phases and their reduced oceanic surface areas would logically lead to drier conditions on the continents (Fairbridge, 1967; Kutzbach et al., 1993). Even equatorial waters were as much as 5 °C cooler, and many subtropical seas in marginal belts became too cold to support coral-reef growth.

Glacial-phase desiccation led to wholesale conversion of vegetation cover toward more arid types, e.g., from rainforest to savanna, and even to total desertification. Radiocarbon-dated fluvial deposits on the Congo River (near the equator) are found interbedded with desert sands – deposits are derived from sources in the Kalahari to the south and the Sahara to the north (Fairbridge, 1976). In the upper Amazon rainforest of today, there are traces of sub-Andean dunes oriented northward. Biotic survival of tropical organisms, including primates, was only possible in “Refugia,” the oasis-like sanctuaries where rainforest could be maintained. In the northern Mediterranean, the cold adiabatic winds radiating from the Alpine ice caps led to frost action on a giant scale and sheets of cryoclastic debris (“grèzes litées” in French) and solifluction contributed to the periglacial colluvium (Lowe and Walker, 1997).

Probably the most dramatic evidence of glacial-phase aridity is found in the ice-cores of Antarctica and Greenland. Everywhere, precisely at the interglacial/glacial boundary, the amount of terrigenous, airborne debris (aerosols: dust and silt) rises by one to two orders of magnitude (Jouzel et al., 1993).

Glacial-stage winds of great intensity were dominated by convective turbulence in contrast to the zonal circulation of the interglacials (Lamb, 1977). Monsoonal winds virtually ceased as year-round snow cover helped create a quasi-permanent central Asian anticyclone. Even in northern Australia, the summer monsoon failed and sand dunes spread out across the continental shelf.

High-resolution proxy chronologies

The relatively short cycles can only be identified by a combination of astronomic analyses with the natural records as preserved in “proxy” sequences of uniform periodicities and quality. Such climatic proxies are provided by the annual layers in ice cores or in lake sediments and by similar seasonal banding in tree rings or stalactite growth (see *Paleoclimate proxies, introduction*; this volume). Geochemical studies of the various types of materials disclose seasonal and long-term fluctuations that help determine the various cycles. Most instructive are the ^{14}C flux rates analyzed in the wood of tree rings because these values reflect (inversely) the Sun’s particulate radiation. Thus, the radiation cause can be monitored and compared with the climatic effect (Stuiver and Braziunas, 1993).

Of the many proxies, tree ring densities have been checked and rechecked against hundreds of time series, extending now over more than 12,000 years. Their most consistent and stable periodicities determined by power-spectrum analysis (Thomson, 1990) fall into a harmonic series: 104.26, 208.52, 417.045, . . . Extending it one more step gives 834.09, which corresponds to 75×11.12 year, the mean sunspot cycle, thus providing a simple linkage of solar events and terrestrial climate.

Use of long proxy time series (ice cores, tree ring ^{14}C flux, sediment cores) is highly desirable for the bridging of certain solar disturbances, but can be susceptible to small errors and regional bias. Of these, the series with the strongest planetary-solar links is the 69.507–208.52–417.04–834 year sequence seen in the tree-ring ^{14}C flux (Stuiver and Braziunas, 1993). It conforms precisely to the 2.172 year QBO ($69.507 = 32$ QBO), thus linking the short-term solar flux with long-term planetary periods (69.507 year = Uranus-Jupiter-Venus Lap) (see also Fairbridge and Sanders, 1987).

Confusing to many analysts are the luni-solar forcings that were postulated by Ekholm and Arrhenius (1898) when they showed that both the 18.6 year nodal cycle and the 22–23 year solar cycle were present in the 800 year Scandinavian history of auroras. Also from Scandinavia came herring fisheries data of the same length (Pettersson, 1912, 1914), together with the longer cycle of 93 years. Wood (2001) studied oceanographic tide systems and found that the 93 year period represented “maximized declination and nutation, at alternating lunar syzygy phases.” Basically, he found only two tide cycles, “type A,” 1.1318 year (14 lunar months), and “type B,” 18.03 year, which is also recognized in astronomic observations as the “Saros” of the Babylonians.

Attention should be paid to the high latitudes, particularly the North Magnetic Pole and the auroral oval, because of the ^{14}C isotopes produced by high-energy extra-galactic (“cosmic”) particle collisions with atmospheric nitrogen. Measured in tree rings, this ^{14}C flux is modulated by sunspot and other cycles in the (magnetic) solar wind.

The existence of see-saw atmospheric pressure fluctuations at high latitudes was first drawn to attention by Sir Gilbert Walker

as the “North Atlantic Oscillation.” It was first associated with storminess cycles by Fairbridge and Hillaire-Marcel (1977), which were discovered in the periodicity of emerged beach ridges on the eastern Hudson Bay, dating back 8,300 years. Further work on the ridges in the southwestern part of the bay by Douglas Grant (pers. comm.) permitted the construction of a histogram showing that the storminess cycles occurred in three peaks, approximately 11–12, 22–24 and 45–47 years. Higher harmonics occur in the extreme fluctuations of the ^{14}C flux rates and the peaks in beach ridge heights.

Astronomic relationships between planetary motions, solar activity and terrestrial climate have long been controversial. First proposed two centuries ago for the sunspot cycle by Sir William Herschel, the variability of that cycle (11 ± 6 year) made it extremely difficult to handle as a statistical parameter. However, the 45 year mean periodicity of the 8,300 year Hudson Bay beach series is incontrovertible. After glacio-isostatic correction, the data plot on a practically straight line, dating back to the inundation of Hudson Bay (“Tyrrell Sea”) by the postglacial global eustatic rise.

The construction of a given beach ridge at this latitude requires a gradual transgression, i.e., a warm-summer climate cycle accompanied by mild-wet westerly airflow. Its building phase terminates with a rapid regression and cooling associated with easterly or northerly winds due to a high pressure system in the northeast. Hudson Bay is frozen over in winter, so the winter season’s climate is irrelevant. Diaries kept by the fur-trading officials indicate the length of ice-free conditions. The longest ice-free seasons were 1750–1800, a trend confirmed by tree-ring evidence for Kuujuarapik (Great Whale River) by Jacoby and D’Arrigo (1989) and other sources.

A related problem is the precise astronomic phase of the 45 year cycle. For example, the years AD 1761–1762 were marked by the triple conjunctions of Jupiter-Saturn-Uranus, together with secondary (but brief) alignments with the inner planets, Mars-Earth-Venus-Mercury (46.3383 year). The key sunspot maximum was 1761. Further discussion of solar and planetary cycles and their climatic consequences can be found in Fairbridge and Sanders (1987); also see Charvátová (1995) and Jelbring (1995).

Conclusions

The biogeophysical laws that govern this planet can be summarized in five general “Earth Laws” that have influenced the course of the Earth’s paleoclimatic history. The first law relates to the long-term evolution of the Sun, its sources of energy and to planetary dynamics. As a member of the Solar System, the Earth is also affected by the Sun’s electromagnetic radiation, mainly in the visible range, and by a stream of ionized, magnetized particles (the solar wind).

The Solar System is subject to cyclical phenomena on many timescales. Cyclical variations in the Earth’s orbital parameters (eccentricity, obliquity, precession) on the order of 2×10^4 to 10^5 years have led to the Quaternary ice ages (i.e., the astronomical theory of glaciations proposed by Milankovitch). Less well established are the possible climatic effects of variations in sunspot activity at around 11 years, the 18.6 lunar nodal cycle, or of planetary alignments, such as the beat frequency of the two largest planets, Jupiter and Saturn, at ~ 19.86 year, the “heartbeat” of the Solar System. Indications of these

cycles appear in a number of paleoclimate proxies, such as the ^{14}C flux recorded in tree rings. The longest cycle is the rotation of the Solar System about the galactic disk at ~ 240 Myr (second Earth Law). It has been suggested that passage of the Solar System through the spiral arms of the galaxy might subject the Earth to an increased rate of comet infall, possibly leading to cooling episodes.

The Earth is a dynamic planet. Although the gravitational differentiation of the Earth occurred early in its history, the surface and atmosphere have continuously changed over time, shaped by internal driving forces such as plate tectonics and volcanism (third Earth Law), as well as interactions with the Sun, the Moon, giant planets (first Earth Law) and the biosphere (fourth Earth Law). The history of the Earth is recorded in its rocks.

The long-term stability of the Sun on the main sequence has enabled the development of more advanced forms of life without interruption for over 3 billion years (fourth Earth Law). The significance of this for paleoclimatology is that the Earth has always had a sufficient reservoir of liquid water to maintain life. In other words, the Earth has never experienced a runaway greenhouse effect, as on Venus, nor a totally frozen state, as on Mars.

The fifth Earth Law relates to the principle of homeostasis – that of a dynamic equilibrium, involving complex feedback loops that tend to keep natural systems in relative balance. In spite of severe perturbations, such as produced by bolide impacts or volcanic mega-eruptions, a tendency exists for a return to previous conditions. Although relatively abrupt wide excursions or swings may occur, these always remain within limits.

In summary, the Earth's paleoclimate history is the consequence of a complex interplay of internal and external forcing through multiple feedback loops. Plate tectonics shapes paleogeography, which in turn determines land-sea differences in albedo and in the heat budget. These in turn affect its atmospheric and oceanic circulation patterns. Quasi-periodic changes in the Earth's orbital cycles lead to slight variations in incoming solar radiation, producing glacial-interglacial climate oscillations. More speculative is the role of solar activity, and lunar and planetary dynamics on climate. Implicit in such proposed correlations are several important inferences that are still rather controversial and will require more thorough investigation: for example, suggestions that (i) planetary dynamics control solar emission variability; and that (ii) solar emissions, both electromagnetic and particulate, control short-term terrestrial climate variables.

ECCENTRICITY

The orbit of the Earth around the Sun is an ellipse. The eccentricity of the orbit is a measure of its elliptical shape, i.e.,

$$e = \frac{\sqrt{a^2 - b^2}}{a}$$

a being the semi-major axis and b the semi-minor axis. Its present-day value is 0.0167, a small value corresponding to a nearly circular orbit. The eccentricity varies through time because of the mutual gravitational forces exerted on each other by the Earth, the Sun and the other planets of the solar system. The value of the eccentricity has remained less than 0.07 over the last 3 million years. (Berger and Loutre, 1991).

The amount of energy received by the Earth from the Sun is directly dependent on the eccentricity. Its global annual mean value per unit area is

$$\frac{S}{4\sqrt{1 - e^2}}$$

with S the total solar irradiance measured at a distance a from the Sun (Berger and Loutre, 1994). This annual mean irradiance is only slightly variable with eccentricity. The maximum change reached for the largest value of e is less than 0.2%. On the other hand, the eccentricity plays a role on insolation by modulating the amplitude of climatic precession.

Eccentricity varies with a quasi-period of $\sim 100,000$ years superimposed on a longer quasi-period of $\sim 400,000$ years (Berger, 1978). The eccentricity becomes very close to zero every 400,000 years (Figure E2).

Marie-France Loutre

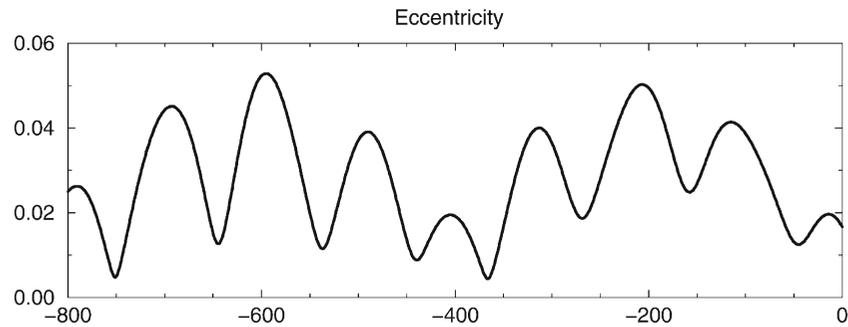

Figure E2 Long term variations of the eccentricity over the last 800,000 years.

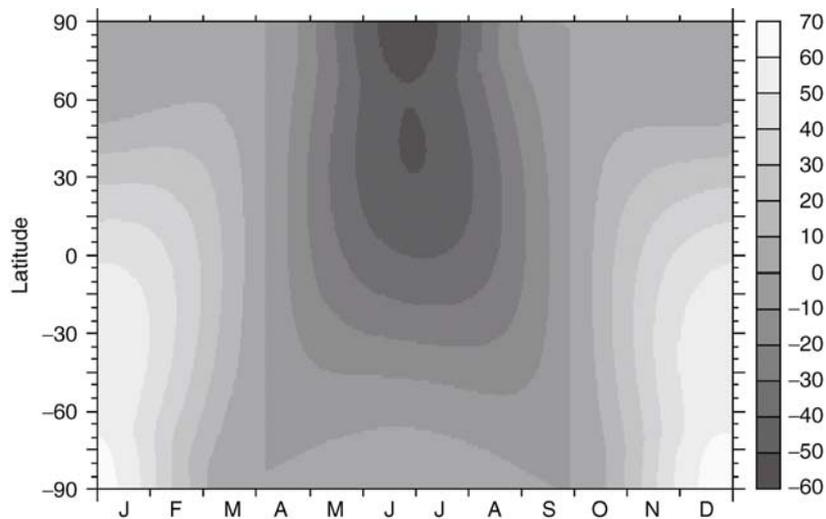

Figure E3 Variation of the mean irradiance (W m^{-2}) following an increase of the eccentricity from 0 to 0.055 (for the present-day value of obliquity, $\varepsilon = 23.446^\circ$ and longitude of perihelion, $\bar{\omega} = 102.04^\circ$). The mean irradiance is presently maximum at the South Pole at the December solstice (563 W m^{-2}), with a secondary maximum at the North Pole at the June solstice (527 W m^{-2}). At the equator, it is 439 W m^{-2} at the March equinox and 433 W m^{-2} at the September equinox. The difference between the polar values reflects the difference in the distance from the Earth to the Sun for these two solstices. The same holds for the equatorial values for the two equinoxes.

EEMIAN (SANGAMONIAN) INTERGLACIAL

The Eemian has been defined as an interval dominated by forest elements that were preceded by an open vegetation cover of the previous glacial and succeeded by open vegetation of the last glacial complex (Turner and West, 1968). Thus, the Eemian is a terrestrial biostratigraphic unit associated with the last interglacial. Due to plant migration as well as climate and vegetation gradients, the lower and upper boundaries of the Eemian are time-transgressive. Eemian forests dominated NW Europe from ~ 126 to 115 kyBP, whereas Eemian forests in SW Europe may have persisted 5,000 year longer, from ~ 126 to 110 kyBP (Kukla et al., 2002). In practice, the term Eemian is widely applied to pedostratigraphic, biostratigraphic, and chronostratigraphic aspects of the last interglacial. The regional equivalents of the Eemian are known as Mikulinian in eastern

Europe, Kazantsevo in Siberia, Ipswichian in Great Britain, Ribains or Luhe in France, and Riss/Würm in the Alpine region.

In contrast to the Eemian, the last interglacial is a chronostratigraphic unit, i.e., boundaries are time-parallel. The last interglacial is the most recent interval when the global climate was as warm or even warmer than today (Kukla et al., 2002). The eustatic sea-level record is recommended as a master reference for the timing of the last interglacial (Muhs, 2002), because sea-level change represents a climate proxy that is globally in phase and its relicts such as coral reefs can be dated accurately. Furthermore, the boundaries of the interglacial can be defined reasonably well: when sea level was as high or higher than today, it can be assumed that the global climate was as warm or warmer than today. High-precision uranium-thorium dating of raised coral reefs indicates that the most recent interval when global sea level was as high or even higher than present occurred between 128 and 116 kyrBP (Muhs, 2002). Thus, the last interglacial lasted 12,000 years from 128 to 116 kyrBP. An alternative approach to delimit the last interglacial is to adopt arbitrarily the quasi-isochronous boundaries of marine isotope substage MIS 5e. When so defined, however, the last interglacial envelops the major cold event Heinrich 11 (H11).

The Sangamonian in North America is based on the Sangamon Geosol, a strongly weathered and traceable paleosol developed in the parent material of the penultimate glacial and buried by sediments of the last glacial. Thus, the Sangamon Geosol is a pedostratigraphic unit associated with the last interglacial. The lower and upper boundaries of the Sangamon Geosol are diachronous due to changes in parent material, drainage, and climate. The formation of the Sangamon Geosol lasted about 100 kyr, therefore much longer than the last interglacial (Hall and Anderson, 2000). Nevertheless, the Sangamonian Stage has been defined as a chronostratigraphic unit. Some authors correlate the Sangamonian Stage with the interval of MIS 5 (~130–75 kyrBP), whereas others restrict it to MIS 5e (~130–115 kyrBP).

Environmental conditions of the last interglacial world (128–116 kyrBP) were relatively similar to those of our current warm period, the Holocene. The major difference from the present is that early humans living at that time, such as the Neanderthals, did not influence the last interglacial environments. In general, the last interglacial world was slightly warmer and moister. The atmospheric composition was comparable to that of the pre-industrial Holocene. The continents were in their present position and the global sea level was at its maximum about 5 m higher than today. The principal features of atmospheric and oceanic circulation approached those of the current world. The coastlines were, aside from areas affected by isostatic depression, similar. The mountain ranges were the same as today, although their morphology has been further modulated in areas glaciated during the last ice age. The global landscape zones paralleled those of today: Polar ice caps existed in Greenland and Antarctica, although they were reduced in dimension. Frost-deserts and open tundra-type formations were present in the polar regions. Dense coniferous forests covered the higher latitudes of the Northern Hemisphere. Broad-leaved woodlands existed in large territories of the mid latitudes, being replaced by steppe communities in regions with lower precipitation. In the lower latitudes, desert-type areas were reduced in favor of savannahs. Species-rich rainforests covered vast areas of the inner tropics.

Because of the close similarity to Holocene environments, the last interglacial is considered to represent the most recent geological analog of our current warm period. Although the

human impact on the atmosphere makes the present climate different from any one in the past, study of the last interglacial and its transition to the next glacial can teach us a great deal about how the climate system operates (Kukla et al., 2002).

Insolation and climate response

Periodic long-term changes in the orbital configuration between the Sun and the Earth result in cyclic variations of the insolation, which are considered to be the main driving force of the glacial-interglacial cycles. The combination of orbital parameters such as precession, eccentricity, and obliquity leads to the occurrence of interglacial climates every ~100 kyr. The duration of interglacials is in general around half of a precession cycle. An exception from this rule might be applied to the present Holocene and the interglacial associated with MIS 11c around 400 kyr ago. Then and now, the influence of precession on insolation variations was damped down due to the almost circular orbit of the Earth. During the last interglacial period, in contrast, the eccentricity was higher and therefore the effects of precession on insolation were pronounced. Hence, warm conditions during the last interglacial lasted around 0.5 precession cycles, i.e., 11 kyr.

The mechanisms of climate response to insolation changes is not clear. It is assumed that the driver of climate is the summer insolation in the high northern latitudes and that due to the inertia of the global system there is a substantial delay in the climate response. Thus, the climatic optimum of the present interglacial was reached some millennia after the insolation maximum. A postponed climate response to insolation changes is also observed at the end of the last interglacial. Once the global system is in an interglacial mode of operation (oceanic and atmospheric circulation patterns approaching those of today), it stays in this mode even when the insolation is continuously reduced (Figure E4). At a certain critical threshold, however, the system shifts abruptly back into a glacial mode of operation. Most likely the concert of continuously reduced insolation, slowly extending ice shields at high latitudes with associated albedo feedbacks, and increasing freshwater input into the region of North Atlantic deep water production forced the system steadily to cross a critical threshold, triggering the abrupt reorganization of oceanic and atmospheric circulation. Such shifts into colder modes of operation occurred at around 115 and 110 kyr BP at the inception of the last glacial (Müller and Kukla, 2004). The Holocene insolation peaked 11 kyr ago. Today, the insolation intensity is as low as during most of the last glacial. Nevertheless, we are still in an interglacial mode due to the inertia of the global climate system.

The climate during the last interglacial has been reconstructed based on various climate proxies such as foraminiferal or pollen assemblages, the ratio of stable isotopes, and macrofossil remains. The reconstructions suggest mean annual temperatures up to 4 °C higher than today in northern Europe, in the northern latitudes of North America, and in northern Asia. More to the south, in Central Europe and in the mid latitudes of North America and Asia, the mean annual temperature rose up to 2 °C above the current values. In the lower latitudes of the Northern Hemisphere, in contrast, the mean annual temperature was similar to the present or even up to 1 °C lower. Thus, the meridional temperature gradient was lower during the climatic optimum of the last interglacial than today. The different meridional heat distribution might be explained by variations in the obliquity of the Earth's axis. During the early part of the last

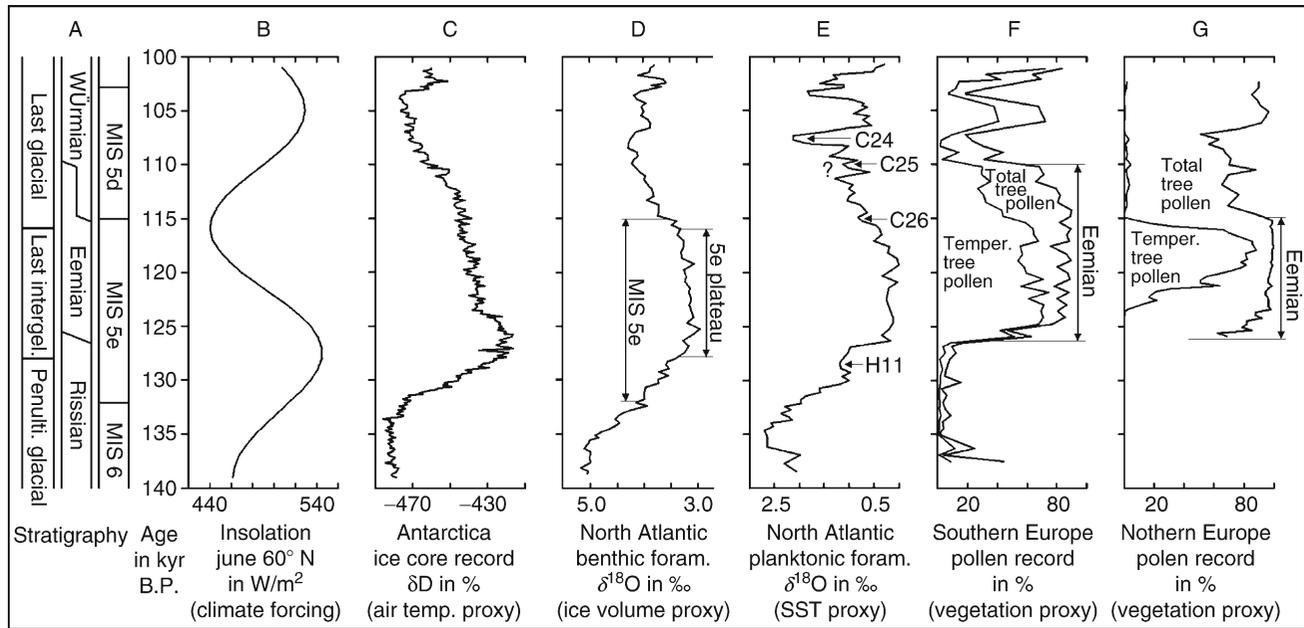

Figure E4 Tentative correlation of last interglacial records: (a) stratigraphy, (b) variations of June insolation at 60° N (Berger and Loutre, 1991), (c) δD record from the Vostok ice core (Petit et al., 1999), (d) benthic $\delta^{18}O$ record from core MD95–2042 off Portugal (Shackleton et al., 2003), (e) planktonic $\delta^{18}O$ record from core MD95–2042 off Portugal (Shackleton et al., 2003), (f) simplified pollen record from Tenaghi Philippon in Greece adopted from Wijmstra (1969), (g) simplified pollen record from Gröbern in Germany adopted from Litt (1994).

interglacial and during its climatic optimum at around 126 kyr BP (Figure E4c), the obliquity was higher than today, providing a stronger insolation to high latitudes, but weaker to the low ones. Furthermore, the perihelion occurred in boreal summer during the early part of the last interglacial, whereas perihelion is in boreal winter today.

Marine environments

A close representative of the last interglacial in deep sea sediments is MIS 5e. The marine oxygen isotope record, measured at benthic foraminifera, reflects mainly the total global ice volume. Consequently, oxygen isotope ratios are also an inverse proxy of global sea level. The changes in the benthic isotope records from various sites on the globe are generally considered to be synchronous. In fact, they might be quasi-synchronous as the mixing of oceanic water masses due to the large-scale overturning takes around 1,000–2,000 years. However, in contrast to the Eemian, the MIS 5e is customarily interpreted as a chronostratigraphic unit. The lower boundary of MIS 5e is defined at the midpoint of the transition between the heaviest $\delta^{18}O$ values during MIS 6 and the lightest $\delta^{18}O$ values during MIS 5e. The upper MIS 5e boundary is defined at the midpoint of the subsequent transition towards the heaviest $\delta^{18}O$ values during MIS 5d. Applying this concept to an oxygen isotope record on a timescale inferred from radiometric dating of coral reefs, MIS 5e lasted from 132 to 115 kyr BP (Figure E4a,d). The benthic isotope record from this site off Portugal shows an interval of quasi-constant light $\delta^{18}O$ values within MIS 5e. It has been assumed that this MIS 5e “plateau” correlates with the period when global sea level was as high or higher than at present, i.e., from 128 to 116 kyr BP (Shackleton et al., 2003). A comparison of the timing of this MIS 5e plateau with European pollen records (Figure E4f,g) suggests that

major global ice sheets, such as the Laurentide and the Scandinavian, had melted $\sim 2,000$ years before the spreading of Eemian woodlands in Europe.

Subsequent to the end of the MIS 5e $\delta^{18}O$ plateau, continental ice accumulated substantially, as reflected by the benthic oxygen isotope record of the interval 116–107 kyr BP (Figure E4d). Most likely, ice accumulation started in the area of the Laurentide and later the Scandinavian Ice Sheets. Eemian woodlands persisted in southern Europe for another $\sim 5,000$ years, well into MIS 5d. Thus, the onset of the last glacial was associated with the establishment of steep meridional climate gradients. Some authors question whether such steep gradients are feasible.

The sea-surface temperature (SST) change during the last interglacial has been reconstructed based on planktonic foraminiferal assemblages, the occurrence of ice-rafted detritus (IRD), $\delta^{18}O$ measurements from planktonic foraminifera, and alkenone. The occurrence of distinct IRD layers within otherwise mainly fine-grained deep sea sediments provides a correlation tool for the North Atlantic. It is assumed that the deposition of these IRD layers occurred within brief episodes (< 500 year) when icebergs moved far south and eastward accompanied by the expansion of cold surface water masses (McManus et al., 2002). The most prominent IRD layers during MIS 5e and 5d are the cold events H11 and C24 (Figure E4e). The H11 Heinrich event occurs at ~ 129 kyr BP, just before the onset of the last interglacial, and C24 at ~ 107 kyr BP, during the first stadial after the last interglacial. As H11 represents a major cold event, which occurred in the lower part of MIS 5e (Figure E4e), it is recommended not to adopt the boundaries of MIS 5e as the delimitation of the last interglacial. This approach would conflict the definition stating “... climate was as warm or even warmer than today” (Kukla et al., 2002).

Less-pronounced IRD layers have also been found at the transition from MIS 5e to 5d and during MIS 5d. The two ice rafting events C26 (at ~115 kyBP) and C25 (at ~110 kyBP) can be traced into the central part of the North Atlantic. A prominent cooling of 3 °C in SST at the transition from MIS 5e to 5d, derived from alkenone records from the Bermuda Rise, may correlate with the C26 event in the North Atlantic. The cold-water event C26 in the North Atlantic most likely relates to the opening of woodlands in NW Europe. If this is so, the event C26 marks the end of the classical Eemian in NW Europe (Figure E4e–g). Based on pollen analysis and varve counts at lake sediments from the famous Bispingen site in northern Germany, it has been determined that Eemian woodlands existed for around 11,000 years (Müller, 1974). Thus, the classical Eemian lasted from 126 to 115 kyr.

Recurring cold events, averaging one event every ~1,500 year, have been recognized in North Atlantic sediments of MIS 5e and Eemian lake sediments in Central Europe (Bond et al., 2001; Müller et al., 2005). By analogy with findings from the Holocene in the North Atlantic, the trigger for this last interglacial cyclic climate variability may have been changes in solar activity, possibly amplified by changes in North Atlantic ocean currents and/or the North Atlantic Oscillation. This sub-orbital cyclicality during the time of minimum global ice volume, however, was strongly subdued in comparison with the high-amplitude climate fluctuations of the last glacial.

Terrestrial environments

The term “Eem” was introduced by Harting (1874), based on the identification of a fauna of Lusitanian and even Mediterranean shells in marine clays buried by the last glacial deposits near the river Eem in the Netherlands. Today, it is customary to interpret the Eemian in a pollen record as an interval dominated by forest elements and associated with the climatic amelioration of the last interglacial. The terms “Eemian” and “last interglacial” should not be used synonymously. The Eemian, is strictly speaking, a biostratigraphic representative of the last interglacial in Europe. The onset of the Eemian is defined at the point in the pollen record when tree taxa exceed 50% of the total terrestrial pollen sum. The Eemian ends at the point when even the percentages of coniferous trees decline significantly. Obviously, this concept implies that, for reasons of climate gradients and plant migration, the onset and end of the Eemian did not occur at the same time in different areas of Europe. Therefore, the Eemian is time-transgressive and should not be used in a chronostratigraphic sense. In fact, it now appears that Eemian woodlands persisted considerably longer in southern Europe (126–110 kyBP) than in northwest Europe (126–115 kyBP) (Figure E4f,g). This implies the establishment of steep vegetation and climate gradients at the inception of the last glacial. The steepening of vegetation gradients might have been influenced by the steepening of meridional SST gradients in the North Atlantic, which in turn is suggested to be connected to a southward displacement of the North Atlantic Current at around 115 kyBP (Müller and Kukla, 2004).

The identification of the Eemian in a pollen record is based on a specific composition and succession of forest elements. In contrast to older interglacials, Eemian pollen records in Europe do not contain *Carya*, *Celtis*, *Eucommia*, *Pterocarya*, *Sequoia*, *Thuja*, and *Tsuga* as these taxa became extinct in this region earlier in the Quaternary. A peculiarity of the Eemian north of the Alps and Pyrenees is the absence of *Fagus* as

today this tree dominates quasi-natural forests in most of these areas. The typical composition and succession of the Eemian is known from master pollen records that reflect the biostratigraphy of several glacial-interglacial cycles (e.g., Reille et al., 2000). Absolute dating of interglacial sediments provides a tool to verify the biostratigraphic evaluation at other sites.

In Central Europe, the typical pollen zones of the Eemian have a remarkable consistency. This consistency is believed to be linked to an open seaway from the English Channel through the North and Baltic Seas to the White Sea, which supported the influence of mild oceanic climates over the entire region. The typical composition and succession of Eemian forest elements in Central Europe is shown in Figure E5. After a pioneer phase with *Juniperus*, *Betula*, and *Pinus*, the Eemian is characterized by the early spread of the deciduous taxa *Ulmus*, *Quercus*, and *Fraxinus* and the subsequent spread of *Corylus*. Within the *Corylus* phase there is a *Taxus* peak (sometimes featured as a double peak). Subsequently, an Eemian pollen record displays the spread of *Carpinus* and *Abies*. The maximum amount of *Carpinus* and *Abies* in the late-temperate phase varies in relation to altitude and proximity to mountain ranges (Müller, 2000). The major spread of *Picea*, occurs in the post-temperate phase of the Eemian. The final phase of the Eemian shows the spread and dominance of *Pinus* before coniferous forests decline.

In northern Europe, Eemian pollen records vary from those in Central Europe. In general, the composition of taxa stays the same. However, the further north a site is located, the more reduced is the percentage of the temperate taxa *Ulmus*, *Quercus*, *Fraxinus*, *Corylus*, and *Carpinus* to the benefit of *Betula*, *Pinus*, *Alnus*, and *Picea*. In northern Scandinavia, Eemian pollen diagrams do not show a temperate phase anymore, but a constant dominance of *Pinus* and *Betula*. Nevertheless, the long-distance wind transport of pollen resulted in grains from Central Europe found even far in the north of Scandinavia (Robertsson, 2000). There, the grains from temperate taxa sometimes reflect the typical Eemian succession of Central Europe.

In southern Europe, the boreal taxa *Betula* and *Picea* are absent south of the Alps and Pyrenees or do not play an important role in the record. The onset of the Eemian starts directly with the spread of deciduous *Quercus*, *Ulmus*, *Corylus*, and subsequently of *Carpinus* and *Quercus* evergreen. Mediterranean taxa such as *Pistacia*, *Olea*, and *Phillyrea* contributed pollen during the first half of the Eemian. Deciduous *Quercus* and *Carpinus* are the dominant taxa during the late-temperate phase of the Eemian. *Abies* was of minor importance. There was no post-temperate boreal forest phase such as in Central Europe, therefore late-deciduous woodlands persisted to the end of the Eemian at around 111 kyBP (Tzedakis et al., 2002). *Fagus* has been found south of the Alps in Italy and Austria during the Eemian.

In North America, pollen investigations in interglacial sediments have not hitherto had the same significance as in Europe. This might be due to the scarcity of interglacial lake sediments or a lack of exploration drilling.

Other representatives of the last interglacial in terrestrial environments are buried soils and geomorphologic features testifying to the absence of glaciers. This is how the classic Sangamonian interglacial has been described in North America. The term “Sangamon” was introduced by Leverett (1898), based on identification of a soil buried beneath till and loess of the last glacial that he observed in railroad cuts in Sangamon

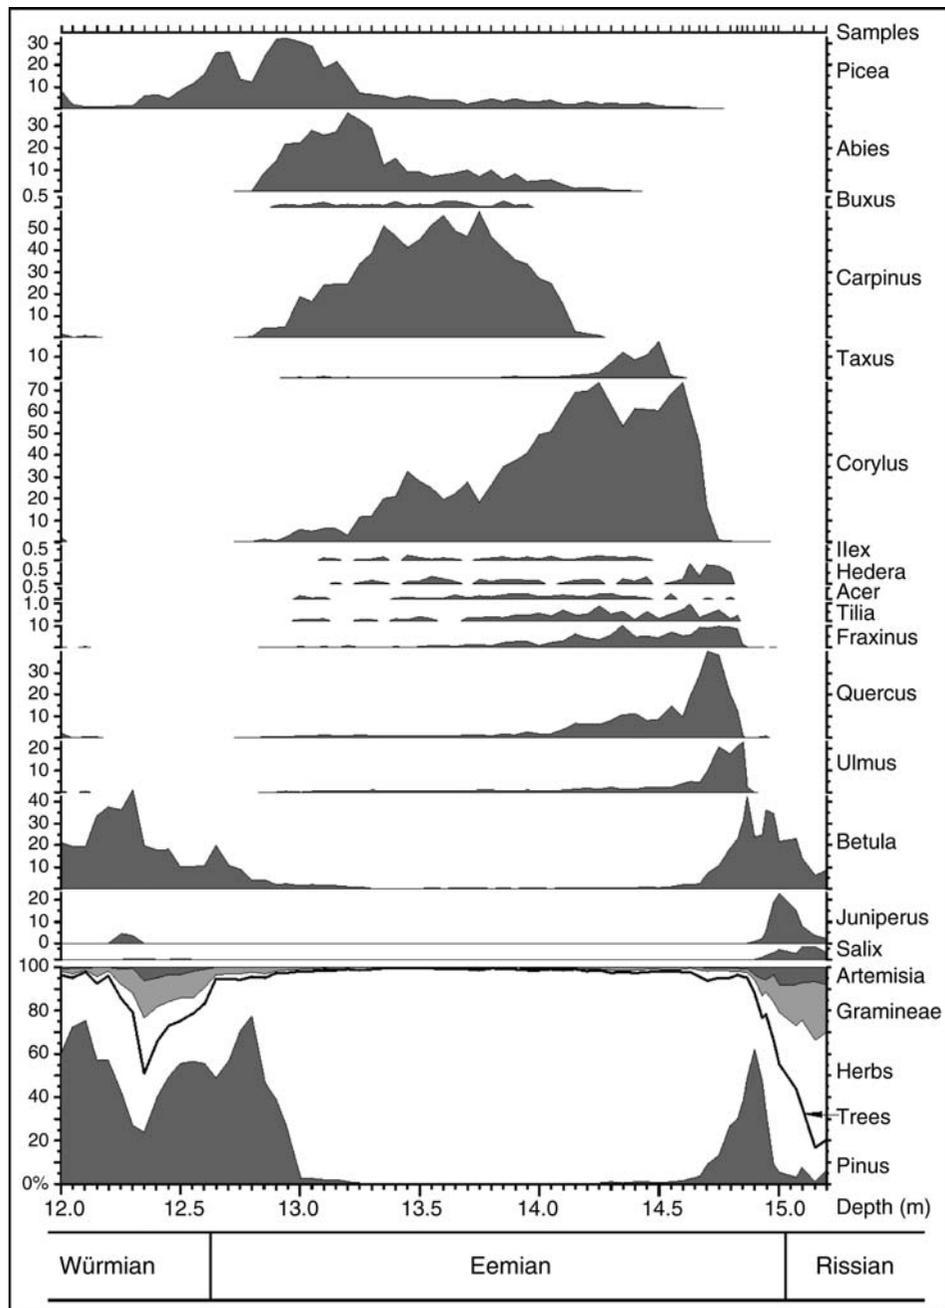

Figure E5 Characteristic taxa composition and succession of an Eemian pollen record in Central Europe (data from Jammertal in SW Germany, adopted from Müller et al., 2005).

County, Illinois. The Sangamon Geosol is a strongly developed paleosol in the parent material from the penultimate glacial (named Illinoian in the USA), and buried by the sediments of the last glacial (Wisconsinan). This paleosol has been described from many locations in the USA. It can be traced from the Great Lakes to Texas, and is frequently used as a marker horizon. The type of soil development varies with changes in parent material and regional climate conditions. In its type area at Athens Quarry, Illinois, the Sangamon Geosol is developed in loess colluvium and shows a remarkable thick Ab-horizon

on top of a Bt-horizon. Overall, soil proxies show that the Sangamon Geosol is more strongly developed than the Holocene soil. However, the differences in soil properties between the Sangamon Geosol and Holocene soil are interpreted primarily to reflect soil development duration, with climatic imprint being secondary. It is assumed that the Sangamon Geosol formed over a much longer time interval than the last interglacial, as is understood in Europe (Grimley et al., 2003). The weathering features of the Sangamon Geosol at its type region indicate that the formation persisted longer than the complete

MIS 5. The time represented in the Sangamon Geosol depends upon whether burial occurred and pedogenesis ceased during the early or late part of the Wisconsin glacial. In contrast to the Sangamon Geosol, the Sangamonian Stage has been defined as a chronostratigraphic unit by the Illinois State Geological Survey. The delimitation of the Sangamonian Stage is arbitrary. Some authors adopt the boundaries of MIS 5, whereas others restrict the Sangamonian Stage to MIS 5e.

The last interglacial paleosol in Europe, frequently found in loess sections, is in general preserved as a well-developed textural Bt-horizon. The last interglacial soil is known as Rocourt soil in NW Europe, as B1b of PK III in the Czech Republic, and as the Salyn soil of the Mezin Complex in Central Russia. The Bt-horizon is usually truncated and partly covered by humus soil sediments (Antoine et al., 2001). In high accumulation loess records, three humus zones have been found on top of the truncated last interglacial Bt-horizon (Bibus et al., 2002). The chernozem-like humus zones are separated from each other and from the Bt-horizon by loess colluvium that contains a mollusk fauna indicative of colder climate conditions. Therefore, it has been concluded that the humus zones developed during MIS 5a to 5c whereas the Bt-horizon is associated with MIS 5e.

Conclusions

- The last interglacial is the most recent interval prior to the Holocene when the global climate was as warm as or even warmer than today.
- Eustatic sea-level changes, a proxy of mean global climate, indicate that the last interglacial as a chronostratigraphic unit lasted from 128 to 116 kyrB.
- The Eemian is a biostratigraphic representative of the last interglacial in Europe.
- The Sangamon Geosol is a pedostratigraphic representative of ice-free conditions between the last and penultimate glaciation in North America.
- Both the Sangamon Geosol and Eemian have time-transgressive boundaries.
- MIS 5e, a close representative of the last interglacial in deep-sea sediments, records the time when total global volume of land-based ice was reduced.

ELECTRICAL CONDUCTIVITY

Electrical measurements are frequently used to determine the chemical characteristics of ice cores in paleoclimate studies. Electrical measurements on ice cores can be made quickly, non-destructively, and with high spatial resolution, but they do not provide information on specific ions. Electrical measurements are used to identify the seasonal variations in chemistry that define the annual layers in an ice core that are used to determine the age of ice, and to determine if the layers in an ice core have been distorted by abnormal ice flow. For these tasks the high spatial resolution and efficiency of the electrical measurements is more important than information on specific ions. Electrical measurements can be classified into two general categories: direct current and alternating current methods.

Direct current methods are conventionally referred to as the Electrical Conductivity Method (i.e., ECM) (Hammer, 1983) and measure the current flow between two electrodes with a potential difference of about 1,000 V. The electrodes typically have a surface area of about 16 mm² and are separated by about 1 cm. Direct comparison of measurements made with different instruments is complicated because of differences in the electrode geometry and the potential difference. Measurements are typically made every 1 mm along a prepared flat surface of the core that is parallel to the axis of the core. The ice lattice prevents lateral movement of all ions except free protons, and hence only protons can carry the direct current. The ECM method is therefore sensitive only to the concentration of H⁺ ions associated with strong acids. The ECM record is typically presented as a continuous high spatial resolution record indicative of the acidity of the ice core. It is particularly well suited for indicating the presence of acids from volcanic activity and identifying annual layers.

Alternating current methods are referred to as Dielectric Property (DEP) measurements. They utilize a capacitor consisting of ice as the dielectric material between two conductive plates (Moore et al., 1989). A thin insulating layer prevents electrical connection between the conductive plates and the ice. The impedance of the ice-filled capacitor is typically measured over a range of frequencies every 1 cm along the core. The ice lattice prevents the lateral movement of all ions except free protons, but the other ions can conduct the electrical current by rotating around a stationary location. The DEP method is therefore sensitive to the concentration of a wide range of ions. The DEP record is typically presented as a continuous record indicative of the total ion content of the ice core. A variation on the DEP method is complex conductivity that uses an alternating current with an electrode geometry similar to the ECM method (Taylor et al., 2004). The complex conductivity method is also sensitive to the total ion content of the ice but has more spatial resolution than the DEP method.

The DEP and ECM methods are typically presented as a single profile along the length of an ice core. Multitrack measurements utilize multiple adjacent profiles that are measured on a flat surface parallel to the axis of the core (Taylor and Alley, 2004). This is presented as a two dimensional image of the conductivity in a vertical plane through the ice core. This enables the inclination and continuity of annual layers to be observed.

EOLIAN DUST, MARINE SEDIMENTS

Introduction

Charles Darwin was the first scientist to comment formally on the red dusts blowing from Africa out across the Atlantic, an event he observed while on the *Beagle* (Darwin, 1846). Marine geologists have known since the late 1950s that dust storms originating in the arid and semi-arid regions of continents carry dust long distances, and that sea-floor sediments in regions far from continents, out of the reach of river-borne sediment, are dominated by eolian dust.

Atmospheric scientists find that most of the dust is transported by a few spring storms. These storms raise the dust high up into the troposphere where it is transported for long distances and eventually removed by both dryfall and rainout (Prospero et al., 1983; Pye, 1987). Satellites now routinely track dust storms that move from the semiarid regions of central China all the way across the North Pacific to California, and from the Sahara across the Atlantic Ocean to the Caribbean and Florida. Since most of the world's continental surface area is in the Northern Hemisphere, the Northern Hemisphere is far dustier than the Southern.

Sources of atmospheric dust

Three main source regions provide dust to the atmosphere and ocean. The two largest are the deserts and basins of central China, north of the Tibetan Plateau, and the Sahara and Sahel regions of North Africa. The third important source of dust is the deserts of Arabia and the Horn of Africa, which provide dust to the northwestern Indian Ocean. The amount of material available for dust transport depends on the climate of the source region, with arid and semi-arid climates providing the most material, and more humid – vegetated – regions providing less. There are, however, hyperarid regions where rain falls very rarely. In these regions, there is not enough water to break down the feldspar minerals that are common in continental rocks into clays. Therefore, this weathering process does not create enough fine-grained material for long-range transport. What little material there was has been stripped away by the wind long ago, a condition known as deflation. The deserts

of Australia fit this description; they are hyperarid, deflated, and supply surprisingly little dust to the oceans. As a result of this physical and climatic geography, there is about an order of magnitude less dust deposited in the Southern Hemisphere. The total amount of dust delivered to the ocean is estimated to be about 0.1 to 0.2×10^{15} t yr⁻¹, which is roughly 1% of the total river load of 15 to 20×10^{15} t yr⁻¹ (Rea, 1994). Nonetheless, pelagic clays composed of eolian dust characterize the surface sediments of about one third of the ocean floor, an area similar to that of all land surfaces.

Size of dust grains

The large spring dust storms raise a broad mixture of grains from the desert floors, but after a transport distance of 1,000 or 2,000 km, the sand and coarse silt sized grains have fallen out and the remaining suspended minerals are fine silt and clay-sized. The size of these distal dust grains, now preserved in abyssal sediments, reflects the dynamic equilibrium between the supporting energy of the transporting winds and gravitational settling. Equilibrium grain size changes very little with increasing distance from the source region, and maps of the median grain size of dust in North Pacific sediments show little variation across this broad expanse of ocean (Rea and Hovan, 1995). Thus, at any one location, the size of these equilibrium dust grains preserved in deep sea sediments is a record of the energy of the transporting winds, with stronger winds resulting in coarser grains. Numerous grain size studies of dust show that it has a median diameter of 2–4 microns. The hypothesis that dust grain size provides a record of wind strength was tested by examining dust captured in sediment traps during an experiment conducted in the Arabian Sea. There, the dust grain size was coarsest when winds were strongest, but not necessarily when the most material was being transported (Clemens, 1998).

This observation indicates one more aspect of dust deposition that is important: that dust grain size is independent of the amount (and source) of dust deposited. Cross-plots of grain size and dust supply data from any one core show a random scatter. This independence means that scientists may discover the source area climate from the dust supply data and the wind intensity from the grain size data, both from the same set of samples.

Composition, mineralogy and geochemistry

The first modern reports on the subject of Saharan dust in the central Atlantic recognized the red-stained quartz grains accumulating in Atlantic sediments as being from the Sahara. Marine geologists studying the surface sediments of the North Pacific have understood for more than 40 years that the band of quartz-rich sediment extending east from the deserts of central and eastern Asia represented dust coming from China. Studies comparing the detailed mineralogy of the dust with that of the surface sediment show them to be indistinguishable. For the North Pacific region, the average composition of the <2 μm mineral component is dominated by illite, which is 30–40% of the total, with subequal amounts of quartz, chlorite, kaolinite, and plagioclase (10–15% each). Chlorite increases in abundance to the north, and smectite becomes a noticeable minor component nearer to North America (Leinen, 1989).

In the past decade, various technical advances with regard to geochemical analyses have made it possible to perform other studies that provide important information about dust transport and deposition. Trace element geochemistry and radiogenic

isotopic analysis of the dust have allowed scientists to resolve questions of source and how sources have changed over time. The first broadly-based study was of the geochemistry of the surficial sediment of the North Pacific. It showed that dust from China dominates the Pacific surficial sediment all the way south to the Intertropical Convergence Zone (ITCZ) and almost all the way east to North America. North America, on the other hand, supplies very little dust to the North Pacific Ocean. The neodymium, lead, and strontium isotope geochemistry of the dust isolated from sea-floor sediment samples is identical to that of Chinese loess, with a similar bulk geochemistry to that of Paleozoic shales (Jones et al., 1994, 2000). Over the years, scientists have used both the mineralogy, especially the clay mineralogy, and the geochemistry of the dust to determine its provenance, with excellent results. As a result of this kind of work, it is possible to understand the changing sources of dust to the oceans, and that the dust in the Greenland ice cores and Antarctic ice cores originates from Asia and southern Argentina, respectively (see Biscaye et al., 1997).

History of dust deposition

Long-term changes in dust deposition

Several studies of the long-timescale record of dust deposition have been carried out in both the Atlantic Ocean, downwind from the Sahara, and in the North Pacific, downwind from the deserts of central and eastern Asia. Most of this work has aimed to determine the mass accumulation rate of the dust, which is interpreted in terms of the aridity of the continental source regions. Some of these studies have also analyzed the grain size of the dust as an indication of wind strength, and aimed to determine the geochemistry of the dust in order to understand changes in the source region. Furthermore, all of this long-term work has been carried out in the Northern Hemisphere; the history of the Southern Hemisphere is assumed to be similar but that has yet to be shown conclusively. Deposits of nearly pure eolian sediment are known as pelagic clays or red clays after their brick-red to brown color. There are very few fossils in these cores, and because of their slow sedimentation rate, often 30–50 cm per 10⁶ yr, magnetic reversal stratigraphy generally does not work. Thus, age control is poor; often done on the basis of fossil fish teeth, or ichthyoliths. Improving the age control in red clays is an ongoing research topic (Gleason et al., 2002).

Two North Pacific cores have been studied in detail: a giant piston core LL44-GPC3 (this coding refers to the ship that raised the core, the AT&T cable-laying ship *Long Lines*, and that this core was the third Giant Piston Core recovered), and the cores from Ocean Drilling Program (ODP) Site 885/886. Core GPC3 came from the central North Pacific at about 30.3° N, 157.8° W, and ODP Site 885/886 is at 44.7° N, 168.3° W. Both sites now underlie the zonal winds of the prevailing westerlies. The record at GPC3 spans the entire Cenozoic, covering the last 70 million years. The iridium layer corresponding to the meteorite impact at the Cretaceous-Tertiary boundary that may have caused the ultimate extinction of the dinosaurs lies in the lower portion of the core. The materials recovered farther north at Site 885/886 provide a very good record of the last 12 million years. Together, these two records define the eolian depositional record for the latest Cretaceous and Cenozoic time.

Dust accumulation recorded in core GPC3 (Figure E6; Janecek and Rea, 1983; Rea et al., 1985) shows a very low

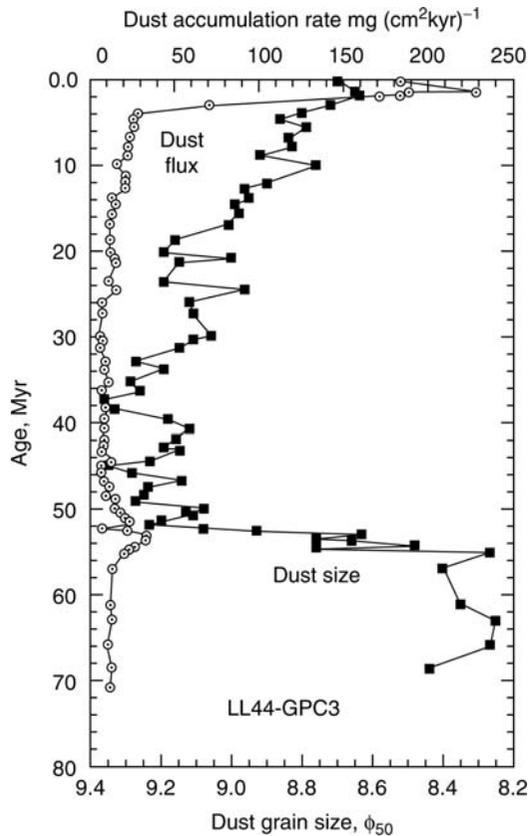

Figure E6 The Cenozoic record of dust deposition from core LL44-GPC3. Grain size values are median diameter in phi-units, where phi is the negative logarithm to the base 2 of the grain diameter in millimeters ($\phi = -\log_2 D_{mm}$). Thus $9\phi = 2 \mu\text{m}$, $8\phi = 4 \mu\text{m}$, etc.

input of dust through most of the Cenozoic. There is doubling of flux values at about 25 Ma, moving upcore from the Paleogene to the Neogene, and a further large increase in dust input at 3 or 4 Ma. This history can be interpreted in terms of changing climates, in this case increasing aridity, in the eolian source region. The size of the eolian grains is a measure of the wind intensity. In the younger part of the record, the size of the dust grains increases towards the present from low values in the Eocene, likely a result of increasing wind intensity accompanying the mid to late Cenozoic cooling of the higher latitudes. The big surprise in the GPC3 data was the very large change in dust grain size in the lower part of the core. We have found this same shift in grain size in other cores from the North Pacific. It represents, apparently, a sudden decline in wind intensity associated with several global changes that occurred in conjunction with the Paleocene/Eocene boundary (Rea et al., 1990) and the onset of unusually warm Eocene climates.

Sediments recovered from ODP Site 885/886 are characterized by a reliable magnetic reversal stratigraphy and so are much better constrained as to age and rate than those from GPC3. Nevertheless, the major late Cenozoic increase in dust flux seen in GPC3 is also the most significant change in this record (Figure E7). This order of magnitude increase in flux begins at 3.6 Ma and represents a significant drying in the eolian source regions in China. Other data indicate a rapid

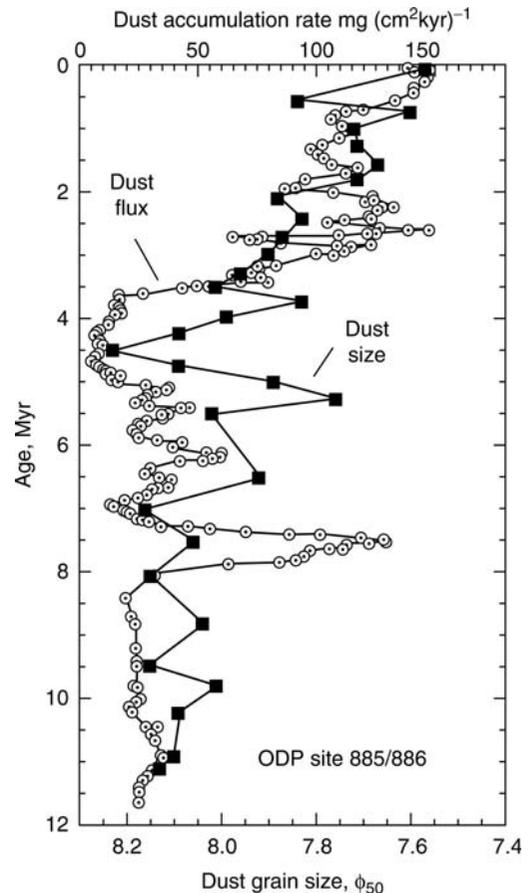

Figure E7 The record of dust deposition and grain size from core ODP Site 885/886 for the last 12 million years.

uplift of the northeastern portion of the Tibetan Plateau then, the deserts of central China being cut off from the moisture source to the south (Rea et al., 1998). The interpretation of the dust flux peak at about 8 Ma is less clear. The size of the eolian grains increases in younger materials. The increase is not regular, and the last shift towards coarser dust grains, hence stronger winds, begins about 4.5 Ma. Many studies of late Cenozoic climate change have shown that major Northern Hemisphere glaciation, the ice age we are in currently, began at 2.6 Ma. Other kinds of paleoclimate records suggest that this time of increasing continental ice cover was preceded by an increase in wind intensity two million years earlier, and an increase in the atmospheric dust loading one million years earlier. It can be concluded that different aspects of the world's climate system change sequentially, one after the other, rather than all at the same time.

Eolian records from the Atlantic and Indian Oceans indicate a late Cenozoic drying of Saharan and Sahelian Africa. The general sense of more dust coming into the oceans during the past three or four million years holds for these studies, but the timing of the aridity increases does not seem to be exactly the same for northern Africa and eastern Asia. A drying of the Northern Hemisphere continents in general concordance with Northern Hemisphere cooling and the ultimate beginning of the Plio-Pleistocene glacial ages has been clearly demonstrated by all studies of dust depositional history.

Orbital timescale changes in dust deposition

The classic terrestrial, Quaternary record of climate change is found in the loess horizons, interspersed with soils, that sweep across the Loess Plateau of China. Loess, a wind blown silt, forms during the relatively cold and dry glaciations, and the soils form during the warmer and wetter interglacial periods. In marine geology, the classic record of Quaternary climate change is found in the oxygen-18 ($\delta^{18}\text{O}$) values of seawater, which respond to the amount of glacial ice piled onto the continents. Linking these two paleoclimate records has been a long-standing goal of paleoclimatologists. The chance to achieve this objective was provided by a core raised from the Shatsky Rise, an oceanic plateau in the northwest Pacific. A study of dust deposition in this core captured the past 500,000 years (Figure E8) of the joint continental and marine history of climate change (Hovan et al., 1991). The flux of dust to the North Pacific varies by a factor of three to five on these glacial-interglacial timescales, with fluxes reaching a maxima during glaciations. As the dust flux maximal also correspond with the timing of loess formation, it is possible to determine the temporal relation between loess formation and the oxygen isotopic record generated from the same core. Spectral analysis of these and other eolian records of suitable resolution have shown the importance of the orbital variability that was first well quantified by Milankovitch in these

paleoclimatic records (Pisias and Rea, 1988; Clemens and Prell, 1990; Hovan et al., 1991).

Provenance studies

The geochemistry of the dust accumulated on the sea floor provides clues as to the source of the dust and the nature of any one source region. Knowing which continent, Asia or America, has provided the dust to the core location is a critical first step in the interpretation of source area climate. Here, again, the best-studied core is GPC3. Kyte and others (1993) analyzed samples from throughout GPC3 and were able to demonstrate that the dust in the upper portion of that core came from Asia, and dust in the lower part came from America. This observation regarding a change in the bulk geochemistry from a younger material of Asian affinity to an older sediment of American affinity was also noted by Pettke et al. (2002) who measured the Nd and Pb isotopic ratios of the dust. In the present climate regime, the change in dust geochemistry from Asian to American happens at the Intertropical Convergence Zone, and not, as might be expected, at the boundary between the zonal westerlies and the tradewinds. If this observation remains true during the Cenozoic, then the mid-Cenozoic geochemical transition observed in GPC3 marks the past location of the ITCZ, a location far north of the equator, perhaps 20° – 25° N (Rea, 1994; Rea et al., 2000; Pettke et al., 2002).

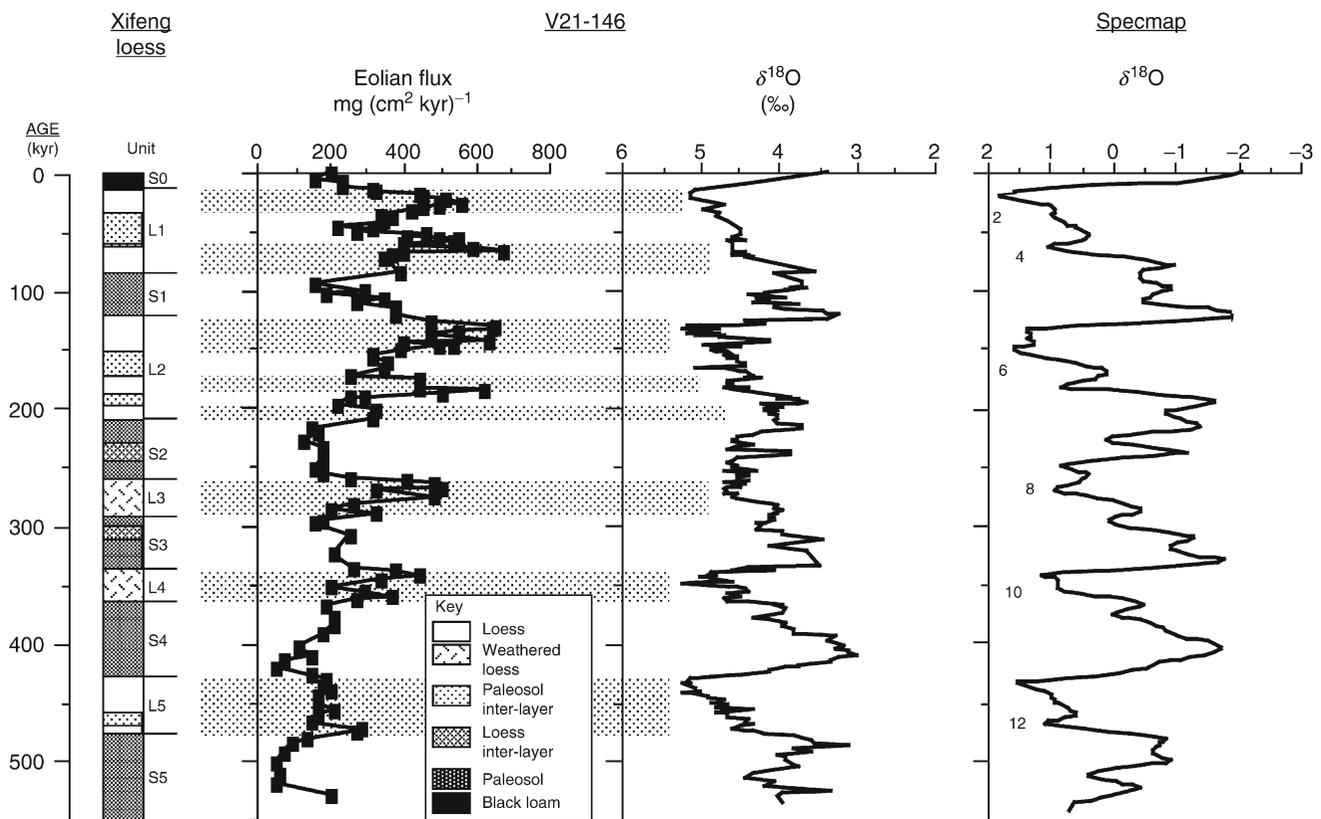

Figure E8 The record of dust deposition in the northwestern Pacific Ocean for the past 500,000 years. The column on the left shows the classic Chinese loess stratigraphy from the section at Xifeng. Data from core V21-146 raised from Shatsky Rise at 37.7° N, 163.0° E includes eolian flux and the $\delta^{18}\text{O}$ values measured by N. Shackleton on benthic foraminifera. The right column is the standardized $\delta^{18}\text{O}$ record of the marine geologists developed by the SPECMAP project. Even numbers denote glacial stages where isotopic values are more positive.

It is also possible to learn more about the eolian source areas than just where they are. For instance, Pettke et al. (2000) examined samples from ODP Site 885/886 and determined the $^{40}\text{Ar}/^{39}\text{Ar}$ ages of six dust samples whose stratigraphic ages ranged from 1.2 to 11.1 Ma. The mineral ages of those samples, dominated by illite, is about 200 million years. The 200 Myr age was interpreted to represent the formation age of the illites, and demonstrates that the processes of weathering, erosion, and late Cenozoic transport of those illites has not affected their argon-argon ages. This implies that other geochemical attributes of dust minerals may reflect the ultimate origin of those minerals and not the continental climate regime immediately prior to their transport to the sea.

Summary

Wind-blown dust forms a minor portion of deep sea sediment on a volumetric basis, but much of the world's ocean basins are characterized by a terrigenous sediment component that is dominated by eolian dust. These dust deposits provide paleoclimatic information not available from any other source. Studies of wind-blown dust fall into three categories: determination of its mass accumulation rate, an indicator of source area aridity; dust grain size, an indicator of transport energy; and dust composition, used for provenance studies. Dust records provide a useful and direct method to examine the evolution, usually climate related, of continental surfaces, and the only method to examine the geologic history of the Earth's wind systems (Rea, 1994). This last aspect is particularly important, as atmospheric circulation is an equal partner with ocean circulation as a global agent of climate change.

EOLIAN SEDIMENTS AND PROCESSES

Introduction

The word “eolian” (or “aeolian”) comes from the Greek “Aeolus.” Aeolus, in Greek mythology, was the god of the winds. “Eolian” thus refers to any process of sediment entrainment, transport and deposition by wind. Study of eolian processes and sediments is a part of the disciplines of geomorphology, sedimentology and paleoclimatology. Extensive reviews of the use of eolian deposits in paleoclimatology can be found in Pye (1987), Pye and Tsoar (1990), Lancaster (1995), Livingstone and Warren (1996) and Kohfeld and Harrison (2001).

Eolian deposits of interest to paleoclimatologists include, in order of decreasing particle size, windblown sand, loess, and long-range-transported (“LRT” or “aerosolic”) dust. Syers et al.

(1969) presented a useful fivefold classification of eolian materials based on dominant particle size, transport pathway and range and persistence in the atmosphere. In their scheme, there are continua of (a) coarse-to-fine grained materials, (b) kilometer-to-10¹³ km ranges of transport, and (c) ground level-to-interplanetary space levels of transport (Figure E9). Thus, eolian sand is in a boundary-layer zone of transport (within 2 m of the ground surface) and loess occupies a range of relatively short-to-intermediate-distance transport within the lower troposphere. It is important to note, however, that some near-source loesses contain eolian sand. Similarly, most loess deposits contain some particles that are in the size range of aerosolic dust (10–1 μm) and these particles are capable of much longer-distance transport in the middle and upper troposphere. There is even a fraction of most loesses that contains particles in the stratospheric dust particle size range (<1 μm). These particles are capable of transport at very high altitudes in the stratosphere over thousands of kilometers of distance.

Eolian sand

Eolian sand consists of all deposits of sand-sized particles (2.00–0.05 mm diameter) that have been transported by the wind. Although most investigators think of dunes when considering eolian sand, there are also low-relief landforms composed of wind-blown sand called sand sheets. Most investigators, however, have directed attention to dunes in studies related to paleoclimatology. Hack (1941), in studying the origin of dunes in the Navajo Country of northeastern Arizona, proposed that the degree of activity of sand dunes (as well as the specific type of dune form) is a function of the balance between sand supply,

wind strength and duration, and amount of vegetation cover. Sixty years of study since that time have confirmed this basic model. Lancaster (1988) showed that the degree of activity of linear dunes in the Namib and Kalahari Deserts of southwestern Africa is a function of the amount of time that wind is above the threshold velocity for entrainment of sand grains and the balance between precipitation and potential evaporation, a proxy for amount of vegetation cover. Muhs and Holliday (1995) confirmed that the Lancaster “dune mobility index,” as it has come to be called, explains the varying degrees of dune activity in the Great Plains and desert southwest of the United States.

The importance of the Hack-Lancaster models of dune activity to paleoclimatology is that they provide a basis for interpreting past periods of eolian sand deposition or eolian sand stability. Assuming that there is an adequate supply of sand, the entrainment and transport of sand by wind will occur when a vegetation cover is lacking. Plant-covered dunes remain stable because much of the shear stress from wind is imparted to the vegetation rather than to the sediment grains. Lack of a protective vegetation cover usually occurs when potential evapotranspiration exceeds precipitation, a condition that characterizes arid, semiarid and subhumid regions. Thus, in a stratigraphic sequence of eolian sand and intercalated buried soils (paleosols), periods of relatively greater aridity are represented by eolian sand and periods of relatively greater humidity are represented by paleosols (Figure E10).

Because they are transported by the wind, stabilized eolian sands are also a direct reflection of past atmospheric circulation.

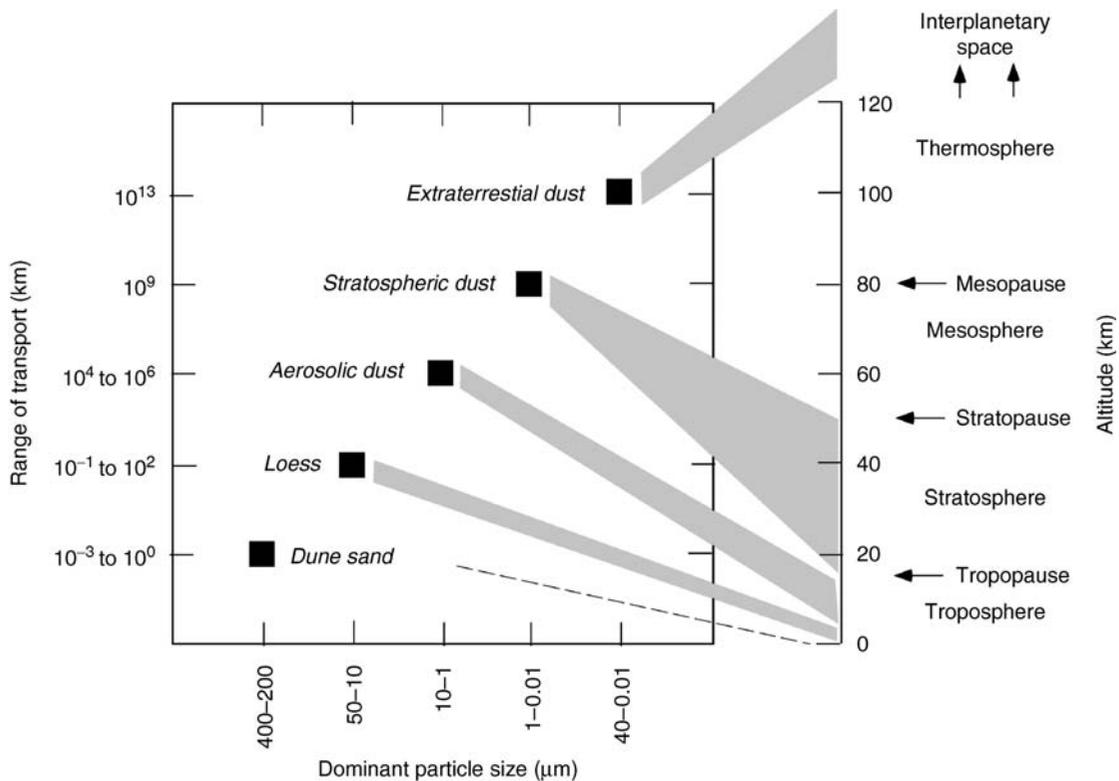

Figure E9 Diagram showing the continuum of eolian materials, with range of transport as a function of dominant particle size and generalized zone of transport in the atmosphere (based on Syers et al., 1969).

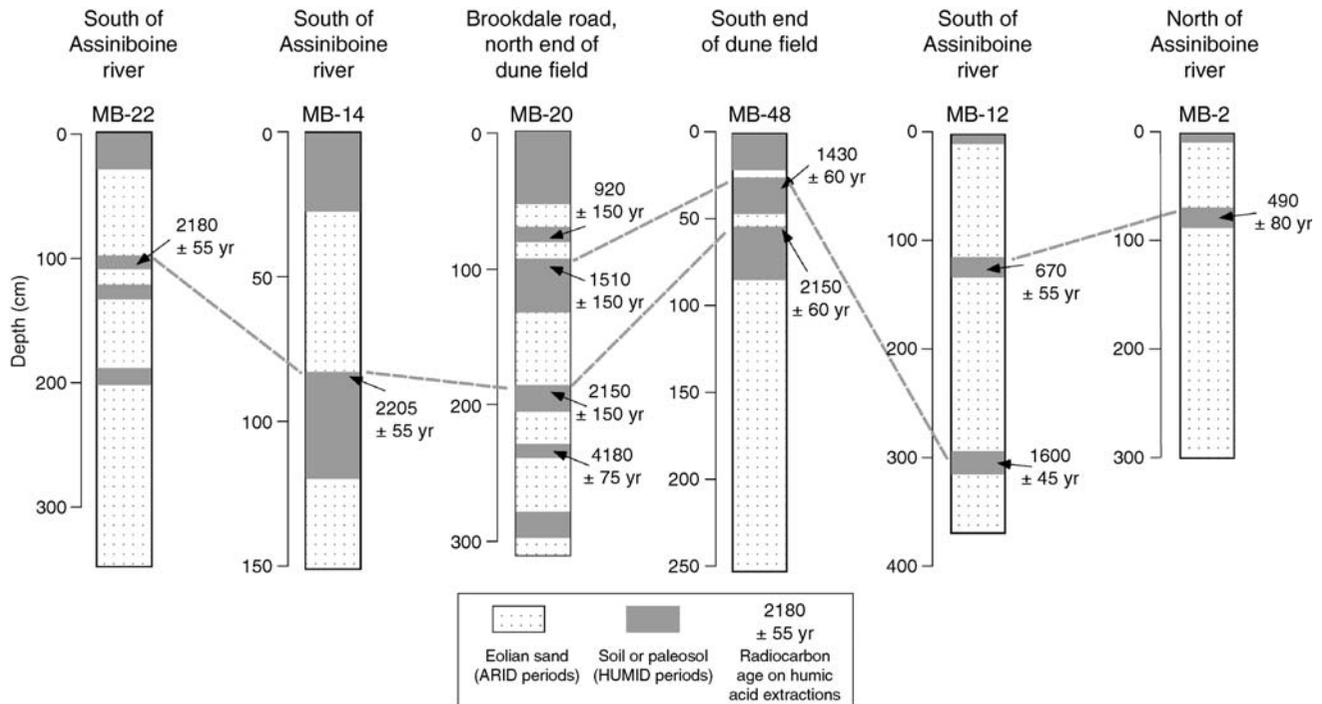

Figure E10 Stratigraphy and uncalibrated radiocarbon ages of late Holocene eolian sands from sections in the Brandon Dune Field, southern Manitoba, Canada. Episodes of eolian sand deposition represent relatively arid periods in the region, whereas paleosols represent less-arid periods when vegetation stabilized the dunes (redrawn from Wolfe et al., 2000).

Based on observations of actively moving sand dunes, eolian geomorphologists have developed an extensive classification of dune types that can be related to dominant wind directions (Pye and Tsoar, 1990; Lancaster, 1995; Livingstone and Warren, 1996). Linear dunes have long axes that parallel the dominant sand-moving winds and barchanoid ridges have long axes that are orthogonal to the predominant wind direction. Some dune types with superficially similar forms are actually formed by opposing directions of dominant winds. For example, barchan dunes have a crescentic shape with arms that point downwind, whereas parabolic dunes have a crescentic shape with arms that point upwind. Recognition of the differences between these two dune types requires field study. Nevertheless, stabilized dunes that have preserved their original forms provide valuable information about past wind regimes.

Field studies have shown that combined geomorphic, stratigraphic and geochronologic studies can document regional-scale changes in atmospheric circulation. For example, Lancaster et al. (2002) showed that linear dunes in western Mauritania are of three different ages, based on optically stimulated luminescence (OSL) ages, ~25–15 ka (last-glacial age), 13–10 ka (Younger Dryas), and <5 ka (late Holocene). These investigators found that last-glacial dunes are oriented northeast and Younger Dryas-age dunes are oriented north-northeast (Figure E11). In contrast, late Holocene dunes are oriented north-to-south, consistent with modern northerly winds that characterize the dominance of the Azores high over the region in summer. Thus, the greater proportion of easterly and northeasterly winds that built the last-glacial and Younger-Dryas-aged dunes reflect a different circulation regime at those times.

Other regions also show considerable change in the directions of dune-building winds over short timescales. In the central Great

Plains of the United States, late Holocene dunes are parabolic forms and have orientations that are very similar to modern dune-forming winds. For example, late Holocene parabolic dunes in the Great Bend area of central and western Kansas have arms that point to the southwest, consistent with modern southwesterly winds. However, prior to the late Holocene (perhaps during a mid-Holocene warm-dry period), winds apparently came from the northwest, based on geochemical trends (Arbogast and Muhs, 2000). Thus, dune-forming winds shifted at least 90° from their mid-Holocene direction to their present direction in the late Holocene. These data suggest a more zonal circulation pattern in the central Great Plains during the mid-Holocene than occurs today.

Loess

Loess, or windblown silt, is one of the most extensive surficial deposits on the Earth and may occupy as much as 10% of the land's surface, worldwide. Loess consists dominantly of particles between 50 and 2 microns, although some sand (>50 microns) and clay (<2 microns) are typically present. Unlike eolian sand, loess does not form distinctive landforms. Commonly, loess forms a blanket over a pre-existing landscape without much geomorphic expression. Loess ranges in thickness from a few decimeters to many tens of meters. It covers extensive areas of central North America, Alaska, Europe, Russia, Central Asia, China, Argentina and New Zealand and is the parent material for some of the world's most fertile soils. Extensive areas of loess occur near regions of active or past glaciation or in semiarid regions where there are abundant supplies of silt-rich sediments.

Loess has several distinctive characteristics that are important in paleoclimatology. Because much loess is glaciogenic,

a first-order significance of this sediment is that in many areas it marks glacial periods of the past. In some parts of North America and Europe, loess can be linked directly to its glacial sources, which supports the interpretation that it is primarily a record of past major ice sheet advances (see review in Bettis et al., 2003). The general model in such regions is that glacial grinding produces abundant silt-sized particles, which, after deposition in outwash deposits, are entrained by the wind. Thus, in a sequence of loess deposits with intercalated paleosols, unaltered loess marks periods of glaciation whereas paleosols mark interglacial or interstadial periods.

It is not always certain that loess is derived strictly from glaciers, however. For example, there has been a vigorous debate on the issue of whether Chinese loess has glacial or non-glacial (“desert”) sources and it is possible that it has both (Smalley, 1995; Derbyshire et al., 1998; Wright, 2001; Muhs

and Bettis, 2003). It is known, for instance, that loess in some regions, such as eastern Colorado in central North America, definitely contains a substantial nonglaciogenic component (Aleinikoff et al., 1999). Nevertheless, radiocarbon dating shows that the most recent period of thick loess deposition in Colorado was similar to that in areas proximal to the Laurentide Ice Sheet (see review in Muhs and Zarate, 2000). Thus, it appears that even where loess has its sources in non-glacial materials, the combination of dry, sparsely vegetated landscapes, a reduced intensity of the hydrological cycle and stronger winds may enhance the production and transport of windblown silt. These conditions are thought to be characteristic of glacial periods in many regions. Records of loess deposition in areas such as the Great Plains of North America and China have, therefore, records of glacial-interglacial cycles that compare favorably to the long-term record of such cycles in deep-sea cores (Figure E12). It is often possible to make what appears

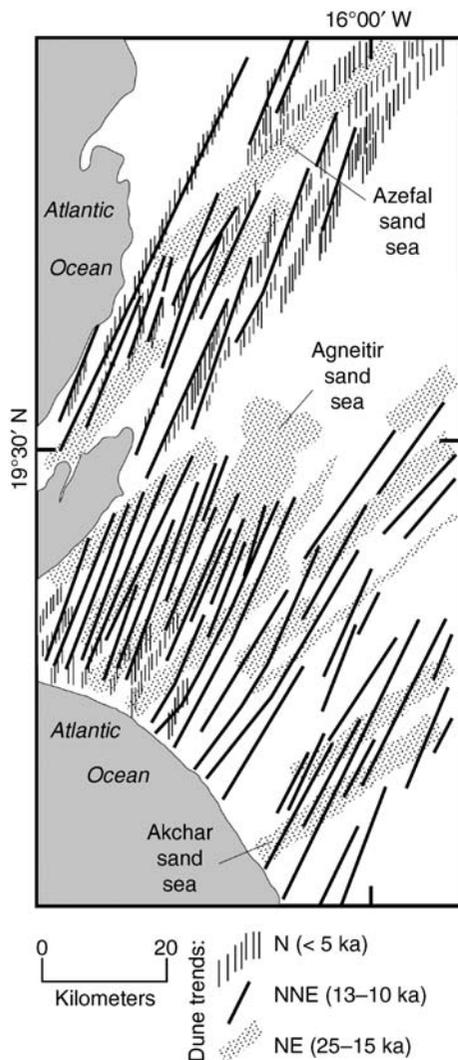

Figure E11 Map showing orientations of three ages of dunes in the western Sahara Desert of Mauritania, mapped from Landsat imagery (northerly dunes are shown schematically). The changes in orientation of the long axes of the different-aged dunes reflect shifts in wind direction (redrawn from Lancaster et al., 2002).

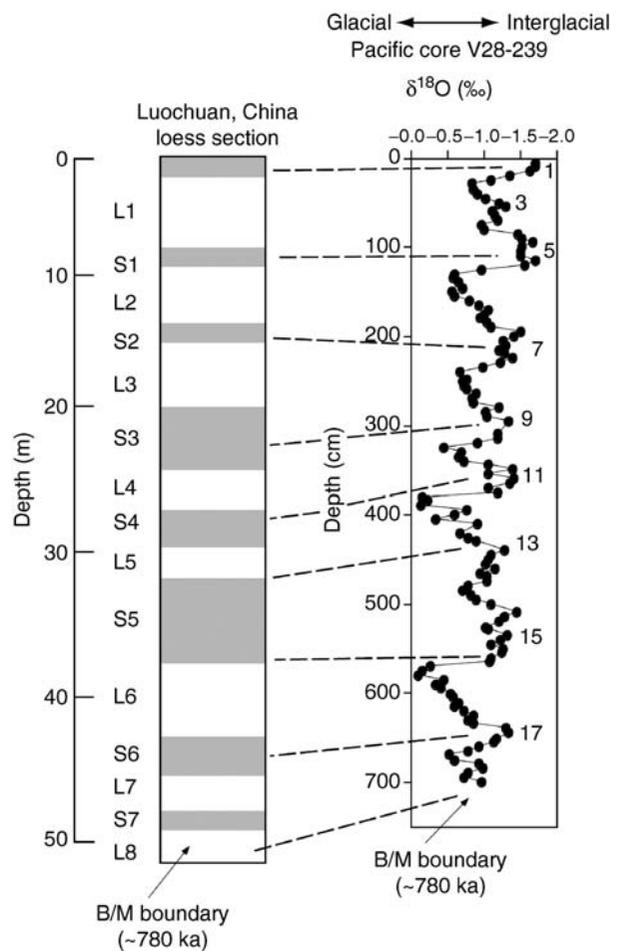

Figure E12 Stratigraphy of the Luochuan loess section, Chinese Loess Plateau, and proposed correlations to the deep-sea oxygen isotope record. Interglacial periods (odd numbers) are indicated by paleosols (shaded) in the loess record and by lighter (i.e., more negative) oxygen isotope values in the deep-sea record. Luochuan loess stratigraphy and location of the Brunhes-Matuyama (B/M) boundary (~780,000 year ago) are from Kukla and An (1989); oxygen isotope data and Brunhes-Matuyama (B/M) boundary) data for Pacific core V28-239 are from Shackleton and Opdyke (1976).

to be a one-to-one correlation between interglacial paleosols in a loess column and periods of isotopically light values (= interglacials) in a deep-sea core. However, it is important to note that the loess record is often incomplete. Erosion of either loess or paleosols can remove key periods that represent glacial or interglacials, respectively. On the other hand, if loess deposition rates are low during a particular glacial period, then a single paleosol may represent an interglacial period, a succeeding glacial period and the next-youngest interglacial period.

Beyond the identification of glacial-interglacial cycles, loess can provide valuable data for other paleoclimatic questions. Because it is transported by the wind, loess, as with eolian sand, can provide a direct record of past atmospheric circulation. Many studies have shown that loess has distinct decreases in thickness, grain size, carbonate content and geochemical properties away from a source (Ruhe, 1983; Muhs and Bettis, 2000; Porter, 2001). These distance-decay functions reflect the downwind processes of sediment-load reduction, coarse-load winnowing and syndepositional weathering. Identification of distance-decay functions in a number of loess bodies can yield paleowind directions, which in turn can be used to reconstruct regional circulation

patterns. Muhs and Bettis (2000) showed that in the North American midcontinent, loess-transporting winds were dominantly from the west or northwest during the last glacial period. Such a paleowind reconstruction has an apparent disagreement with atmospheric general circulation models (AGCMs) that simulate a northeasterly flow of air over central North America during the last glacial period, due to the presence of an anticyclone over the Laurentide Ice Sheet (COHMAP Members, 1988; Bartlein et al., 1998; Kutzbach et al., 1998). Modeling by Bromwich et al. (2005), however, shows that the zone of northeasterly winds may have been relatively narrow.

Because stronger winds can transport coarser-diameter grains, changes in mean particle size at a given locality indicate changes in the strength of particle-transporting winds. On the Chinese Loess Plateau, the median diameter of loess particles is a function of winds driven by the East Asian winter monsoon (Porter and An, 1995). Thus, at a single site, coarser particles indicate stronger winds and therefore a stronger East Asian winter monsoon. Porter and An (1995) showed that during the period since the last interglacial complex (i.e., since ~80,000 year ago), there have been 10 maxima in median particle diameter over the period of loess deposition (Figure E13).

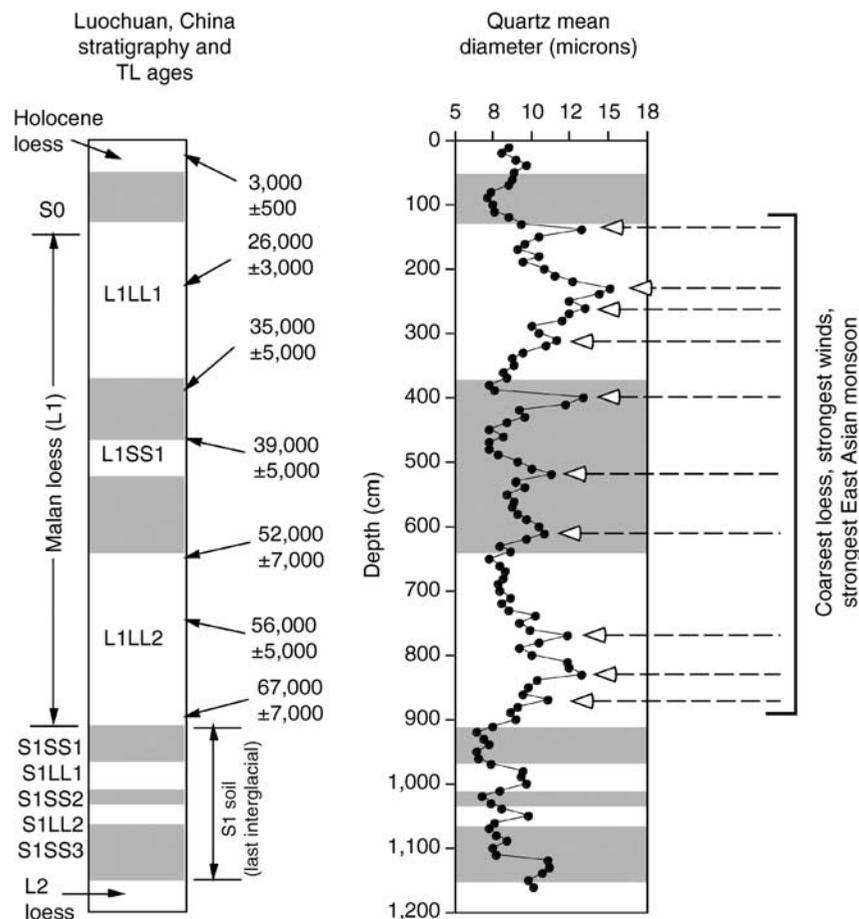

Figure E13 Stratigraphy, thermoluminescence ages, quartz mean diameter and inferred wind strengths over the last interglacial-glacial cycle at Luochuan, China. Loess units are white with an "L" prefix; paleosols are shaded with an "S" prefix. Stratigraphy and quartz mean diameter are based on Porter and An (1995) and Xiao et al. (1999); thermoluminescence ages are from Forman (1991).

Aerosolic (LRT) dust

Geologists, soil scientists and atmospheric scientists now recognize that fine-grained, aerosolic (<10 microns diameter) dust can travel distances of an intercontinental scale. Dust from the Sahara and Sahel regions of Africa travels yearly across the Atlantic Ocean on the easterly trade winds and what has been called the “Saharan Air Layer” to the Americas. Deposition occurs over a latitudinal span from northern South America at least to Florida (Prospero et al., 1970, 1981; Prospero and Lamb, 2003). The volume of this dust is large enough that it is easily visible on satellite imagery (e.g., Chiapello et al., 1999). Asian dust is transported east to the western Pacific Ocean basin and to islands at least as far as Hawaii (e.g., Olivarez et al., 1991). Dust from Australia tracks both to the northwest, towards the Indian Ocean, and southeast, towards New Zealand (McTainsh, 1989; Hesse and McTainsh, 1999).

There are excellent long-term records of LRT dust flux in diverse geologic settings (Figure E14 and E15). Dust can be recognized in (a) deep-ocean basin cores (e.g., Hovan et al., 1989; Ruddiman, 1997); (b) ice cores from Greenland and Antarctica, as well as smaller ice caps (e.g., Mayewski et al., 1994; Petit et al., 1999); and (c) lake basins (e.g., Xiao et al., 1999; Muhs et al., 2003). In addition, under favorable circumstances (a basaltic or carbonate bedrock that is compositionally distinct from dust) LRT dust can be identified as a contributor to soils on oceanic islands (see review in Birkeland, 1999).

In ocean cores and ice cores, where interglacial-glacial cycles are easily identified, it is apparent that global dust flux was high during glacial periods and low during interglacial

periods (Figure E14 and E15). Mahowald et al. (1999), Kohfeld and Harrison (2000) and Harrison et al. (2001) have reviewed the possible causes of higher dust flux during glacial periods, particularly the last glacial period. These factors include stronger or more persistent winds, greater aridity, decreased intensity of the hydrological cycle, decreased vegetation cover, increased sediment availability, or some combination of these factors. If sources of the dust in ocean, lake and ice cores can be identified, it is possible to reconstruct global-scale circulation during past periods of high dust flux.

Effects of dust on climate

There is an increasing recognition that dust, in addition to being a robust recorder of climate change, has possible effects on climate itself (Tegen, 2003). A traditional view has been that high dust flux cools the atmosphere, due to radiative backscatter to space. However, while this process has been well documented (e.g., Tegen et al., 1996), it is now known that the effect of dust on climate is actually quite complicated, and depends on the size, mineralogy and chemistry of the particles, plus the albedo of the surface over which particles are being transported (Arimoto, 2001). For example, Tegen et al. (1996) point out that over light surfaces (i.e., those with a high albedo, such as glaciers, snow-covered landscapes and sparsely vegetated landscapes) airborne dust absorbs radiation and reduces the solar flux that otherwise would be reflected back to space. Overpeck et al. (1996) generated an atmospheric model in which increases in airborne dust could produce a warming effect over such regions, downwind of dust sources. They point

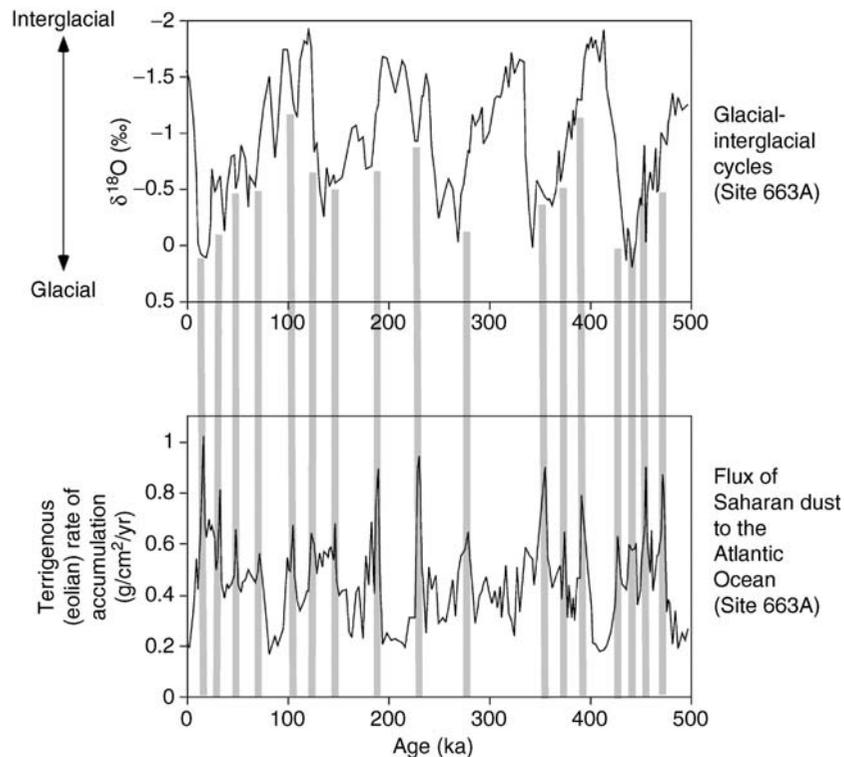

Figure E14 Records of dust flux from Saharan Africa to the Atlantic Ocean over glacial-interglacial cycles of the past 500,000 year. *Top:* Glacial-interglacial cycles in oxygen isotope record of foraminifera in deep-sea sediments at site 663A in the Atlantic Ocean. *Lower:* Accumulation rates of terrigenous sediments at site 663A – a measure of Saharan dust flux to the Atlantic Ocean. *Grey bands* show correspondence between generally cold (glacial or stadial) periods with periods of maximum dust flux. Site 663A data from deMenocal et al. (1993).

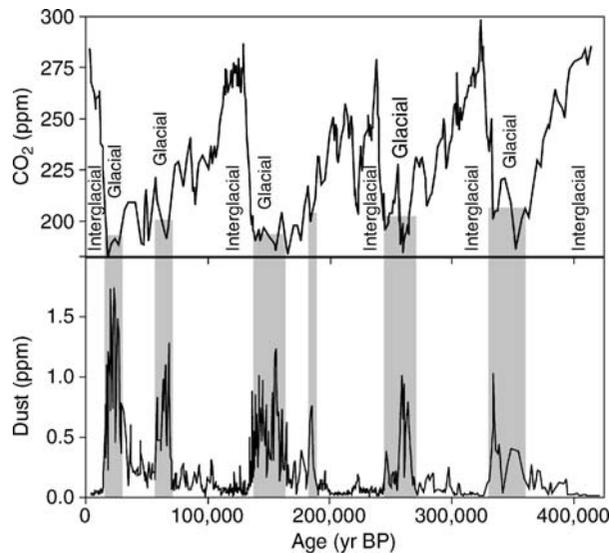

Figure E15 Top: Glacial-interglacial cycles in Vostok, Antarctica ice cores over the past ~400,000 year, as recorded by atmospheric carbon dioxide concentrations in gas bubbles. Bottom: Concentrations of dust in the same Vostok ice core record, showing correspondence between times of high dust flux and glacial periods (all data from Petit et al., 1999, 2001).

out that peaks in dust flux, as recorded in ocean cores and ice cores, occur just before glacial terminations, suggesting a causal relation.

In addition, dust can have indirect effects on climate. For example, phytoplankton growth in the oceans is limited in part by the degree of iron fertilization (e.g., Hutchins and Brunland, 1998). Fine-grained airborne dust has relatively high amounts of iron and iron content increases in a downwind direction in both China and North America (Eden et al., 1994; Muhs and Bettis, 2000). Thus, increased delivery of available iron to the oceans from the continents could, in principle, increase phytoplankton production, which in turn could draw down atmospheric carbon dioxide. Field studies show that in fact increased concentrations of dust-derived iron do enhance such primary production (Boyd et al., 2000). A decreased concentration of carbon dioxide in the atmosphere could result in cooling, due to a decreased greenhouse effect.

Summary

Eolian sediments consist of wind-blown sand, silt (loess) and fine-grained, long-range-transported (LRT or aerosolic) dust. For paleoclimatologists, eolian sand deposits may indicate periods of relative dryness in a region when vegetation cover is minimal. Buried soils in the same eolian sand sequences usually indicate periods of greater humidity and vegetation cover. Orientations of stabilized dunes can indicate past wind directions. Loess, or wind-blown silt, is often linked to glacial source sediments, although some loess may have a non-glaciogenic origin. Thus, loess deposits may mark glacial periods, but may also indicate dry, windy conditions in a sparsely vegetated source area. The geologic record indicates that major periods of loess deposition, whether glaciogenic or non-glaciogenic, occurred during glacial periods, when, in general, climates were drier than today. Although loess does not form distinctive landforms such as dunes, trends

in particle size, thickness and geochemistry can identify the dominant silt-transporting wind direction and yield valuable information to the paleoclimatologist about past circulation regimes. Aerosolic, or very fine-grained LRT dust, is best recorded in ocean sediments, ice caps and lake sediments. As with loess, the greatest flux of LRT dust during the Quaternary was during glacial periods. In addition to serving as a paleoclimate proxy, fine-grained dust may also affect climate itself, by warming or cooling the atmosphere through radiative scatter and by providing nutrients to the oceans and the continents.

EOLIANITE

The abundance of sand and scarcity of land plants within deserts and along wave-dominated beaches allows the wind to build dunes. Along many mid-latitude coasts, much of the material available for transport is composed of calcium carbonate minerals – calcite and aragonite. Although the term *eolianite* is sometimes used by geologists for “all consolidated sedimentary rocks that were deposited by the wind” (Sayles, 1931), it has also been

used for carbonate-rich coastal dunes of Quaternary age. Here the term is used for eolian deposits of any age in which carbonate grains constitute greater than 50% of all detrital grains (carbonate eolianite of Abegg et al., 2001).

Most Quaternary carbonate eolianites appear to have been deposited during interglacial episodes within a high sea-level setting. Abundant calcareous skeletal material was generated in the warm, clear, shallow water that covered broad coastal platforms, and dune ridges were built by onshore winds. In some areas, however, it has been demonstrated that eolianites developed during glacial episodes when low sea level exposed the platforms to wind action. Low sea level, however, facilitates cementation of carbonate sediment by rainwater. Thus, even though glacial episodes may have been windier than interglacials, a greater quantity of uncemented carbonate sand was probably available for wind transport during interglacials.

Large-scale cross-stratification produced by deposition of sand on the steep leeward faces of migrating dunes is ubiquitous within most carbonate eolianites. Similar cross-strata can be produced in certain subaqueous settings, however. The best criterion for recognizing ancient eolian deposits is the inverse-graded lamination produced by migrating wind ripples (Hunter, 1977). The shells of land snails are relatively common within Quaternary eolianites; these typically are the only carbonate skeletons larger than sand-size. A diverse assemblage of trace fossils is also commonly present, and can include insect and crustacean burrows (Curran and White, 2001) as well as vertebrate tracks (Fornos et al., 2002). Rhizoliths – organo-sedimentary structures produced by the growth of plant roots – are abundant in many carbonate eolianites. Cementation of the dune sand can be quite rapid, and thick caliche (calcrete) develops in areas with a seasonal water deficit. This tendency toward early lithification enhances the geologic preservation of eolianite.

Numerous carbonate eolianites have been recognized among the late Paleozoic limestones of North America. Like Quaternary eolianites, these strata accumulated during a time when shorelines migrated rapidly due to the waxing and waning of large polar ice sheets (Rice and Loope, 1991). More recently, however, carbonate eolianites have also been found within Jurassic and Cretaceous sections, suggesting that these rocks are not necessarily indicative of “icehouse” conditions (Loope and Abegg, 2001).

The deposition of carbonate eolianites is ultimately dependent on the availability of sand-sized, unlithified carbonate sediment. This material is most voluminous in areas where the supply of terrigenous (siliciclastic) sediment is low. Areas with an arid climate, low relief, and high wave and wind energy are thus especially favorable; the southern and western coasts of Australia have generated huge deposits during the Quaternary (Brooke, 2001).

ESKERS

Eskers are ridges of glaciofluvial sediment deposited in ice-walled channels or subglacial tunnels. Those deposited supraglacially are closely related to kames. Eskers appear in the postglacial landscape as long sinuous ridges of sand and gravel, and can be used to reconstruct glacial drainage patterns. Because eskers form in a variety of different glacial settings and take a variety of specific forms they are valuable indicators of former glacial conditions.

Subglacial eskers most commonly form in channels running through the ice at the glacier bed and are sometimes referred to as tunnel-fill eskers. Where water flow in the tunnel is at high pressure the routing is controlled by ice surface gradient and the pattern of water pressure beneath the glacier, so eskers can flow uphill as well as down and do not follow the topography. Similarly, supraglacial eskers draped onto the ground when lowered by ice wastage will not necessarily follow the topography. However, water flowing through a subglacial tunnel at atmospheric pressure must follow the topography and eskers of this type will not flow uphill. Eskers can occur as single ridges or in braided patterns, and can also be discontinuous or “beaded.” The morphology of eskers has been related to the hydraulic conditions in which they form, but the origins of many specific eskers remain disputed. For example, some models propose that braided eskers occur subglacially in response to very high water pressures, while others suggest that braiding is a characteristic of supraglacial systems. Eskers are uncommon in areas characterized by widespread subglacial deformation. This is partly because deformation would destroy eskers even as they form and, more importantly, because deforming bed environments are not typically characterized by water drainage through tunnels cut into the ice. Eskers have therefore been cited as evidence against subglacial deformation in areas where they occur.

Eskers comprise a variety of facies ranging from silt and sand to gravel and boulders. Some sedimentary structures are similar to those in open-channel fluvial deposits, but some

characteristics of esker sediments are specific to tunnel hydraulics. Many eskers have a core of poorly sorted sands and gravels. It has been suggested that in pressurized tunnels all of the sediment may be in motion as a single mass and that deposition occurs rapidly when the tunnel is blocked or water supply decreases at the end of the melt season. Above the unsorted core many eskers display arched bedding of sorted sands and gravels. These may be deposited during low discharge periods following the deposition of the core.

The largest eskers are hundreds of kilometers in length, hundreds of meters wide and tens of meters high. In some areas they stand prominently above the surrounding landscape and provide convenient route ways for road building. Benn and Evans (1998), Bennett and Glasser (1996) and Hambrey (1994) provide useful reviews.

EVAPORITES

General features

Evaporites are rocks formed by minerals that precipitate from brines concentrated by solar evaporation. Evaporite minerals may precipitate in subaqueous environments from a standing body of water as surface and bottom nucleates (syndimentary or primary deposition) or in subaerial and shallow subsurface settings as intrasediment crystal growth, cement and replacement (diagenetic or secondary deposition).

Evaporites may form by evaporation of seawater, non-marine waters (such as meteoric, hydrothermal, volcanogenic and diagenetic reaction waters) or by mixing of various proportions of these waters. Non-marine evaporites may show a distinctively different mineralogy, but most saline minerals precipitate from the evaporation of any kind of water mixtures (Table E1; Hardie, 1984).

The main conditions for evaporite formation in a basin are:

1. evaporation rate exceeding rainfall, surface water and groundwater inflows (negative water balance),
2. closed or restricted hydrologic circulation, and
3. sufficient solute supply in the inflow waters.

Evaporite sedimentation may occur in a variety of depositional settings and may show complex associations of depositional features, including clastic structures.

The interpretation of ancient evaporite sequences is complicated by the common tendency of most evaporite minerals to undergo strong modifications during diagenesis and burial that partially or completely obliterate their original sedimentary features. For example primary gypsum is transformed into anhydrite during diagenesis and/or burial and is converted back to gypsum at surface exposure (Murray, 1964). Since evaporite rocks are composed of soluble minerals, their preservation in the rock record is critical. Evaporite deposits can be partially or completely dissolved just after deposition or later at burial and exposure conditions.

Evaporite minerals are highly sensitive to tectonics and may recrystallize, may be easily deformed and may flow to form salt pillows and diapirs. The presence of evaporite deposits in sedimentary successions may also influence mountain chain development by acting as detachment layers for thrusting (salt tectonics).

Evaporite sediments may be a source of hydrocarbons, but most importantly, salt tectonics may be responsible for the creation of complex hydrocarbon traps. Loading of evaporites by the overlying sediments and/or extensional tectonics lead to flowage of salts with the formation of salt domes that generate positive subsurface structures. These structures are potential hydrocarbon traps and evaporites, being relatively impermeable, may also act as seals for hydrocarbon reservoirs.

Table E1 Some of the most common saline minerals in marine and non-marine settings (data from Hardie, 1984)

Mineral	Composition	Marine	Non-Marine
Anhydrite	CaSO ₄	X	X
Aphthitalite (glaserite)	K ₂ SO ₄ · (Na, K)SO ₄		X
Antarcticite	CaCl ₂ · 6H ₂ O		X
Aragonite	CaCO ₃	X	X
Bischofite	MgCl ₂ · 6H ₂ O	X	X
Bloedite (astrakanite)	Na ₂ SO ₄ · Mg SO ₄ · 4H ₂ O	X	X
Burkeite	Na ₂ CO ₃ · 2Na ₂ SO ₄		X
Calcite	CaCO ₃	X	X
Carnallite	MgCl ₂ · KCl · 6H ₂ O	X	X
Dolomite	CaCO ₃ · MgCO ₃	X	X
Epsomite	MgSO ₄ · 7H ₂ O	X	X
Gaylussite	CaCO ₃ · Na ₂ CO ₃ · 5H ₂ O	X	X
Glauberite	CaSO ₄ · Na ₂ SO ₄	X	X
Gypsum	CaSO ₄ · 2H ₂ O	X	X
Halite	NaCl	X	X
Hanksite	9Na ₂ SO ₄ · 2Na ₂ CO ₃ · KCl		X
Hexahydrate	MgSO ₄ · 6H ₂ O	X	X
Kainite	MgSO ₄ · KCl · 11/4H ₂ O	X	X
Kieserite	MgSO ₄ · H ₂ O	X	X
Leonhardtite	MgSO ₄ · 4H ₂ O	X	
Leonite	MgSO ₄ · K ₂ SO ₄ · 4H ₂ O	X	X
Mirabilite	Na ₂ SO ₄ · 10H ₂ O	X	X
Nahcolite	NaHCO ₃		X
Natron	Na ₂ CO ₃ · 10H ₂ O		X
Pentahydrate	MgSO ₄ · 5H ₂ O	X	
Pirssonite	CaCO ₃ · Na ₂ CO ₃ · 2H ₂ O		X
Polyhalite	2CaSO ₄ · Mg SO ₄ · K ₂ SO ₄ · 2H ₂ O	X	X
Shortite	2CaCO ₃ · Na ₂ CO ₃		?
Sylvite	KCl	X	X
Tachyhydrite	CaCl ₂ · 2MgCl ₂ · 12H ₂ O		X
Thenardite	Na ₂ SO ₄		X
Thermonatrite	Na ₂ CO ₃ · H ₂ O		X
Trona	NaHCO ₃ · Na ₂ CO ₃ · 2H ₂ O		X

The interpretation of ancient evaporite sequences is challenged also by the observation that only a small proportion of the deposits in the rock record formed in settings like those of today, but most thick and extensive deposits of the past (saline giants) apparently have no modern equivalent. To study these deposits, non-actualistic models have been proposed.

Evaporites have an important economic value both intrinsic and indirect, because of their association with base metal ore deposits and hydrocarbon accumulations.

Seawater evaporation

The evaporation of seawater leads to the precipitation of an ordered sequence of minerals of increasing solubilities. The marine evaporite minerals are many (Table E1), but the most common are gypsum (anhydrite) and halite (Table E2). First to precipitate from evaporating seawater is CaCO_3 , but in very small amounts. Gypsum precipitation starts after carbonates, when 85% of seawater is lost by evaporation. Deposition of gypsum accounts for 3.6% of the total volume of precipitates. Halite precipitates when 90% of the water has evaporated and forms 78% of the volume of solids (Table E2). After halite precipitation the mineral succession (potassic salts) is complex because the residual brine tends to react with the precipitates (back reactions).

Allowing a column of 1,000 m of seawater to evaporate completely, only about 14 m of precipitates would form and among them halite is the predominant salt (Table E2). This indicates that the thickness of evaporite deposits is directly controlled by the rate and mode of replenishment of evaporated seawater. Thick marine evaporites may thus accumulate only in basins where hydrologically restricted circulation allows large seawater volumes to be introduced and evaporated without a significant dilution of the basinal brines.

Rates of evaporite deposition from marine waters are potentially higher than those of any other sediment. In optimum artificial environments, such as solar evaporation works, accumulation rates of up to 40 m and 100 m per 1,000 years have been reported for gypsum and halite, respectively (Schreiber and Hsü, 1980). These data suggest that an evaporite basin may be filled extremely rapidly, for example, the > 2 km of salts beneath the floor of the Mediterranean that accumulated during the Messinian in less than approximately 640 kyr (Krijgsman et al., 1999).

Modern evaporites

Climatic conditions and geologic context

Modern evaporite deposits accumulate in arid and semi-arid regions of the world in the global high pressure belts of the subtropical horse latitude and the poles, and in the midlatitude intracontinental desert and steppes that are isolated from oceanic

moisture (Figure E16). These desert areas are located in two belts approximately between 15° and 45° north and south of the equator. Other arid areas where evaporites can form are the rain shadows of high mountain chains, which may be present at any latitude. Examples are the Patagonian and Nevada-Utah orographic deserts, which are located in the Andes and the Sierra Nevada rain shadows, respectively.

The great part of present-day evaporite deposition occurs in closed continental basins (playa lakes), whereas coastal settings are volumetrically less significant. Marine evaporites are confined to coastal supratidal settings (sabkhas) and to low-lying areas where seawater seeps into pools and small basins (salinas). Even in Antarctica small amounts of evaporite minerals are forming in lakes by brine mixing, freezing, evaporation and sublimation (Carlson et al., 1990).

Closed basin conditions may have various origins: (a) tectonic basins, including fault-bounded intermontane basins and intracratonic structural sags, (b) interdunal depressions in sand seas, (c) wind deflation hollows, (d) abandoned fluvial channels, (e) volcanic or bolide impact craters and (f) depressions formed by combinations of the above (Smoot and Lowenstein, 1991). Solutes are supplied by rivers, springs, groundwater and rainwater and by wind-blown aerosols and dust.

Supratidal evaporites: sabkhas

Sabkhas are salt-encrusted surfaces commonly associated with brine bodies. They can be continental or marine, the latter being the most common and the most studied (see Kendall and Harwood, 1996 for review). Coastal sabkhas form prograding supratidal flats, commonly adjacent to protected lagoons. These supratidal flats consist of marine or continental carbonate and/or siliciclastic sand and mud sediments with binding microbial and algal mats. The sabkhas are subaerially exposed for most of the time and are strongly influenced by wind scour and storm-driven floods that truncate their top, maintaining flat deflation surfaces. The wind erodes the topmost dry and uncemented sediments lying above the capillary zone.

Evaporite minerals (gypsum, anhydrite and halite) are precipitated within the sediments by evaporation of capillary brines (evaporite pumping) and as surface crusts. Brines are supplied by marine seepage, marine flooding, inflowing continental groundwaters and ephemeral sheet floods (Yechieli and Wood, 2002). Gypsum forms as discoidal crystals, rosettes, clusters and cement. Anhydrite commonly replaces gypsum and forms single nodules, layers and contorted bands of coalesced nodules displacing or replacing the host sediments (entherolitic anhydrite). Halite is less common and is found as ephemeral surficial crusts and displacive cube crystals within the sediments (e.g., Gornitz and Schreiber, 1981).

Table E2 The theoretical precipitation sequence of salts from seawater as a function of evaporated seawater, salinity and density at the beginning of each salt precipitation (data from Sonnenfeld and Perthuisot, 1989). Also shown are the approximate thickness of the various salts precipitated by the evaporation of a column of seawater 1,000 m high and the percentage of precipitated salts (recalculated data from Handford, 1991)

Component	Evaporated seawater (wt-%)	Salinity (wt-‰)	Density (cm^{-3})	Salt thickness from 1,000 m of seawater (m)	Total precipitates (%)
Mg and K salts	99	variable	1.283–1.3235	2.9	17.7
Halite	90	350	1.212–1.2185	12.9	78
Gypsum	85	250	1.0897–1.115	0.6	3.6
Carbonates	75	140	1.10	0.1	0.4
Seawater		35	1.0245		

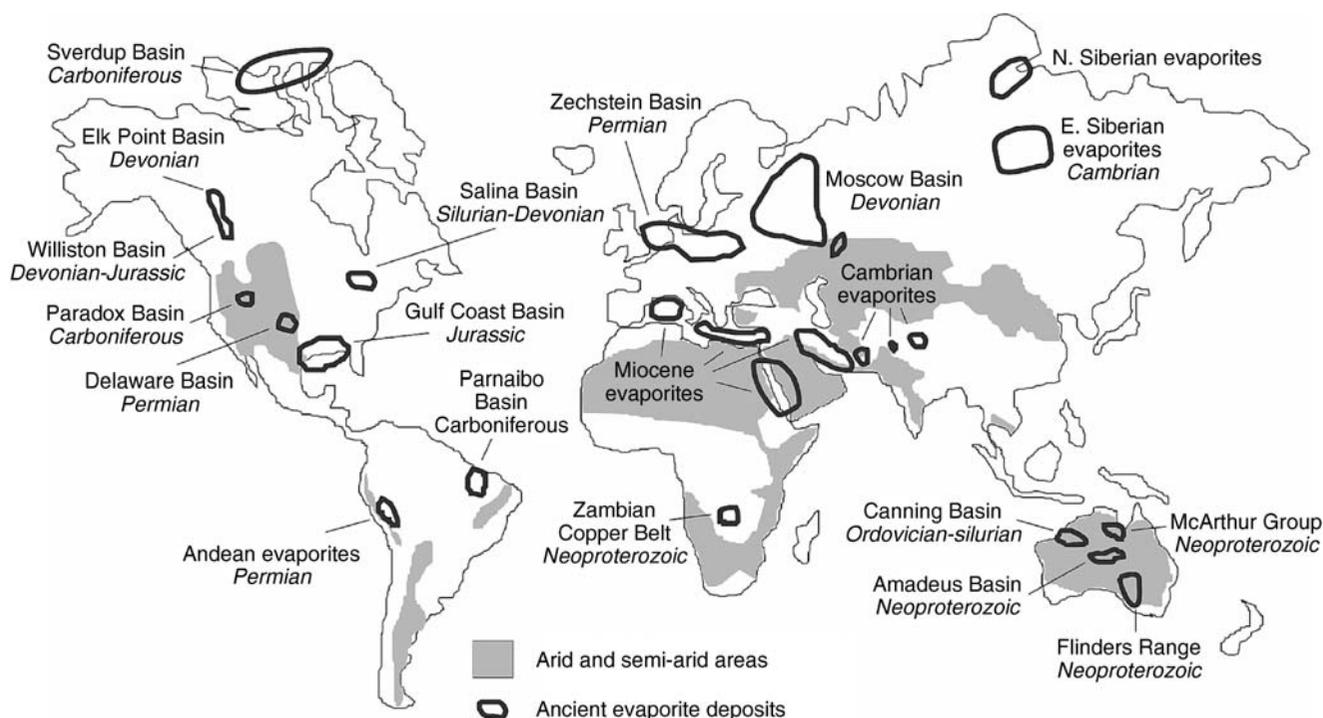

Figure E16 Map showing location, approximate size and age of the major ancient evaporite deposits of the world (simplified from Warren, 1999). Also shown are the arid and semi-arid climate areas where present-day evaporites are forming (simplified from Yechieli and Wood, 2002).

Coastal sabkhas are found: (a) as prograding supratidal flats above sea level along protected coastlines, (b) in depressions associated with salt pans between dunes or beach ridges, (c) at the margin of salinas associated with salt lakes fed by marine seepage through barriers, and (d) at the top of evaporite-filled salinas. Coastal sabkhas may pass landward into continental sabkhas as marine brines are replaced by continental waters during coastal plain progradation (Kendall and Harwood, 1996). Rates of deposition in modern sabkhas are high: thickness may reach 1 m in 1,000 years with 1 km progradation (Schreiber and Hsü, 1980). Sabkhas are present along the shores of the Persian Gulf, The Red Sea, west and southern Australia and North Africa.

Shallow-water evaporites: salinas

Modern shallow-water evaporites form in small salt lakes, commonly associated with sabkhas, fed by marine (salinas) or non-marine waters (playas). Salinas may be desiccated (salt pan), periodically dried out (ephemeral) or permanently covered by water (perennial). Desiccated and ephemeral salinas produce brine-pan sequences, whereas perennial salinas generate continuous subaqueous deposits.

Carbonates associated with shallow-water evaporites are characterized by biologically induced micrites and pelletal muds with microbial mats. The evaporite sedimentary features include tiny prismatic gypsum laminites (cumulates), beds consisting of large, commonly twinned, vertically-oriented bottom-grown gypsum crystals and clastic gypsum (Schreiber, 1988; Schreiber and El Tabakh, 2000). Precipitation of halite occurs at the bottom of the basin or more commonly at air-brine interface, with the formation of floating pyramidal hopper crystals

that may coalesce to form rafts. These halite rafts sink to the bottom of the basin and continue their growth as vertically-oriented crystal (chevrons). These crystals are milky-colored because they contain a large amount of fluid inclusions. Successive phases of halite deposition truncated by dilution episodes produce layered cuboid and chevron halite beds with microkarst pits (Shearman, 1970). Desiccation and dissolution features are common in shallow-water evaporite settings.

Modern salinas and playas are small and in many cases have been converted into sabkhas and brine pans by rapid evaporite filling. They are located in the coastal plain of the Gulf of Eilat (Red Sea), along the coast of south and western Australia and Baja California (Mexico). Useful modern examples for studying shallow-water evaporites are the artificial solar works, such as those of the Dead Sea.

Ancient evaporites

Evaporites through time and space

The oldest evaporite deposits that are still preserved in the rock record are present in Oman and Australia and date back to the Neoproterozoic. Pseudomorphs after evaporite minerals are common in the Proterozoic but have been reported in rocks as old as the Archean. The oldest pseudomorphs (3.45 Ga) have been described in South Africa and Australia and consist of barite, although their origin as actual evaporite replacements has been strongly argued (Nijman et al., 1998).

The frequency of evaporite deposition has oscillated significantly during the geological past. Peaks of large-scale evaporite deposition occurred in the Cambrian, Permian and Jurassic-Cretaceous, with less significant concentrations during the Triassic and the Tertiary (Figure E16).

Some of these deposits have huge dimensions: hundreds of kilometers in size and several kilometers thick (Figure E16). None of the evaporite giants of the past compare in extent and thickness to the scarce modern evaporite deposition and some of the facies observed in the rock record have no present-day analogs. Some of the reasons for these discrepancies are: (a) wider arid and semi-arid belts in the past because of warmer world climates; (b) larger shallow epeiric seas formed by long-term tectonic quiescence and low amplitude sea level fluctuations; (c) restricted seawater inflow to large oceanic margins and lake basins formed by rifting, continental collision and trans-tensional faulting combined with climate changes.

Another problem in studying ancient deposits is the difficulty in distinguishing between marine and non-marine evaporites (Hardie, 1984; Smoot and Lowenstein, 1991). A distinction can be possible when diagnostic saline mineral assemblages, associated fossils and regional depositional settings are recognized, but these criteria can be ambiguous or inapplicable. Any mineral combinations precipitated by seawater evaporation can be reproduced in non-marine settings, including gypsum and halite. The only mineral associations that cannot be produced by seawater without major modification by non-marine inflow are: (a) Na-carbonates, (b) Na-silicates and (c) Na- and Ca-borates.

Many deposits in the rock record have both marine and non-marine influences or alternations between them. These influences and alternations may be the result of mixing of marine and non-marine waters in isolated coastal lakes and intercalations of continental with coastal marine deposits.

Ancient sabkhas

Ancient sabkhas are identified by comparison with their modern analogs. Ancient sabkha evaporite beds are thin (less than 1 m), show evidence of exposure and erosion at the top and occur in basin margin settings. Gypsum in ancient sabkhas has been replaced by anhydrite during burial diagenesis.

Many evaporite deposits have been interpreted as sabkhas in the past based on the sole presence of anhydrite nodules (called "chicken wire") in thick evaporite cycles. We know today that the presence of anhydrite nodules by itself cannot be considered a criterion for sabkha identification because they can form in a variety of conditions, including early and late diagenesis (Schreiber and El Tabakh, 2000). Some thick sequences previously interpreted as sabkhas have been reinterpreted as subaqueous deposits (Warren and Kendall, 1985; Kendall and Harwood, 1996). The best known example of an ancient sabkha in the rock record is the Jurassic Purbeck of southern England (Shearman, 1966).

Ancient shallow-water evaporites

Shallow-water evaporites formed huge deposits in the geologic past on wide shelves and platforms that have no modern analog (basin-marginal platform evaporites). These deposits consist mostly of large vertically-oriented gypsum crystals associated with carbonate and bedded halite. Gypsum in ancient deposits has been commonly replaced by nodular anhydrite during burial diagenesis. Characteristic of shallow water deposits is the presence of dissolution surfaces and clastic evaporites. Clastic gypsum, commonly converted into anhydrite, shows all ranges of sedimentary features, indicating that gypsum can be eroded, transported, and deposited in the same fashion as other clastic sediments (Schreiber, 1988).

Ancient bedded halite rocks commonly recrystallize to form banded sequences composed of clear crystals, usually free of fluid inclusions, and do not retain their original sedimentary features, although a number of early Phanerozoic halites still maintain their depositional characteristics.

Typical ancient shallow water evaporites are described in the San Andres Formation of the Palo Duro Basin, Permian of Texas (USA) and in the marginal facies of the Messinian evaporites in the Mediterranean.

Ancient deep-water evaporites

Deep-water evaporites form saline giants precipitated from large-size brine bodies that lack any modern analog and can thus be identified solely by their vertical and lateral continuity (basin-central or basinwide evaporites). The modern Dead Sea, which is a closed perennial saline lake, may be considered a sort of deep-water analog just from the hydrodynamic point of view, because its water composition and mineral associations are peculiar (Hardie, 1984; Kendall and Harwood, 1996).

Ancient deep-water evaporites are composed mostly of finely laminated sulfate-carbonate couplets and laminar and bedded halite, commonly organic-rich, that can be correlated over wide areas (several hundreds of km in some cases; Dean and Anderson, 1982).

Most of these deposits are crystal cumulates that sank from the brine surface down to the bottom of the basin. The deepwater origin is inferred also by the absence of dissolution surfaces, a feature related to a vertical density stratification that is thought to be typical of deep evaporite basins. Mass-flow and turbidite deposits produced by the resedimentation of shallow-water evaporites are commonly associated with deep evaporite facies.

Deepwater evaporites are described in the Castile Formation of the Delaware Basin, Permian of Texas and New Mexico (USA), the central portion of the Salina Formation, Upper Silurian of the Michigan Basin (Canada and USA) and the central part of the Zechstein evaporates (Permian of northern Europe).

Evaporite geochemistry

Geochemistry is a significant tool that can help in documenting the origin and the post-depositional evolution of the evaporite deposits. Investigations may include analyses of fluid inclusions, trace elements (Br, Sr, Rb, Cs and Pb), Br/Cl ratios, $^{87}\text{Sr}/^{86}\text{Sr}$ ratios and S and O isotopes. Among these, the Br/Cl ratios in the chloride salts provide information on the evaporative concentrations and the hydrologic history record. The marine evaporite rocks may be dated by comparing their $^{87}\text{Sr}/^{86}\text{Sr}$ and $\delta^{34}\text{S}$ values with the secular variation curves of these isotopes in seawater.

Composition of fluid inclusions in marine halites has been used to constrain secular variations in the major ion chemistry of Phanerozoic seawater (Mg^{2+} , Ca^{2+} , Na^+ , K^+ , Cl^- and SO_4^{2-}) as a function of seafloor spreading rates, volcanism, global sea level, and mineralogy of marine limestones and evaporites (Lowenstein et al., 2001; Horita et al., 2002).

Microthermometric measurements on fluid inclusions in halite have been used to reconstruct the paleoclimate record of the past 200 kyr in Death Valley (Lowenstein et al., 1999) and the mid-Permian of western Kansas (Benison and Goldstein, 1999). This can be done because homogenization temperatures of fluid inclusions in subaqueously-formed halite record brine temperatures during salt crystallization that closely correlate with air temperatures.

EVOLUTION AND CLIMATE CHANGE

Introduction

Darwin's model (1859) for evolutionary change was based on a single branching tree of life, originating with one species at a point in deep time and concluding with the spectacular organic variety of modern ecosystems. Through time, the splitting of species developed both the biocomplexity and biodiversity of life present today, during some 4,000 million years of organic evolution. Nevertheless the process was not a gradual progression; life evolved at variable rates, commonly punctuated by a series of catastrophic events of varying magnitudes (Benton, 1995). Patterns, rates and trends in evolution were governed by a range of biological, chemical and physical factors; moreover their distributions and affects were rarely even or random. Climate is the manifestation of long-term, time-averaged atmospheric change, in simple terms, weather. The various patterns of climate change exerted a strong influence on a number of types of evolutionary process. Temperature was probably the most important climatic factor in marine environments, whereas in the more complex terrestrial milieu, temperature together with rainfall, solar luminosity and wind strength exerted their influence on the distribution and evolution of biotas. Climate, particularly temperature, is thus one of a number of factors including also sea-level change and volcanicity that may have been associated with both small and larger-scale evolutionary events (Figure E17). Climatic change has demonstrably driven the migration of biotas; less clear, however, is its control on microevolution processes at the species level. On a larger scale, extreme climate change has forced the restructuring of the planet's ecosystems and more rarely caused major extinction events.

Climatic fluctuations through time

Short-term trends

Many climatic events are short term, occurring within a time span of 100,000 years (Cronin, 1999). Many Earth surface processes respond rapidly to climate change, for example the atmosphere and ocean surface waters can change within days to a few years whereas the deep water of the ocean basins and terrestrial vegetation may take centuries to alter; the buildup of ice sheets and associated sea-level changes, however, occur over millennia. Changes in precipitation and temperature in the recent past may have influenced the course of human events and almost certainly impacted on the direction of hominid evolution during the late Pliocene and Pleistocene. Many short-term climatic fluctuations have been related to Milankovitch cycles associated with the eccentricity, obliquity and precession of the Earth's orbit, and generally lasted from 20,000 to 400,000 years. These short-term trends are associated with evolutionary changes at the speciation level and more local regional changes in the composition and structure of ecosystems.

Long-term trends

Data available for the late Proterozoic and Phanerozoic suggest that during the last 900 million years the Earth oscillated between greenhouse and icehouse conditions at least five times (Frakes, 1979; Frakes et al., 1992). These megacycles, first developed by Alfred Fischer, have been compared with patterns of change in extinctions, sea-level and volcanicity (Figure E18). Moreover, there may be a correlation between all three of these

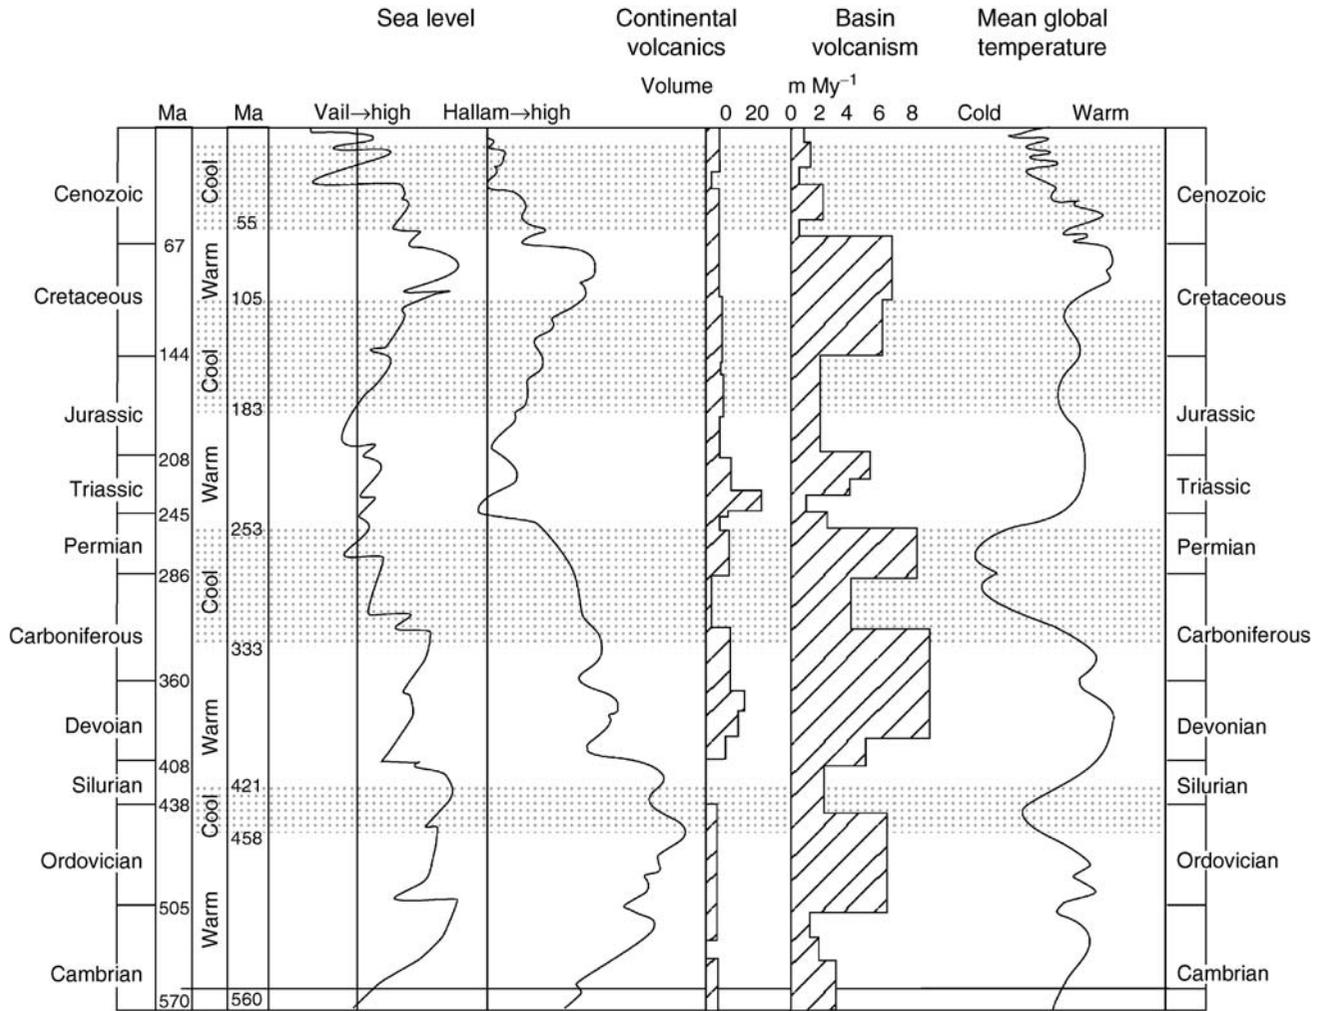

Figure E17 The relationships between temperature, volcanism and sea-level change during the last 570 million years (redrawn and replotted from Frakes et al., 1992).

variables and the assembly and breakup of the supercontinents. In marine environments, two extreme states occurred: The ice-house state involved stratified, stable oceans, cool surface waters between 2 and 25 °C and bottom waters ranging from 1 to 2 °C, together with rapidly moving bottom waters, rich in oxygen and with high productivity in areas of upwelling. On the other hand, greenhouse oceans were less stable and poorly stratified, with surface waters ranging in temperature from 12 to 25 °C and deep-water temperatures between 10 to 15 °C. Slow bottom currents carried little oxygen and productivity was generally low. Extinctions were associated with the transitions between these oceanic states. In addition to these major climatic fluctuations, a series of major extinction events, some associated with extra-terrestrial causes, clearly prompted major climate change over several million years. Such events caused major taxonomic extinctions together with major restructuring of the marine and terrestrial ecosystems. Generally, greenhouse biotas were most susceptible to extinction; their species were more specialized and thus exposed to environmental change.

Biocomplexity

Microevolution

Evolution at the species level is based on the natural selection of individuals from genetically and morphologically variable populations. Parts of populations with different samples of genetic material may become isolated from the parent population by physical or ecological barriers, leaving this subset free to evolve in a different direction, where selection pressures may also be different. Allopatric speciation based on the founder principle has been widely used to account for evolutionary change. A further mechanism is genetic drift, whereby small peripheral isolates of a population may break away from the parent population to establish new species eventually. Moreover, species evolution may have occurred in two quite different ways. Phyletic gradualism implies gradual morphological change whereas the punctuated equilibrium model involves rapid, sudden changes in morphology followed by intervals of no change, or stasis. Microevolution has been demonstrated

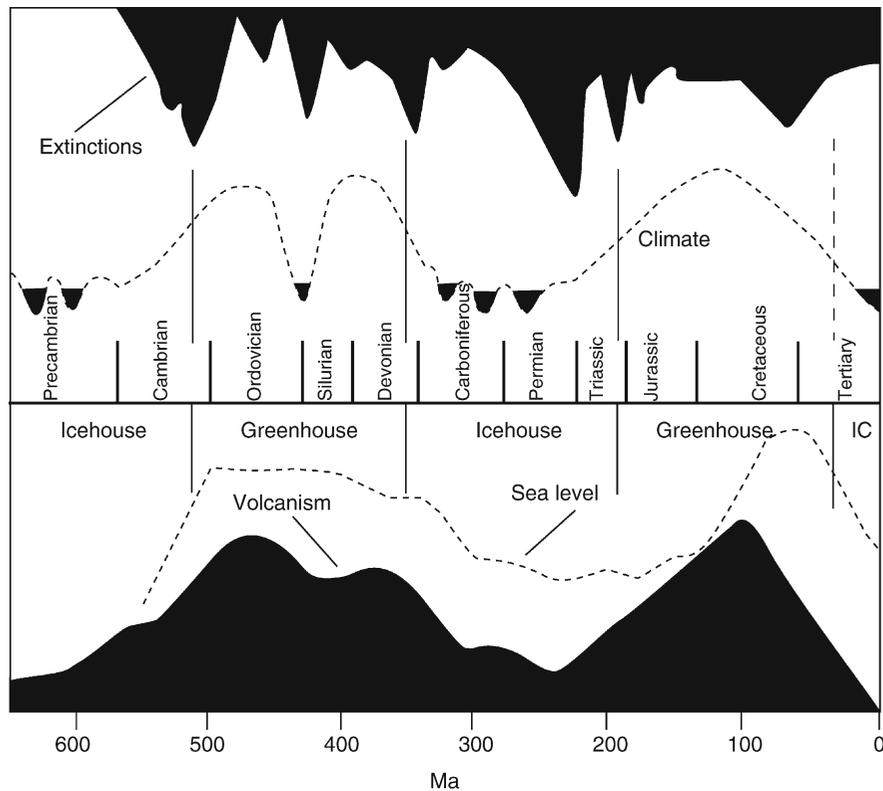

Figure E18 Alternations between icehouse and greenhouse states: the so-called “Fischer cycles.” The relationships between climate, extinctions, sea-level and volcanism are also indicated (adapted and redrawn from Fischer in Berggren and van Couvering, 1982).

in many fossil lineages (Benton and Pearson, 2001) although the link between speciation events and climatic change is more controversial. In general terms, marine plankton show gradual evolution whereas marine invertebrates and vertebrates display punctuated equilibria. Moreover, it is probable that narrowly fluctuating, changing environments hosted persistent gradualistic evolution whereas widely fluctuating environments were better characterized by morphological stasis (Sheldon, 1996). This resistance to morphological change has been demonstrated in a number of lineages such as Ordovician trilobites (Sheldon, 1987) and Pliocene mollusks (Williamson, 1981).

Short-term climatic fluctuations, for example those associated with Milankovitch cycles, can clearly disrupt and promote the reassembly of both marine and terrestrial communities (Bennett, 1997) and in some cases drive local extinctions and radiations, for example in the conodont and graptolite faunas of the Silurian (Jeppson, 1990). Regarding possible speciation, at least two outcomes are possible: Widespread evolutionary stasis or the development of isolated populations forming the focus of genetic and morphological divergence (Sepkoski, 1998). The Plio-Pleistocene deposits of East Africa have provided some of the best constrained studies of the relationship of climatic change to evolution. Datasets comprising a variety of mammals including hominoids have formed the focus for microevolutionary studies (Vrba, 1993). Cooler climates in the early Neogene prompted biotic turnovers in the evolution of animals with larger bodies and either relatively smaller or larger body parts (Vrba, 1996). The relative enlargement of the hominoid brain

exemplifies the latter. Some similar trends are apparent in Jurassic and Cretaceous marine environments. Deeper-water pelagic faunas are more diverse, such that communities that are more complex and have larger predators occur in oceans with raised temperatures.

Macroevolution

Macroevolution involves the study of larger scale evolutionary processes, usually involving major and rapid morphological change in a number of contemporary organisms. Generally, the appearance and disappearance of higher taxonomic groups during adaptive radiations or mass extinctions signal macroevolutionary change. Adaptive radiations are usually associated with the development of a successful morphological innovation and the exploitation of new ecospace. Such major evolutionary changes depend on many factors, both intrinsic and extrinsic, and are difficult to relate directly to climate. Many adaptive radiations, however, occur following major extinction events and take advantage of a range of vacant niches. Nevertheless, many, such as the diversification of skeletal organisms, reef-building organisms and the first predators, are clustered at the Precambrian-Cambrian boundary (Benton and Harper, 1997), associated with increasingly warm climates and higher sea levels. On land, the radiation of early terrestrial tetrapods in the early Carboniferous together with the diversification of large flying insects in the first extensive forests during the late Paleozoic, in cooler climates and more exposed land areas, have also been correlated with higher levels of atmospheric oxygen (Bernier et al., 2000).

Megaevolution

The appearance of entire new biotas and commonly grades of organization, for example the origin of life itself, the development of photosynthesis and the appearance of the metazoans rank, together with the origin and diversification of skeletal organisms, are megaevolutionary events (Benton and Harper, 1997). Data are as yet too imprecise to relate these events to climate change. However, there are a few indications. The first two events have been associated with a stable Archean crust and relatively cooler climates, favorable for carbon-based life to evolve. Metazoans appeared and diversified after the decay of the near global ice sheets of Snowball Earth whereas skeletal organisms radiated during the greenhouse climates of the early Cambrian.

Biodiversity

The fossil record holds a unique database of the diversification of life on land and in the sea (Harper and Benton, 2001). Range data of animals and plants through time form the basis of the study of biodiversity (Conway Morris, 1999). Qualitative and quantitative analyses have revealed that time trends are not random; biodiversity dynamics and the appearance of evolutionary innovations suggest that a nonrandom group of both intrinsic and extrinsic processes controlled changes in biodiversity (Jablonski, 1999). Climate is one of a number of important factors that mediates the planet's biodiversity through time.

Extinctions

During the Phanerozoic, animals and plants experienced a steady turnover in species. Clearly, climate change was one of a range of causes for background extinctions, particularly when habitats were destroyed and the tolerance range of individual species was exceeded. In addition, five major extinctions and a number of more minor events have been recognized in the fossil record, based primarily on paleontological data (Hallam and Wignall, 1997). All five, the end-Ordovician, late Devonian, end-Permian, end-Triassic and end-Cretaceous have been associated with major climatic changes linked to a range of terrestrial and extra-terrestrial causes (Brenchley and Harper, 1998). The end-Ordovician event was marked by a rapid transition from greenhouse to icehouse conditions associated with an increase in polar ice, a cooling of oceanic surface water and cycling of carbon within a changing oceanic system; most clades and ecological groups were affected and up to 85% of all species probably disappeared. The late Devonian event was less severe with the loss of about 80% of species during a phase of climatic cooling associated with sea-level change and anoxia. The end-Permian extinction was the most marked with about 95% of all species affected. All clades and ecological groups were devastated during a range of climatic changes, linked to a runaway greenhouse (Benton and Twitchett, 2003). The end-Triassic event witnessed the demise of about 75% of species, particularly the terrestrial vertebrates, during an event dominated by climate and sea-level changes together with anoxia. The end-Cretaceous event was near instantaneous with the disappearance of about 75% of species across a number of clades, including the ammonites and dinosaurs but particularly the plankton. Major climatic change has been linked to a bolide impact. Two more minor events, the Turonian-Cenomanian (loss of 50% of species) and the Eocene-Oligocene (loss of 35% of species) events have been linked to climatic changes associated with bolide impact or comet showers, respectively.

Radiations

Some intervals of apparent adaptive and rapid speciation can be related to climate change. Most profound was the emergence of the soft-bodied Ediacara fauna following the reversal of Snowball Earth. These remarkably diverse animals occupied a range of marine environments and ecological niches during the warmer climates of the late Proterozoic. The Cambrian explosion, marked by the rapid diversification of skeletal organisms with a spectrum of new body plans within the early part of the period, may have been associated with a continued rise in temperature, intense biological production and high rates of phosphate deposition coincident with changing patterns of oceanic circulation. The Ordovician radiation nevertheless marked the most significant diversification in numbers of marine organisms. The firm establishment of greenhouse conditions is correlated with widespread carbonate platforms and relatively high sea levels. This radiation set the agenda for Paleozoic marine life or perhaps marine biotas throughout the entire Phanerozoic (Alroy et al., 2001). The progressive diversification of marine life within the Modern evolutionary fauna following the end-Permian extinction event is again associated with persistent rises in temperature and sea level within a prolonged greenhouse phase.

On land some broad patterns are recognizable; for example the radiation of the pteridophyte plants together with the amphibians and mammal-like reptiles occurred during the cooler climates of the Carboniferous and Permian whereas the large reptiles, for example the dinosaurs, diversified during the warmer climates of the Jurassic and Cretaceous, together with the gymnosperm plants. Following the end-Cretaceous extinction event, angiosperm plants together with the mammals continued to diversify against a background of declining temperature.

Biotic change

In addition to the development of biocomplexity and biodiversity, a number of patterns of long-term change in the Earth's paleobiotic ecosystems can be detected (Figure E19a–c). Such large-scale ecologic changes are more closely related to major swings in climate associated with extinction events. Nevertheless, in many cases the severity of the ecologic crisis was decoupled from changes in biodiversity (Droser et al., 2000) suggesting that the environmental controls on both processes were different.

Precambrian

The Precambrian covers some 80% of geological time but organic remains are relatively few and many are controversial (Brasier et al., 2004). The era includes a series of major biological events, for example the origin of life and photosynthesis and the appearance of multicellular organisms together with the rise of the earliest metazoans and the evolution of the first skeletal animals. The origin of life (Rosing, 1999) and photosynthesis (Rosing and Frei, 2003) may have marked the establishment of more stable but warm climates on Earth following the development of continental crust together with marine basins and coincident with the cessation of meteorite showers. The role of climate during much of the later Archean and Proterozoic is unclear, while the development of an oxygenated atmosphere and hydrosphere favored the radiation of aerobic multicellular organisms (Knoll, 2003). Anaerobic environments and their organisms were marginalized. Moreover, the greater availability of atmospheric oxygen around 2.5–2.3 Ga may

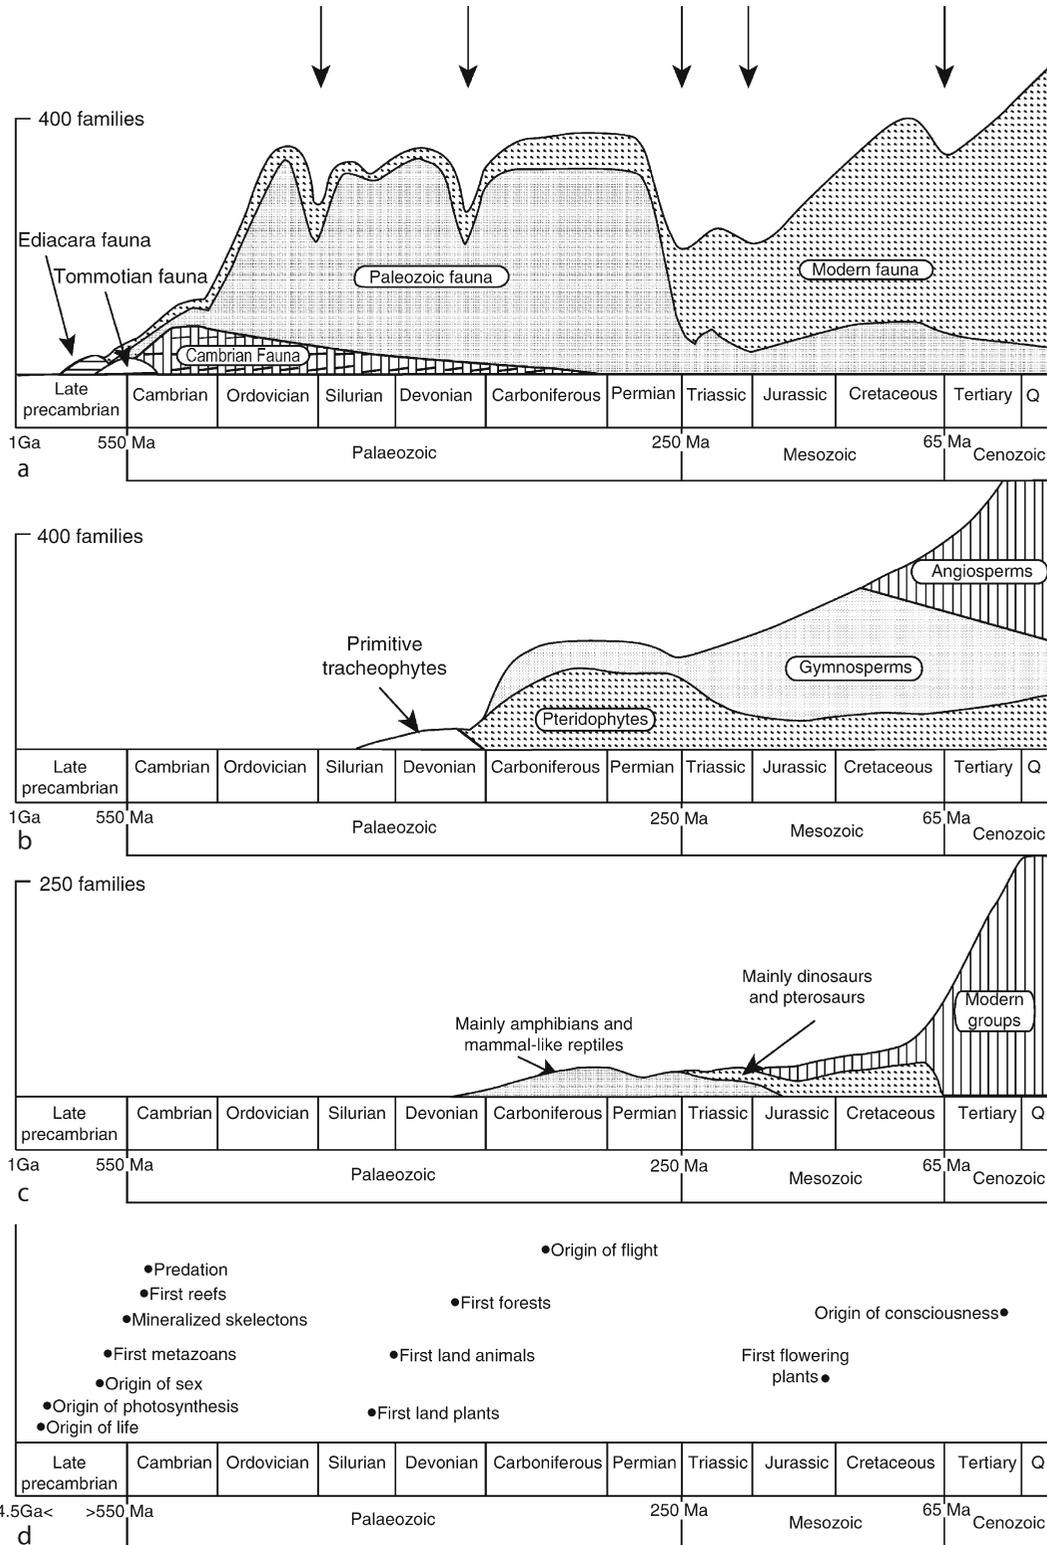

Figure E19 a. The marine evolutionary faunas together with the five big extinction events indicated by arrows, b. The nonmarine evolutionary floras, c. have reduced concentrations of methane, possibly driving the Huronian glaciation (Kasting et al., 2001). Nevertheless, major climate changes at the end of the Proterozoic virtually annihilated life on the planet; subsequent climatic amelioration may have strongly influenced the direction of metazoan life. The Snowball Earth hypothesis (Hoffman et al., 1998) envisages a runaway extreme icehouse state, with ice sheets extending from pole to pole and the oceans covered by sea ice. Marine organisms were thus restricted to refugia as the majority of marine habitats were destroyed. Earth emerged into a subsequent greenhouse state, populated initially by mutations generated during periods of extreme environmental stress. The first signs of relatively abundant metazoan life, the soft-bodied Ediacara biota, occurred globally above the late Proterozoic glacial deposits associated with Snowball Earth. They form the basis for the Ediacara Fauna (Figure E19a).

Phanerozoic

Phanerozoic life can be organized into a number of major evolutionary faunas and floras (Figure E19a). In the sea, the Cambrian evolutionary fauna was characterized by loosely-structured communities with morphologically varied species dominated by trilobites and primitive echinoderms and molluscs. It followed sequentially the appearance of the Tommotian (or Small Shelly) Fauna, dominated by small skeletal organisms. These first skeletal-dominated evolutionary faunas developed during the warmer climates of the early Cambrian. The Paleozoic evolutionary fauna (Ordovician-Permian) was dominated by abundant suspension feeders such as the brachiopods, bryozoans and corals, whereas the Modern evolutionary fauna (Triassic-Recent) consisted predominantly of detritus feeders with a substantial bioturbation of the seabed, together with efficient predators that participated in an arms race with their prey. The sharp transition between the Paleozoic and Modern evolutionary faunas is marked by the end-Permian extinction event (Benton and Twitchett, 2003), when over 95% of all species disappeared.

Similar models have been developed for terrestrial biotas (Figure E19b and E19c). The sequential appearance of evolutionary faunas dominated by the amphibians and mammal-like reptiles, the dinosaurs and pterosaurs and finally the modern groups is partly determined by extinction events: the end-Triassic event marked the transition between the first two groups and the end-Cretaceous event witnessed the demise of the dinosaurs and the rise of the mammals. The floral history of the planet was most affected by the end-Permian event (subsequent rise of the gymnosperms) and the end-Cretaceous event (subsequent dominance of the angiosperms).

Biological feedbacks

The relationship between climate and life suggests the existence of a feedback between the two over time. Today and during the recent past much discussion has been focused on the anthropogenic influences on our climate as we move again into a greenhouse phase. The industrial revolution set the agenda for the sustained use of fossil fuels and the persistent generation of greenhouse gases. Climatic warming will have a greater impact on the biotas of the cold-temperate and polar regions, with a pole-ward shift in climate on the order of 100 km per century (Wilson, 1992). Nevertheless, a number of models for long-term climatic change have also involved the role of feedbacks from biological organisms (Figure E20). Most marked

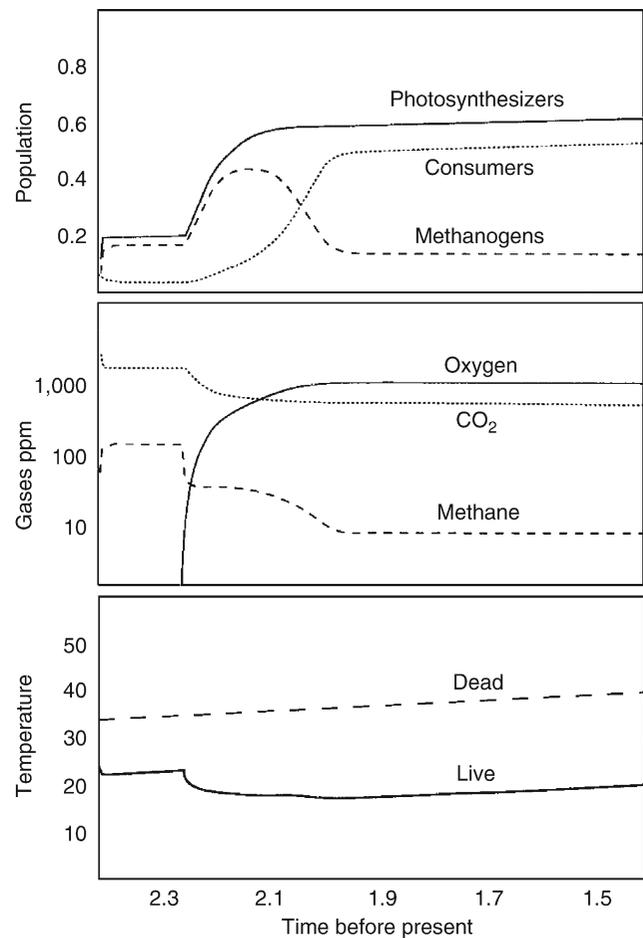

Figure E20 Populations of photosynthesizers, consumers and methanogens (top), the relative ppm of atmospheric gases (middle) and the influence of life on planet Earth during mid Precambrian (replotted from Lovelock, 1998).

are changes during the Precambrian, predicted by the Gaia hypothesis (Lovelock, 2000). The diversification of photosynthesizers, together with consumers from the early Proterozoic onwards, hiked oxygen levels concomitant with declines in greenhouse gases. Such models promote the vital effects of life as a stabilizing influence on the planet's climate, reducing the otherwise steady rise in the Earth's surface temperatures. In the same way, the extensive coal swamps and forests of the later Paleozoic may also have contributed to an interval of cooler climate, as diversifying land plants mediated atmospheric oxygen levels, anticipating the importance of modern rainforests as a climatic buffer.

F

FAINT YOUNG SUN PARADOX

Standard models of solar evolution indicate that the intensity of solar radiation should have increased by about 25–30% over the 4.6 billion year duration of geologic time (Gilliland, 1989). The phrase “faint young Sun” was coined by Sagan and Mullen (1972) to describe the implications of these standard models for Earth’s climate, because early in the Sun’s lifetime, the radiation reaching a planet like Earth today (with both similar orbit and amount of greenhouse forcing) would not have been sufficient to prevent the planet’s average temperature from dropping below the freezing point of water. Sagan and Mullen evaluated the implications of the faint young Sun paradox in the context of geologic evidence from early in Earth’s history that rules out a long-lived frozen state. They argued that a greater amount of greenhouse gas forcing was required to offset the lower solar luminosity of the young Sun. The faint young Sun hypothesis is still being evaluated today and many hypotheses reconcile the reduced solar luminosity with geologic evidence, using refinements of the greenhouse gas arguments of Sagan and Mullen (1972), but some other hypotheses raise the possibility of variations of Earth’s orbital properties and even call into question the standard models of solar evolution.

A significant part of the Sun’s evolution is thought to occur along the main sequence, a field defined by observations of many stars and represented on a Hertzsprung-Russell diagram of luminosity versus temperature. Like other stars, the Sun derives its energy from nuclear fusion in its core and radiates most of this energy from its surface, the solar disc, as continuous blackbody radiation with a maximum in the visible region and tails that extend to the infrared and microwave and also into the ultraviolet and X-ray regions of the spectrum. The amount and spectral characteristics of this blackbody radiation can be described by one principal equation, the Planck function, and two derivative laws, the Stephan Boltzman Law and Wien’s Law. The Planck function describes the spectral characteristics of blackbody radiation (B_λ), and takes the form:

$$B_\lambda = \frac{2hc^2}{\lambda^5 \pi (e^{hc/\lambda kT} - 1)}$$

where c is the speed of light, λ is the wavelength, k is Boltzman constant, T is temperature, and h is Planck’s constant. The Stephan Boltzman Law describes the total energy emitted by a blackbody and is given by:

$$E = 4\pi R^2 \sigma T^4$$

where σ is the Stephan-Boltzman constant ($5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$) and $4\pi R^2$ is the surface area. At its present size and average surface temperature of 5,785 K, the Sun emits a total blackbody energy of approximately $3.8 \times 10^{26} \text{ W}$. The standard solar model indicates that the size of the Sun has increased with time, resulting in an increase in solar radiation (brightening of the Sun) over the course of its 4.6 billion year existence (Gilliland, 1989).

Wien’s Law describes the wavelength of the maximum of Planck’s function as

$$\lambda_{\text{max}} \approx \frac{2898 \mu\text{m K}}{T}$$

where λ is given in μm . Wien’s Law places the peak of radiation in the visible region and this is essential for the Earth’s greenhouse effect.

The underlying principle of the greenhouse effect requires a planetary energy balance (e.g., $E_{\text{incident}} = E_{\text{radiated to space}}$), and an atmosphere that transmits incoming radiation, but absorbs energy radiated from the planet’s surface. Greenhouse gases in the Earth’s atmosphere are transparent to visible radiation, transmitting a high dose of incident solar radiation through the atmosphere to warm the Earth’s surface, but these same gases absorb and reradiate the infrared radiation emitted from the surface. The energy recycled (absorbed and reradiated) by greenhouse gases in the atmosphere contributes a finite amount of surface warming beyond that provided by incoming solar radiation. In today’s atmosphere, the greenhouse effect contributes approximately 33 K of warming, raising the average surface temperature to 298 K.

The warming provided by the present-day greenhouse effect is essential for keeping the average surface temperature of Earth above the freezing point of water, but as recognized by Sagan and Mullen (1972), this amount of warming would not have been sufficient to have kept the surface temperatures above freezing if solar radiation had been lower by more than ~10%. Furthermore, the standard solar model points to as much as 25–30% lower solar luminosity 4.6 billion years ago than today. Moreover, for the vast majority of geologic time, this standard solar model predicts that incident solar radiation would have been less than 90% of present-day values. It was also recognized that if the mean surface temperature of Earth fell below the freezing point of water, the oceans would have frozen, leading to a negative feedback involving planetary albedo and planetary ice. The amount of radiation available to warm the climate would thus have decreased as ice cover expanded, because more radiation would have been reflected back to space rather than absorbed by the surface and transformed into heat.

Geologic evidence, however, does not point to a long-lived frozen state for early Earth. Rather, the presence of sedimentary rocks suggests the existence of liquid water throughout much of geologic history (Cloud, 1972). In addition, chemical and isotopic characteristics of 4.3–4.4 billion year old zircon grains from the Jack Hills of Australia point to the presence of liquid water within a few million years of the formation of Earth (Mojzsis et al., 2001; Wilde et al., 2001). Sagan and Mullen (1972) argued that the faint young Sun paradox could be reconciled with the geological observations if the Earth's early greenhouse effect provided enough additional warming of the planet (beyond that of the present greenhouse effect) to offset the lower luminosity of a faint young Sun.

Central to the hypothesis of a more efficient greenhouse is the identification of the gas that is responsible for the enhanced greenhouse forcing. Three gases (NH₃, CO₂, and CH₄) have been suggested as the principal cause of the enhanced greenhouse effect during the early parts of Earth's history. Sagan and Mullen (1972) and Sagan and Chyba (1997) argued that NH₃ was the gas responsible for the enhanced greenhouse. Debate about the suitability of NH₃ as an early Earth greenhouse gas has focused on its lifetime in the atmosphere. While Owen et al. (1979) argued that high UV fluxes in a low O₂/O₃ atmosphere would destabilize NH₃, making CO₂ or even CH₄ which are stable in high-UV environments more likely candidates, Sagan and Chyba (1997) argued that a high altitude organic haze, similar to that observed on Saturn's moon Titan, could provide a sufficient UV shield to stabilize NH₃. Most workers agree that CO₂ played a significant role as a greenhouse gas throughout Earth's history, and the debate revolves around its sources and sinks and whether it was the principal greenhouse gas, or whether a second or third greenhouse gas would have been required to sustain the greenhouse forcing necessary to offset the effects of a faint young Sun (Walker et al., 1981; Kasting, 1993; Kasting and Catling, 2003). Using arguments structured around mineral equilibrium and stability of siderite (an iron carbonate) and greenalite (an iron-bearing phyllosilicate mineral) in the 2.7 billion year old Mount Roe paleosol, Rye et al. (1995) placed limits on the amount of carbon dioxide in the atmosphere that would have been too low to have kept Earth's surface above freezing, and called instead for a second greenhouse gas in the early atmosphere, such as CH₄. Pavlov et al. (2000) used an energy balance model to demonstrate that a combination of CO₂ and CH₄ would have sufficed

to offset the effects of the faint young Sun. It is also thought that such a greenhouse gas mixture might carry other consequences for the Earth's early atmosphere and this has been demonstrated for methane by Catling et al. (2001) who explored its sources and its implications for the oxidation state of the early Earth's atmosphere.

Other hypotheses have been proposed to reconcile the geological evidence with the faint young Sun paradox. These include the hypothesis that the standard solar model and its implications about main sequence evolution are not relevant for the Sun. This alternate hypothesis centers around a more massive and more luminous young Sun than that predicted by the standard model and argues that a more massive (larger) Sun would radiate more rather than less energy (Graedel et al., 1991). A second hypothesis calls on changes in Earth's obliquity (tilt of the rotational axis), which if it remained at high values throughout much of Earth's history could have sustained liquid water by keeping parts of the Earth facing the Sun over longer periods of time, which would have led to hotter summers (Jenkins, 2000). This hypothesis is similar to that envisioned by Milankovich for the orbital forcing of glacial and interglacial cycles. These two hypotheses remain to be tested, leaving the most widely held hypothesis – that of enhanced greenhouse gas forcing early in Earth's history – as the preferred one. Among the fundamental issues in identifying the implications of greenhouse gas forcing and climate through deep time is the characterization of the sources, sinks, and stability (feedbacks) of greenhouse gases in models of early Earth atmospheres, such that climate was stabilized over the first 3 billion years of geologic history.

FLOOD BASALTS: CLIMATIC IMPLICATIONS

Introduction

Flood basalts represent large-volume, predominantly effusive, eruptions of magma onto the Earth's surface. The volume of the largest flows exceeds 1,000 km³, some two orders of magnitude greater than the historic basalt flows found on Iceland and Hawaii. Magma contains dissolved volatiles that exsolve as the magma depressurizes and may be released into the atmosphere during and after the eruption. It is these aerosols, a cocktail including dust, H₂O, CO₂, SO₂, HF, and HCl, that have been implicated in climatic change. This has led some authors to propose causative links between flood basalt volcanism, climate change, and mass extinctions (McLean, 1985; Courtillot, 1999; Wignall, 2001). They suggest that dust and volatiles injected into the atmosphere lead to successive, short-term changes in atmospheric composition and temperature, leading ultimately to collapse of global ecosystems. The causative links between large-scale flood basalt volcanism and mass extinctions are, however, poorly defined.

Flood basalts may be erupted onto the Earth's continental crust, in which case they are called *continental flood basalts* (CFB). Most continental flood basalts are erupted subaerially, and any gases that are released enter directly into the atmosphere. Alternatively, flood basalts may erupt in the ocean basins (where they build large *oceanic plateaus*). In this environment, the eruption may be submarine, in which case the volatiles initially dissolve in the ocean. Both continental flood basalt provinces and ocean plateaus comprise the so-called *large igneous provinces* (LIPs) (Coffin and Eldholm, 1994). Most large igneous provinces – and hence flood basalts – originate from mantle plumes, regions of hot mantle ascending from the deep Earth interior.

Volcanism and climate forcing

It is widely recognized that explosive volcanic eruptions can perturb the Earth's climate. The eruption of Pinatubo in 1991 resulted in a small but significant cooling at the Earth's surface, and the much larger eruption of Tambora in 1815 caused even greater cooling (Oppenheimer, 2002). Climate-forcing agents include gases and aerosols, and volcanic eruptions (especially basaltic ones) often produce considerable masses of CO₂ and SO₂. The residence times of sulfate and dust aerosols in the lower atmosphere (troposphere) are short, usually of the order of a few days or weeks. The greatest effects on climate are caused by injection above the tropopause and into the stratosphere,

where the residence times are greater (on the order of 2 years, the turn-over time of the stratosphere). Injection of material above the tropopause adds to the Junge Layer (or Stratospheric Aerosol Layer), a sulfate-bearing layer in the lower stratosphere. This in turn leads to heating (through absorption of incident radiation) of the stratosphere, and concomitant cooling of parts of the troposphere. For example, the radiative forcing 1 year after the Pinatubo eruption (when ~20 Mt of SO₂ was injected in to the stratosphere), was about -4 W m^{-2} (IPCC, 2001).

Lakagigar, Iceland, 1783

While explosive volcanic eruptions are usually considered as transitory events for the purposes of climate modeling, effusive flood basalt events are different, because the source may be active for several months, years or even decades. The Lakagigar (“Laki”) eruption in SE Iceland in 1783 is the best documented and most recent basalt eruption, and offers an analog of much larger eruptions in the geological past. Approximately 15 km³ of basalt was erupted over a period of about 8 months (the bulk being erupted in a series of short explosive pulses during the first few months), causing local environmental devastation (most notably the Haze Famine), and cooling of the Northern Hemisphere climate (Thordarson and Self, 2004). Three aspects of the Laki eruption are important here: firstly, compared with explosive eruptions such as Pinatubo and Tambora, the eruption was prolonged, facilitating aerosol formation over several months. Secondly, some episodes of the eruption were sufficiently vigorous to enable injection of material into the lower stratosphere, thus producing hemispheric, as well as local, effects. And thirdly, the aerosols were sulfur-rich, a characteristic of iron-rich basaltic magmas.

Most basaltic eruptions are effusive in nature, producing lava fountains and flows. They contrast with eruption of more silicic magmas, which tend to be explosively ejected, forming tall eruption columns and widely dispersed pyroclastic fallout. The Laki eruption was, however, moderately violent during its early, peak stages, with Strombolian or even sub-Plinian episodes, and eruption columns that may have reached altitudes in excess of 13 km (Thordarson and Self, 2004). Most of the time, however, venting was effusive. Volatile dispersal was therefore both local, with low-level emissions from the vent and lava flow, and more widespread, with injection into the tropopause and lowermost stratosphere.

The volatile budget of the Laki eruption has been extensively investigated (Thordarson et al., 1996). Pre-eruption concentrations of volatile species were determined from glass inclusions and these were used to estimate the total volatile release from the erupted magma. During the eruption period, ~122 Mt of SO₂ (approximately the current global annual anthropogenic output) was released into the atmosphere, together with a mixture of F (7 Mt), Cl (~15 Mt) and H₂O (~235 Mt) (Thordarson et al., 1996). Most of these volatiles were released during the first three months of the eruption. It is estimated that approximately 80% of the SO₂ mass (~100 Mt) was injected into the lower stratosphere, the bulk of which was probably rapidly converted to sulfuric acid aerosols (equivalent to ~190 Mt) (Thordarson and Self, 2004). The remainder (~20 Mt SO₂, equivalent to ~40 Mt of H₂SO₄), was emitted from the cooling lava flow and formed a local, low-altitude, toxic haze.

The injection of sulfuric acid into the lower stratosphere and polar jet stream is thought to have been responsible for the atmospheric haze observed over large parts of Europe

throughout 1783. This haze is estimated to have extended to an altitude of at least 16 km, resulting in substantial dimming of the Sun.

during several of the summer months of the year 1783, when the effect of the Sun's rays to heat the Earth in these northern regions should have been greatest, there existed a constant fog over all Europe

this fog was of a permanent nature; it was dry, and the rays of the sun seemed to have little effect towards dissipating it. (Benjamin Franklin, 1784)

The eruption and the accompanying haze have been implicated in the subsequent high temperatures recorded in July, 1783, and the successive Northern Hemisphere cold winters of 1783/1784 to 1785/1786 (for a more complete description, see Grattan, 2005). It is likely that the high July temperatures resulted from the development of anticyclones over central or northern Europe, allowing warm air to flow from southern Europe (Thordarson and Self, 2004). Whether or not these changes in large-scale weather systems were influenced by the Laki eruption is not known. The winters of 1783/1784 to 1785/1786 were unusually cold, with an average temperature drop of 1.5 C over Europe and North America (Thordarson and Self, 2004). This temperature drop is consistent with the radiative forcing predicted by the injection of SO₂ into the stratospheric aerosol layer.

A full understanding of the Laki flood basalt eruption is important for two reasons. Firstly, such eruptions are not uncommon. On Iceland, for example, there have been four such eruptions in the last 1,200 years, Laki merely being the latest. Similar (but often larger) lava flows have built the Icelandic crust, dating back more than 12 million years, and similar eruptions may occur in other basaltic provinces associated with mantle plumes (e.g., Afar, Ethiopia; Hawaii). Secondly, the eruption provides important information about much larger events that have occurred in the geological past, and which have been implicated in mass extinction events.

Columbia river flood basalt province

The Miocene flood basalts of the Columbia River Province in northwest USA are among the best studied on Earth. The total volume of the province is of the order of 175,000 km³, and many of the individual flows have eruptive volumes in excess of 1,000 km³. Most the province was erupted between about 16.5 and 14.5 Ma. It is estimated that the eruption of the Roza flow (ca. 1,300 km³ of basalt; ~14.7 Ma) produced a phenomenal mass of aerosols: approximately 12,000 Mt of SO₂ (equivalent to 23,000 Mt of H₂SO₄), 680 Mt of Cl and 1690 Mt of F (Thordarson and Self, 1996). The effect of this aerosol loading on the global climate is likely to have been substantial, but with our current understanding of the duration and eruption intensity of large flood basalts, it is difficult to quantify. Estimates of the duration of large flood basalt eruptions vary from a few weeks (Shaw and Swanson, 1970) to a few years (Self et al., 1996). Given the eruption profile of Laki, where 80% of the magma was released during the first 3 months of the eruption, it is possible that the bulk of the Roza magma was also extruded within a relatively short time (months?), even if the eruption subsequently continued to be active for several years. If this is the case, then a substantial proportion of the SO₂ could have been injected into the stratosphere atop vigorous fire fountains and Plinian-style eruption columns (Stothers et al., 1986). Repeated SO₂ and dust injection, over a period of

several years, may also have occurred. Substantial cooling of at least the Northern Hemisphere troposphere would have ensued, but given that the response of the global climate to such (cumulative) mass loading is likely to be strongly non-linear, the precise outcome is difficult to predict. Immediate and dramatic cooling (for at least the duration of the eruption) would have been likely; transient "volcanic winters" could have ensued, and acid rain would have caused local environmental devastation.

Even more difficult to predict is the global response to successive flood basalt eruptions. The Columbia River Province comprises some 300 flow units, mostly erupted over a period of about 2 Ma. This gives an average interval between each flood basalt eruption of 7,000 years. The repose time between individual eruptions is clearly sufficient for the climate to recover, at least from the cooling effects of sulfate injection, although Thordarson and Self (1996) have suggested that the eruption of the Columbia River flood basalts was a contributory factor in the Miocene global cooling event that began at about 15–14.5 Ma.

Not only did the flows release large quantities of SO₂, however, but they also vented prodigious masses of CO₂, which, being a greenhouse gas, could have caused global warming. Are these masses significant? Estimates of the CO₂ content of basaltic magma vary dramatically, because the gas has a low solubility in the melt at near-surface conditions, and is rapidly exsolved. However, based on pre-eruptive values of 7,000 ppm CO₂ in basalts from ocean island volcanoes (Bureau et al., 1999), and assuming that 99% of the CO₂ is lost to air, then 1 m³ of basalt will release a little over 18 kg of CO₂. Using these figures, the total amount of CO₂ released from the Laki eruption was of the order of 270 Mt (or 73 Mt carbon), and from the Roza flow, a little over 23,000 Mt (6,300 Mt C). As the residence time of CO₂ in the atmosphere is much greater than that of SO₂, knowledge of the eruption profile is less important than it is for SO₂.

The current anthropogenic output is approximately 7,000 Mt C yr⁻¹. The mass erupted from Laki was insignificant, on a global scale. The flux from the Roza flow was likely to have been enhanced by burning vegetation, etc., but even assuming that the bulk of the CO₂ was degassed in the early stages of the eruption, the flux rates were not substantially greater than today's anthropogenic output. Note that total C release from the whole of the eruptive portion of the Columbia River basalt province was on the order of 800,000 Mt, a seemingly vast amount, but given that the eruption occurred over a period about 2 million years, the average flux was only 0.4 Mt C yr⁻¹, a fraction of the current anthropogenic output.

Flood basalts and mass extinctions

The "big three" mass extinctions of the last 300 Ma all coincide (within the precision of current dating techniques) with major flood basalt events. These are the Siberian Traps with the end-Permian extinction at 250 Ma; the Central Atlantic Magmatic Province with the end-Triassic extinction (200 Ma); and the Deccan Traps with the end-Cretaceous (K-T) extinction (65 Ma; Figure F1). The likelihood of these associations being pure chance is remote: about 1 in 2,000 (White and Saunders, 2005), and several other volcanic provinces – either continental or oceanic – are contemporaneous with other mass extinction events and other evidence of significant changes in ocean chemistry (for example, formation of black shales during periods of oceanic anoxia at 90 Ma; Kerr, 1998). Both the Siberian and

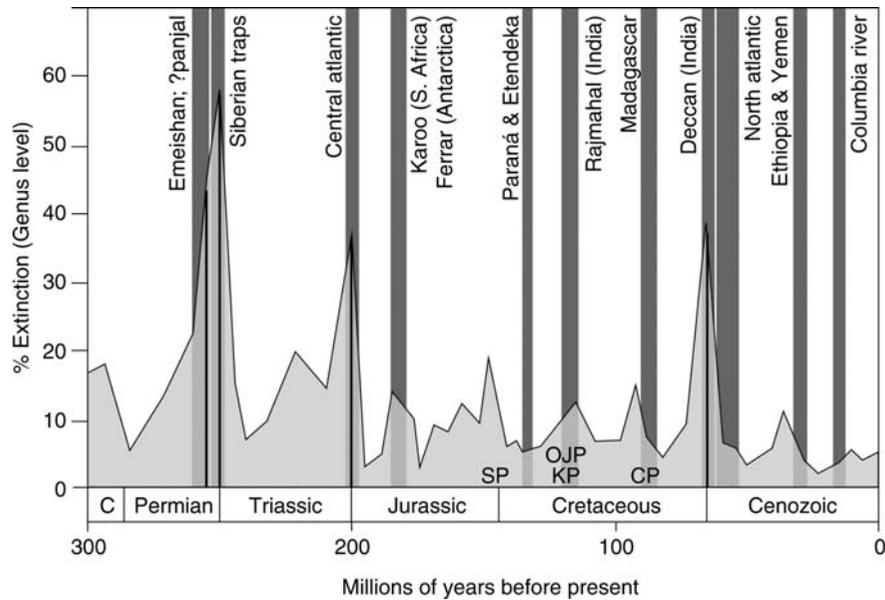

Figure F1 Extinction rate versus time (multiple-interval marine genera: modified from Sepkoski, 1996) compared with eruption ages of continental flood basalt provinces. Three of the most severe extinctions, the P-Tr, the Tr-J, and the K-T, correspond with eruption of the Siberian Traps, Central Atlantic Magmatic Province, and Deccan Traps, respectively. Oceanic plateaus may also have had profound environmental consequences (Kerr, 1998) (S: Sorachi Plateau, Japan; K: Kerguelen Plateau; OJ: Ontong Java Plateau; C: Caribbean-Colombian) (modified from White (2002) and White and Saunders (2005)).

Deccan Traps are substantially larger than the Columbia River Province, with eruptive volumes of the order of 3.5 million km³ (Reichow et al., 2002) in the case of the former, and around 0.75 million km³ in the case of the Deccan Traps. The total eruption duration may have been as short as 0.5 Ma, but is likely to have been longer than this; there is considerable uncertainty about the duration of volcanic activity in both provinces. Assuming this “worst case” scenario (0.5 Ma), and using the same volatile concentrations as in the Roza flow, produces average fluxes of 20 and 34 Mt C yr⁻¹ for the Deccan and Siberian Traps, respectively, and 38 and 66 Mt SO₂ yr⁻¹ for the two provinces. At face value it is difficult to see how these fluxes could lead directly to global ecosystem collapse; they are too low. Magmatic fluxes are far from regular, however, and successive flows may occur sufficiently frequently that SO₂ could accumulate in the atmosphere over several years or decades. This would lead to substantial climate forcing and, initially, tropospheric cooling. Meanwhile, simultaneous release of CO₂ could, on a longer time-scale, lead to an *increase* in global temperatures. This in turn could trigger the catastrophic release of carbon from terrestrial and marine methane hydrates, as indicated by the isotopically light carbon signature found in several horizons associated with mass extinction and flood basalt events (Wignall, 2001).

Conclusions

From the historical observations of the 1783 Laki event, it is evident that even a relatively small basalt eruption is capable of causing climate change on a hemispheric scale. This is in addition to the local devastation caused by acid rain and release of a range of toxic gases. The height of the convection column associated with basaltic eruptions is less than with major explosive events, but injection of gas and dust into the stratosphere is likely given the high magmatic flux rates. Unlike explosive

eruptions, flood basalts can erupt for several months if not years, leading to prolonged discharge of volatiles. The largest documented flood basalts indicate release of prodigious volumes of gas, especially SO₂, into the atmosphere, leading to the likelihood of substantial, short-term cooling of the lower atmosphere. Simultaneous release of carbon dioxide may cause longer-term global warming if the excess volcanic CO₂ cannot be removed (e.g., by biological activity) sufficiently quickly, and if flood basalt eruptions occur in rapid succession. This may trigger release of methane hydrates and initiate collapse of global ecosystems. Detailed modeling of the effects of flood basalt eruptions on global climate is required to ascertain the full significance of volcanic forcing.

FORAMINIFERA

Foraminifera are single-celled eukaryotic organisms that live in both the marine and fresh water environment. They range in size from 100 μm –15 cm in length. Foraminifera (often referred to as forams) are classified primarily by the composition and morphology of their tests (shells). Tests can be made of organic compounds, sand grains, and other particles cemented together (agglutinated), or secreted calcium carbonate (CaCO_3). Many groups are commonly made of a number of chambers, added during growth (Figure F2). The arrangement of these chambers and the position and shape of apertures are important for taxonomic classification.

Foraminifera exhibit both benthic (live on (*epifaunal*) or in (*infaunal*) the substrate) and planktonic (passive floating)

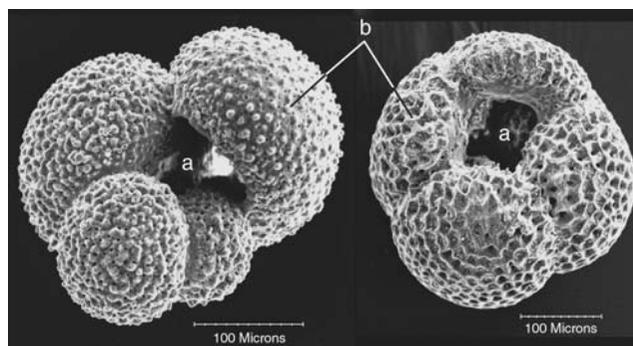

Figure F2 SEM image of the planktonic foraminifera *Globigerina bulloides* d'Orbigny (left) and *Dentoglobigerina altispira* Cushman and Jarvis (right) showing apertures (a) and chambers (b).

lifestyles. There are approximately 40 species of planktonic foraminifera in the ocean today. This comprises about 1% of the extant species of foraminifera. In the open marine environment, benthic foraminifera are usually much more diverse yet occur in lower abundances than planktonic foraminifera.

The geologic history of fossil foraminifera begins in the earliest Cambrian. Foraminifera probably existed as cells without fossilizable coverings long before that. In the Jurassic, foraminifera adapted to a planktonic mode of life.

Foraminifera were probably first recorded by the Greek historian Herodotus in the fifth century BC in his observations of large disc-shaped fossils (now known as the benthic foraminifer *Nummulites gizehensis*) found in the building stones of the Egyptian pyramids (Haynes, 1981). Prior to the advent of the microscope, seventeenth century naturalists observed foraminifera with hand lenses and often classified them as gastropods or cephalopods because many possess a coiled chamber arrangement. As microscopy advanced, more detail in the structure of foraminiferal tests was observed and they were recognized as single-celled organisms.

Foraminiferal studies advanced with the advent of the *Challenger* expedition of 1872–1876. Brady (1884) illustrated a number of foraminifera from this first oceanographic cruise and our understanding of foraminiferal biogeography began to take shape. During the early to mid twentieth century, the petroleum industry's need for age control and environmental interpretation led to great advances in micropaleontology, more in general, and much more data on foraminifera. The next major advance was the development of scanning electron microscopy, which enabled detailed analysis of test wall ultrastructure for the first time. The Deep Sea Drilling Project and its successor, the Ocean Drilling Program, have provided a wealth of quantitative data on both temporal and geographic distribution of benthic and planktonic foraminifera.

Applications in paleoclimatology

Foraminifera have been widely used in several areas of paleoclimatology. Calcium carbonate tests are thought to be secreted in equilibrium with sea water at the time of formation. For this reason, foraminifera have been the most widely used organisms for shell chemistry (Mg:Ca) and stable isotope geochemistry ($\delta^{18}\text{O}$, $\delta^{13}\text{C}$). Their small size, abundance, and distribution make them ideal environmental indicators. With the knowledge

that different species of planktonic foraminifers live at different depths and reach maximum abundance at different times of the year, geochemical analyses of foram tests can provide a wealth of information on the composition and structure of the water column. With benthic foraminifers providing information on bottom waters, elaborate paleoenvironmental and paleoclimatic information can be obtained from samples containing foraminifers.

Quantitative analysis of assemblages of planktonic foraminifers has been widely used to reconstruct past sea-surface temperatures using a transfer function or nearest analog approach. Transfer functions range from simple (Ericson and Wollin, 1956) to complex factor analytic approaches pioneered by Imbrie and Kipp (1971). This later technique formed the basis of the CLIMAP Last Glacial Maximum reconstruction (CLIMAP, 1981) and has been modified and used to reconstruct paleoclimate conditions during other time periods back to the mid-Pliocene warm period (Dowsett et al., 1999). With the recognition that planktonic foraminiferal distribution on the sea floor closely matches overlying oceanic conditions, total faunal analysis has become a mainstay of paleoenvironmental and paleoclimatic reconstruction.

The temporal framework upon which paleoclimate reconstructions are based is of fundamental importance. The same characteristics that make planktonic foraminifers so useful for geochemical analysis—high abundance, small size, facies independence, ease of identification and high preservation potential—make foraminifers ideal for biochronological (including biostratigraphy and correlation of marine sediments) analyses. For any pre-Pleistocene study, foraminiferal biochronology is usually still one of the leading tools in terms of accuracy and utility. Planktonic foraminifer zonations have been developed by a number of workers and individual biotic events (first and last appearances in a temporal sense) have been dated by calibration to magnetostratigraphy (Berggren et al., 1985, 1995; Dowsett, 1989).

In summary, foraminifers are the original multi-tool for paleoclimatology. The quantitative distribution of foraminifers in both temporal and spatial dimensions provides information on age of sample and any number of aspects of the paleoceanographic environment. When combined with geochemical and isotopic

analysis of foraminifer tests, no other fossil group has provided so much to the field of paleoclimatology.

G

GEOCHEMICAL PROXIES (NON-ISOTOPIC)

Introduction

The utility of geochemical proxies requires chemical analysis of geological samples. Since there is no means of directly measuring past climates and environments, proxy indicators are employed as indirect measures of the main processes. Information for environmental reconstruction comes from both organic and inorganic sources, even though organic matter (OM) typically constitutes a minor fraction of sediments. These proxies may reveal details about paleotemperature, phytoplankton community structure, vegetation history, dust provenance, nutrient cycles and availability, ocean circulation and paleoredox conditions (Figure G1).

Technical terms and concepts

Since sedimentary organic matter is the residue of past biota, its type and quantity reflects environmental conditions affecting past ecosystems. Analysis of organic matter involves identifying both its general source from bulk elemental compositions, stable isotopes and Rock-Eval pyrolysis data, and its detailed origins from analyses of biomarker molecular compositions (see below). Changes in organic *composition* can be interpreted as proxies for varying sea-level, ocean currents, temperature and continental climates, while changes in *abundance* may signify variable paleoproduction or preservation conditions.

Inorganic proxies are typically measured from constituents of the hard parts of previously living biota such as calcitic plankton and coral. The rate of incorporation of metal ions as compared with the principal component calcium varies according to environmental conditions. Therefore, proxies for past temperature and nutrients are derived from metal ratios such as Mg/Ca, Sr/Ca and Cd/Ca. Complementary information from multiple proxies can be obtained during a single suite of analyses for major and minor metal abundances.

The longevity of a particular record has a profound effect upon its constituent components. Geochemically, these components can be classified as either *labile* (readily undergoing

change or breakdown), or *refractory* (resistant to change, especially to heat). As a deposit ages, more refractory components become relatively enriched, while labile components are scarcely preserved. *Diagenesis* causes both the concentration and composition of sedimentary organic matter to diverge from the original biologically synthesized material. The lability of geochemical components renders them more susceptible to diagenesis. Ultimately, the geochemical composition of a paleoenvironmental record may look a lot different from the time of its creation or original deposition. Comparison of multiple geochemical proxies helps to compensate for the effects of diagenetic alteration and improves their interpretation for a more complete paleoenvironmental reconstruction.

Significance of geochemical proxies

The faithful reconstruction of paleoclimates and paleoenvironments requires the availability of reliable records. For placement in a temporal framework, the age of a particular record must be known, or assumptions regarding its continuity must be made. While “geochemical fossils” exist and are readily exploited for their paleoenvironmental data, fossil records are typically incomplete. Furthermore, the preservation of these records is rarely uniform. For this reason, continental (terrestrial) records of paleoenvironmental change (e.g., coal, evaporites, loess) have generally been regarded as discontinuous or a palimpsest, written and rewritten throughout the history of geologic time. Sedimentary records from lakes and other terrestrial depositional environments are typically Holocene (post-glacial) in age, although some low-latitude lakes (e.g., Lake Tanganyika) and cave deposits (e.g., speleothems) have yielded longer records. Conversely, vast sediment deposits underlying the world’s oceans may have been accumulating quasi-periodically for millions of years. For this reason, the majority of geochemical proxies are derived from aquatic-environment sediments, though many techniques may be universally applicable. Deep-sea sedimentation rates are typically a few centimeters per 1,000 years and with few exceptions reveal only decadal to millennial-scale changes in paleoclimate. Conversely, lacustrine records may offer short and regional records of paleoenvironmental change at a seasonal or annual scale.

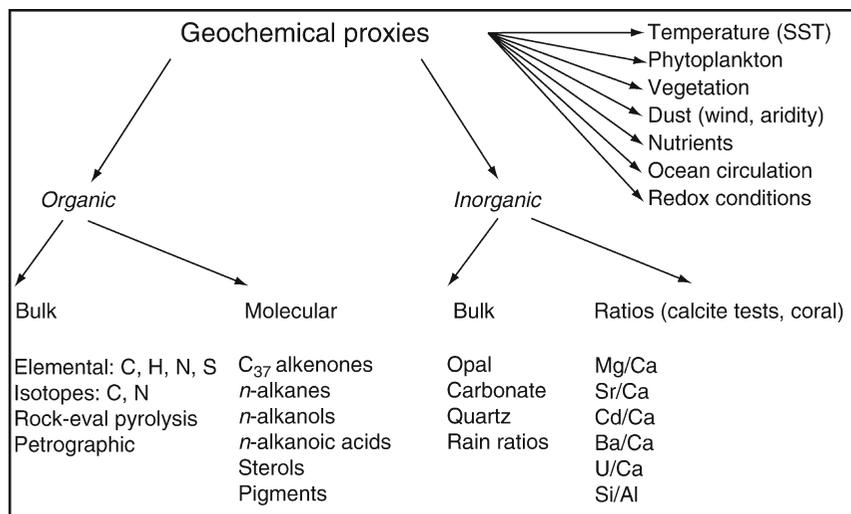

Figure G1 Summary of principal geochemical proxies and derived information used for environmental reconstruction.

Bulk organic geochemistry

Organic molecules are created in the biosphere by biological processes. The geosphere (lithosphere, hydrosphere and atmosphere) provides the substrate for these biological processes and is the ultimate sink for residual organic molecules. Organic geochemistry reveals the origin and fate of organic molecules and their utility as geochemical and paleoenvironmental proxies as they are preserved in the geosphere. Since both production and preservation of organic matter are affected by environmental change, bulk sedimentary organic matter and a large number of biomarker compounds, together with patterns of compound classes and their isotopic compositions, have enabled organic geochemists to deduce much about the environmental conditions that impacted ecosystems at different times and places in the geological past.

The primary source of organic matter in aquatic systems is planktonic photosynthetic production. Large variations in the rate of production are effected by nutrient availability in surface waters. Availability is controlled by nutrient (nitrate, phosphate) transport from land to lakes and oceans, and the efficiency of nutrient recycling within these systems. Animals and microbes may use such primary organic matter as a source of carbon and nutrients for significant secondary production of reworked, degraded organic matter with its own distinctive geochemical signature. Detritus from land plants and a small amount of organic matter from animals may make additional contributions to sedimentary organic content. Therefore, determinations of the relative importance of algal productivity, land-plant productivity and transport processes are a critical part of paleoenvironmental reconstruction.

The information obtained from organic geochemical proxies is diverse. Mass accumulation rates of organic carbon reveal the biological paleoproductivity and the environmental conditions that influenced the preservation of this organic matter. The composition of organic matter can be informative about aquatic and continental vegetation, which in turn depends on climatic factors such as temperature, moisture availability and wind strength. Quantities and isotopic contents of sedimentary organic matter (carbon, nitrogen) provide detailed histories of elemental cycling at both local and global scales. Environmental

(e.g., sea surface) temperatures can be deduced from the sedimentary molecular residues of organisms that lived at such times in the past. The typically small eolian (wind-derived) fraction of an organic mixture may contain distinctive components that record atmospheric transport processes. Comparison of multiple indicators (the “multi-proxy” approach) typically leads to better, more confident interpretations.

Preservation of the organic signal

Of the proxy indicators that depend on fluxes, bulk organic carbon accumulation measurements are perhaps the most widely used and common. Organic matter is intrinsically unstable in oxidizing environments and degrades in the photic zone, during particulate sinking and subsequent sediment bioturbation. Many attempts to relate total sedimentary organic input to surface net export have been made since the ground-breaking work of Suess (1980) and Berger et al. (1987). It has been shown that after remineralization, rarely more than a few percent remains to form the organic geochemical sedimentary record. The fraction of carbon buried is primarily a function of water depth, deep water oxygenation and linear sedimentation rate (Müller and Suess, 1979). Away from potential allochthonous (e.g., downslope) sources and under oxygenated states, environmental conditions cause the organic matter flux (amount per unit time) surviving degradation to decrease with increasing water column (depth) due to microbial oxidation (Figure G2). Degradation rates are greatest for fresh organic matter, but decline with depth as the residual detritus contains progressively more resistant organic matter. If a significant proportion of the accumulating sediment constitutes lithogenic particles, then this additional flux (ballast) may improve preservation of the organic flux to the seafloor. An important bias in the source of sedimentary carbon can affect the record of low (export) productivity zones, such as the inner ocean, where lateral advection from the continental shelf is often significant.

Former rates of primary production can be estimated from the organic carbon content of marine sediments according to the productivity-depth relationship and knowledge of the mass accumulation rate. For example, Stein (1986) proposed

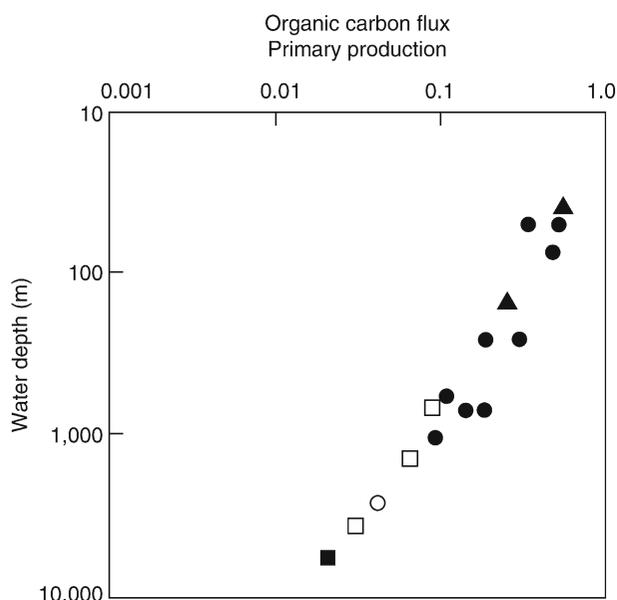

Figure G2 Concentrations of organic carbon on sinking particles collected by sediment traps at various depths in the ocean (figure compiled from Meyers, 1997; reprinted from *Organic Geochemistry*, 27, Meyers P.A., *Organic geochemical proxies of paleoceanographic, paleolimnologic, and paleoclimatic processes*, pp. 213–250, Copyright (1997), with permission from Elsevier).

Paleoproductivity, $\text{gC m}^{-2} \text{yr}^{-1}$

$$= 5.31 [C_{\text{org}}(\text{DBD})]^{0.71} \times \text{SR}^{0.07} \times \text{WD}^{0.45} \quad (1)$$

where C_{org} is weight percentage of marine organic carbon, DBD is dry bulk density in g cm^{-3} , SR is sedimentation rate in cm kyr^{-1} , and WD is water depth in meters at time of deposition.

The oxidation of organic matter and animal respiration removes dissolved oxygen in aquatic environments. Where this rate of removal exceeds the rate of replenishment (from the atmosphere), water column anoxia may develop. Under conditions of high primary production or strong water-column stratification, organic matter fluxes do not appear to decrease with depth (Karl and Knauer, 1991) and sedimentary preservation may be improved (Figure G3).

The rate of delivery of organic matter to the surface layer of sediments effectively determines the amount of benthic alteration in the bioturbated layer. Benthic oxidation will initially utilize interstitial oxygen, but as conditions become progressively more anoxic, nitrate, oxides of manganese, iron and eventually sulfate reduction will occur. These reduced species may be later interpreted as geochemical proxies of anoxia.

Physical sorting during transport and sinking of organic matter can create compositional artifacts since different components are commonly associated with different particle sizes. This complicates the interpretation of co-occurring sedimentary proxies, which may not share the same temporal or spatial origins. For example, C/N ratios of OM can be affected by hydrodynamic sorting: they are generally lower in fine-grained than in coarse-grained sediments, which typically contain more intact land-plant debris. Fine sediments may contain more clay with greater potential for ammonium adsorption. This highlights the problems

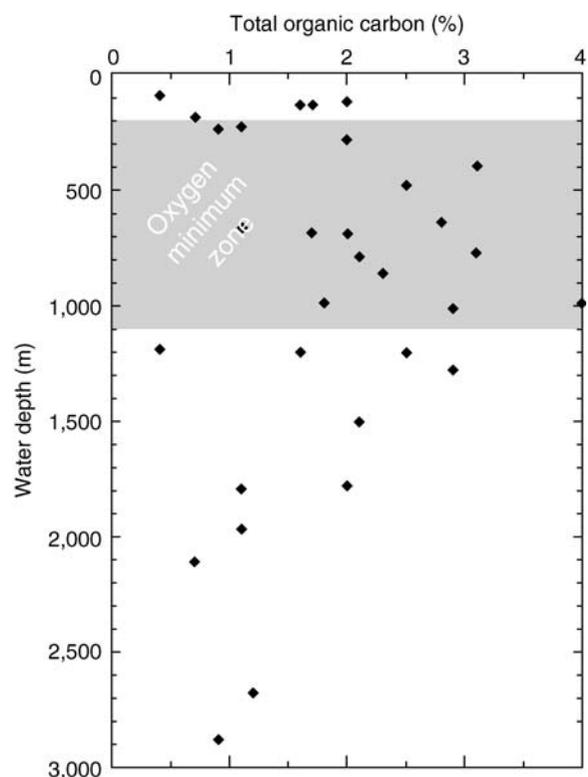

Figure G3 Distribution of total organic carbon in surface sediments of the Arabian Sea as a function of water depth. The shaded area denotes the approximate depth range of the present oxygen minimum zone (OMZ) (reprinted from *Organic Geochemistry*, 31, Schulte S., Mangelsdorf K., and J. Rullkötter, *Organic matter preservation on the Pakistan continental margin as revealed by biomarker geochemistry*, pp. 1005–1022, Copyright (2000), with permission from Elsevier).

of bulk analysis, especially where low organic content results in samples with a significant inorganic nitrogen fraction. Molecular-level analyses are not immune to such biasing of the source information they yield; organic molecules with radiocarbon ages several thousand years older than co-occurring calcitic plankton remains have been found in drift-deposit sediments from the Bermuda Rise (Ohkouchi et al., 2002). Furthermore, geo-lipids typically constitute a small fraction of the residual (sedimentary) organic matter, making insidious abundance variations more common. Although *biomarkers* are relatively resistant to microbial degradation, they may still be subject to diagenetic overprinting.

Analysis of bulk organic matter

Petrographic analysis of sedimentary records can reveal the origin of organic matter, its mode of transport and degree of degradation through microscopic study. Unstructured, amorphous organic flakes and intact debris of algae such as cell walls constitute *autochthonous* organic matter. *Allochthonous* material includes variably-preserved lignin and cellulose debris and soil-derived organic material. Spores, pollen and the residue of forest fires transported by wind form the *eolian* organic fraction. By determining the petrographic composition of sedimentary organic matter, it is possible to supplement information provided by other techniques concerning changes in origins of organic matter over time and sedimentary intervals where diagenesis may have altered or biased the bulk geochemical indicators.

Algal and terrestrial plant origins of sedimentary organic matter can be distinguished on the basis of its elemental C/N ratio. Reliable source information can be derived in moderately preserved organic matter since algae typically have atomic C/N ratios of 4–10, while vascular plants (that is, those composed in part of vascular tissue, including all flowering plants and the higher cryptogamous plants) have C/N ratios of ≥ 20 (Meyers, 1994). This difference relates to the proteinaceous nature of algal matter compared with the abundance of cellulose in (vascular) plants. Diagenesis has the potential to alter the C/N ratio, causing it to increase during preferential degradation of proteinaceous components of algal OM, but decrease during carbon remineralization due to preferential absorption of ammonium(-nitrogen) by clay minerals (Müller, 1977).

Rock-Eval pyrolysis

Quantification of hydrocarbons generated by progressive heating of sediment samples from 200 °C to 600 °C, related to the origin of OM, generates three distinct signals related to the quantity of hydrocarbons, which are gaseous (S_0), volatile (S_1) and released by thermal cracking of kerogen (S_2). Total organic carbon is the sum of the residual and pyrolyzed organic carbon (S_3) content. From these results are derived: (a) the Hydrogen Index (HI), the hydrocarbon potential of the total OM (mg HC/g C_{org}), a proxy for the H/C of OM; and (b) the Oxygen Index (OI), the amount of oxygen (mg CO_2 /g C_{org}), a proxy for the O/C ratio (Espitalié et al., 1977). Values are typically plotted against each other on a van Krevelen plot and grouped according to three main types of organic matter: (a) rich in HC content, derived from microbial biomass or waxy coatings of plants; (b) moderately rich in HC, originating from algae; (c) poor in hydrocarbons, rich in carbohydrates, typical of woody plant material (Figure G4). Values may be affected by organic matter oxidation, particularly after deposition. Oxidation causes a reduction in total organic carbon (TOC)

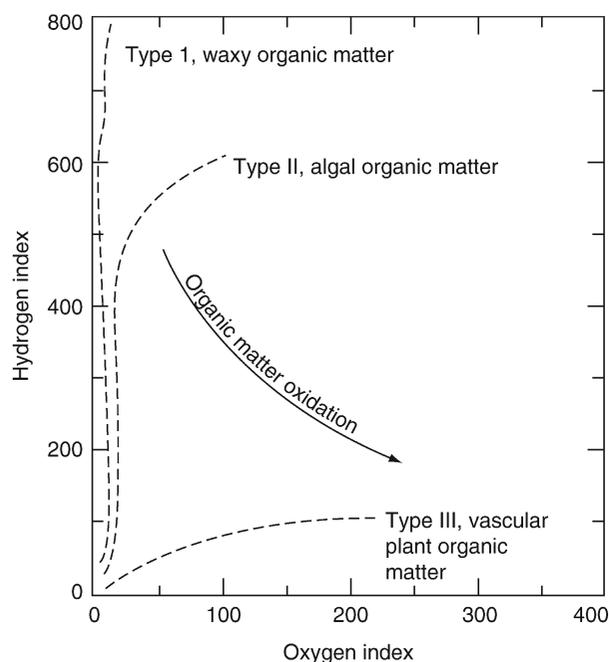

Figure G4 Rock-Eval van Krevelen plot for differentiating sources of sedimentary organic matter.

concentration, C/N ratio and HI values while oxygen content increases, thereby reducing HI/OI and causing Type I or II organic matter to resemble Type III.

Bulk inorganic geochemistry

Bulk geochemical proxies such as opal, carbonate and quartz dust have been traditionally employed to attempt to reconstruct paleoclimate. However, more recent advances in understanding the constraints on delivery and preservation of these sedimentary components limit the usefulness of the data obtained. An alternative technique that overcomes many of the problems of bulk organic matter analysis involves the application of rain ratios between the organic and inorganic components of the sediment record. Berger and Keir (1984) proposed that ratios of organic carbon:carbonate and organic carbon:opal may increase with export production. The ratio of detrital to biogenic content may also be employed to estimate paleoproductivity. The concentrations of certain inorganic proxies, such as aluminum and potassium, have been measured to represent the major part of the detrital sediment content. Found mostly in clays, their sediment depth profile is considered typical for the bulk detrital elements. Thus, the content of elements sensitive to productivity changes or inherently involved in biological and authigenic processes, such as cadmium, barium and silicon, can be successfully normalized with respect to the detrital signal. One limitation of this technique is that it is restricted to areas of predominantly clay deposition, and cannot thus be applied on the continental margins where silt is commonly the dominant matrix size fraction. Nevertheless, several such rain ratios are commonly used. For example, cadmium has been found to be depleted in the surface ocean relative to deeper waters (Boyle et al., 1976), indicating uptake by organisms at the surface and regeneration from deeper sinking biomass. Profiles of cadmium generally resemble those of phosphate (especially enriched in upwelling regions), rather than silicate, confirming shallow cycling in association with labile nutrients.

Inorganic nutrient indicators

More detailed information for the reconstruction of upper ocean nutrient concentrations and water mass formation and circulation has been retrieved from trace metal/calcium ratios in the calcitic tests of planktonic organisms such as foraminifera and coccolithophorids. The ratio of Cd:Ca in carbonate plankton tests has been used to reconstruct the cadmium content of the water in which the organisms grew and to detect changes in the position of the nutricline relative to the thermocline and water column stratification. The ratio of Si:Al content of biogenic opal has been similarly used (Martinez et al., 1996). Cd resembles phosphate in terms of its behavior in seawater (Figure G5). Therefore, measurement of Cd/Ca ratios in the tests of shallow water column foraminiferal species has been employed as a paleonutrient (PO_4^{3-}) proxy in thermocline waters (Boyle, 1988).

The response of benthic foraminiferal cadmium to deep-water Cd concentrations has also been established (Boyle, 1992). Benthic shell Cd/Ca and Ba/Ca have been used to interpret changes in deep-water circulation since the long residence time of Cd limits the impact of changes in mean ocean Cd on glacial/inter-glacial timescales (<5%, Rosenthal et al., 1995), relative to the short residence time of Ba (~10 kyr). Coupled Cd/Ca and Ba/Ca records have proven useful because Cd/Ca is a labile nutrient tracer and Ba/Ca is a refractory nutrient tracer,

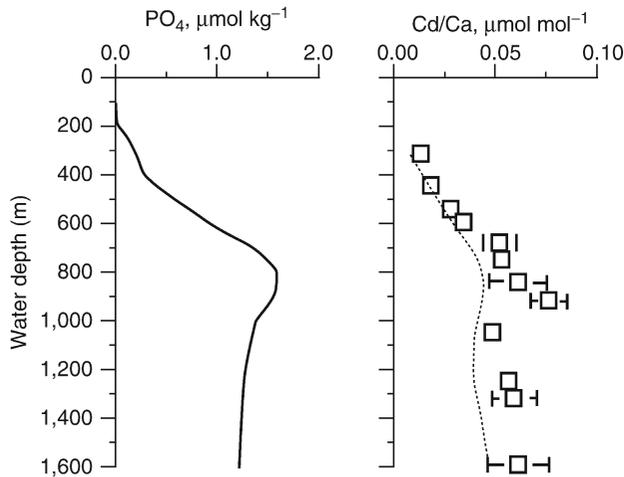

Figure G5 Dissolved PO_4^{3-} water-column profile from the sub-tropical western North Atlantic compared with Cd/Ca concentrations in calcitic foraminifera at similar depths (reprinted from *Geochimica et Cosmochimica Acta*, 61, Rosenthal Y., Boyle E.A., and N. Slowey, Temperature control on the incorporation of magnesium, strontium, fluorine, and cadmium into benthic foraminiferal shells from Little Bahama Bank: Prospects for thermocline paleoceanography, pp. 3633–3643, Copyright (1997), with permission from Elsevier).

each involved differently in biogeochemical cycling. However, there is an apparent depth-related change in the partition coefficient of Cd in calcitic foraminifera. The effects of algal symbionts (Mashiotta et al., 1997) and temperature (Rickaby and Elderfield, 1999) may also influence such estimates.

Trace metal ratios in foraminifera are subject to elevation in instances of (sedimentary) secondary overgrowth or carbonate precipitation on shell surfaces, which can trap contaminants between the shell and the overgrowth layer. Such overgrowths form where Mn^{2+} is mobilized (under oxic conditions), and can therefore be detected in shells with relatively elevated Mn/Ca values (Boyle et al., 1995).

Inorganic temperature indicators

Strontium and magnesium occur in seawater in approximately constant proportions to calcium, and all three elements have long oceanic residence times. Based on this constant source ratio, variations in Sr/Ca and Mg/Ca in foraminifera shells are due to the influence of environmental conditions that control their incorporation or preservation during the process of calcification. Experimental evidence indicates that temperature exerts the dominant control on shell Mg/Ca. Cultured planktonic foraminifera *Globigerina bulloides* and *Orbulina universa* exhibit an increase in shell Mg/Ca of 8–10‰/°C (Nürnberg et al., 1996; Lea et al., 1999). This temperature regulation of co-precipitation of shell Mg probably involves both a thermodynamic response of the inorganic distribution coefficient, and a temperature effect on physiological processes regulating cellular Mg uptake. Secondary influences are attributable to seawater pH and salinity. A smaller but similar kinetic influence of calcification has been recorded in Sr/Ca of coccoliths. However, global foraminiferal Sr/Ca data exhibit a linear decrease with increasing water depth, suggesting that the Sr partition coefficient is most likely a pressure related phenomenon (Rosenthal et al., 1997). Interpretations based on Sr/Ca are also complicated by the much

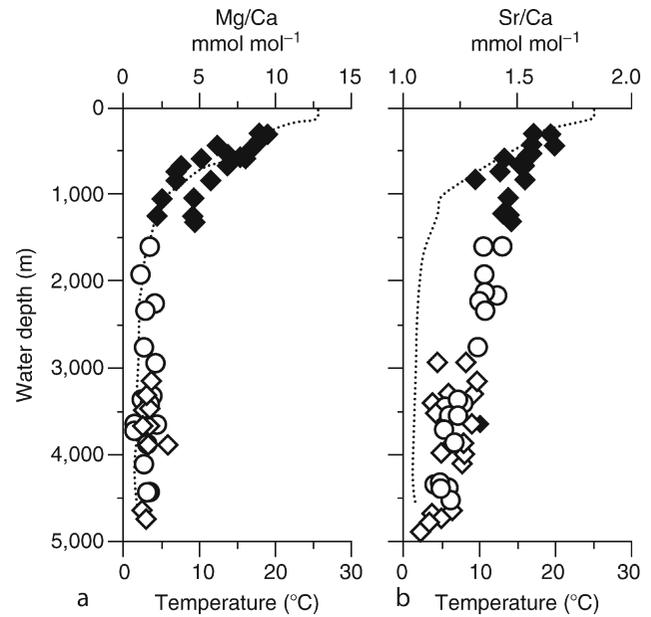

Figure G6 Ocean-wide *Cibicidoides* (a) Mg/Ca, and (b) Sr/Ca data from Little Bahama Bank (\square), Sierra Leone Rise and Ceara Rise (\square), and Ontong Java Plateau (\circ) (reprinted from *Geochimica et Cosmochimica Acta*, 61, Rosenthal Y., Boyle E.A., and N. Slowey, Temperature control on the incorporation of magnesium, strontium, fluorine, and cadmium into benthic foraminiferal shells from Little Bahama Bank: Prospects for thermocline paleoceanography, pp. 3633–3643, Copyright (1997), with permission from Elsevier).

smaller range of Sr/Ca values than Mg values in shells (Figure G6).

Records of Mg/Ca ratios in benthic foraminifera also have been interpreted as an independent proxy for reconstructing the history of Quaternary bottom water temperatures (e.g., Martin et al., 2002). Mg-paleothermometry offers an advantage over other proxies of sea-surface temperatures (SST) because Mg/Ca is measured on the same phase as $\delta^{18}\text{O}$ (a function of both the oxygen isotopic composition of sea water and temperature of calcification) and therefore should record the same calcification temperature. Consequently, paired measurements of $^{18}\text{O}/^{16}\text{O}$ and Mg/Ca can permit an accurate reconstruction of $\delta^{18}\text{O}_{\text{water}}$ and, by inference, paleosalinity. Paired measurements on the same sample may also resolve leads and lags between changes in SST and sea level (Lea et al., 2000, 2002; Figure G7). Unfortunately, there remain some uncertainties about Mg enrichment in species that have undergone gametogenesis, suggesting a significant alteration of Mg/Ca during gametogenic calcite precipitation. This effect has the potential to confound Mg paleothermometry in sedimentary shells containing a varying mixture of gametogenic and ontogenetic calcite. However, recent studies indicate a strong covariance between shell Mg/Ca and ambient temperatures and suggest that, with careful calibration (of single species), it may be a reliable proxy for seawater paleotemperature reconstruction.

Element/Ca ratio analyses of coral skeletal material have also been used to reconstruct SSTs of the tropical oceans. Scleractinian corals secrete skeletons composed of aragonite (CaCO_3), which incorporates both Sr and Ca into its structure. Similar to foraminifera, the incorporation ratio of Sr/Ca is determined by both the Sr/Ca of ocean water and the Sr/Ca distribution coefficient between aragonite and seawater. The former has remained

essentially constant over 10^5 yr timescales because of its long elemental residence times, while the latter is determined principally by the temperature of seawater in which the coral grew (Beck et al., 1992). Not surprisingly, measurements of skeletal Sr/Ca on samples of coral typically show a very strong coherence with SST over seasonal and interannual timescales (e.g., Linsley et al.,

2000; Figure G8). Such SST proxy variations have also been used to reconstruct El Niño Southern Oscillation (ENSO) changes (e.g., Tudhope et al., 2001). By making paired measurements of $\delta^{18}\text{O}$, derived tropical sea-surface salinity (SSS) reconstructions agree with SSS observations at the interannual timescale (Quinn and Sampson, 2002). There also appears to be a relationship between

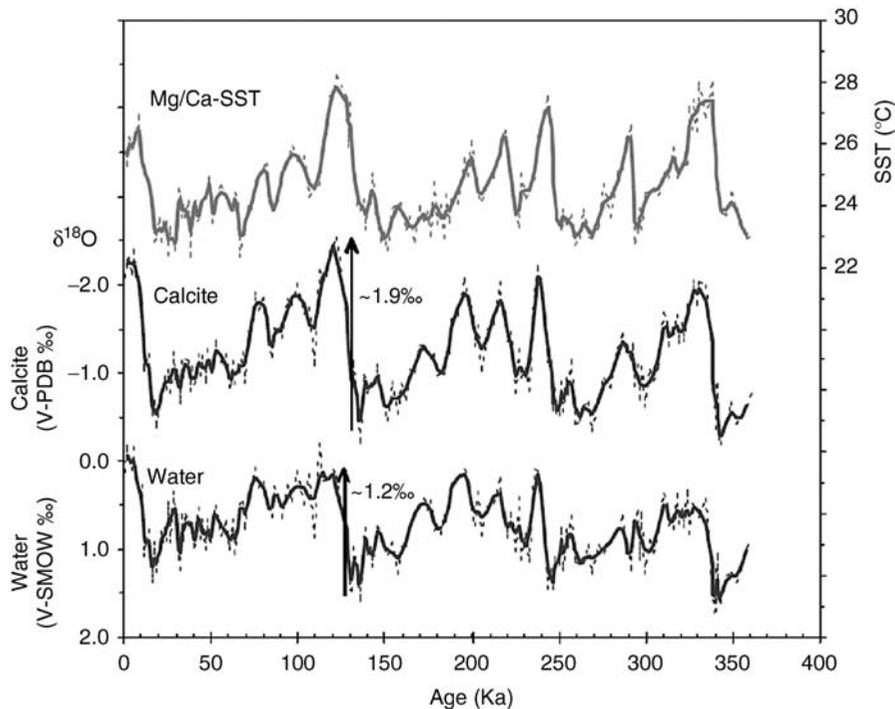

Figure G7 Sea surface temperature (SST) (based on Mg/Ca), $\delta^{18}\text{O}_{\text{calcite}}$ (V-PDB scale), and $\delta^{18}\text{O}_{\text{water}}$ (V-SMOW scale) records from Cocos Ridge core TR163-19, using *G. ruber*-white variety (Lea et al., 2000). The $\delta^{18}\text{O}_{\text{water}}$ record is calculated from the SST and $\delta^{18}\text{O}_{\text{calcite}}$ values. Dashed lines are the measured and calculated data. Heavy lines indicate filtered data (reprinted from Quaternary Science Reviews, 21, Lea D.W., Martin P.A., Pak D.K., and H.J. Spero, Reconstructing a 350 ky history of sea level using planktonic Mg/Ca and oxygen isotope records from a Cocos Ridge core, pp. 283–293, Copyright (2002), with permission from Elsevier).

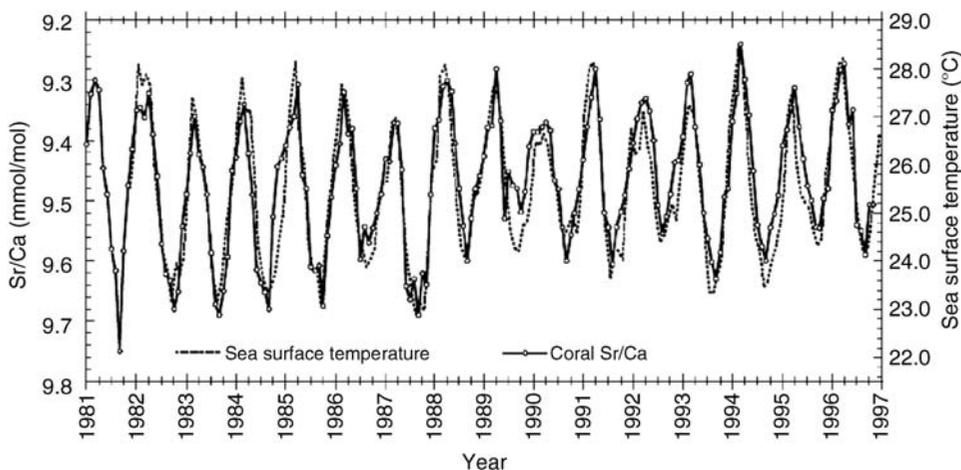

Figure G8 Comparison of instrumental monthly SST for Rarotonga and near-monthly Rarotonga coral Sr/Ca, spanning the interval from 1981 to 1997 (reprinted with permissions from Linsley B.K., G.M. Wellington, and D.P. Schrag, 2000, Decadal sea surface temperature variability in the sub-tropical South Pacific from 1726 to 1997 A.D., Science, 290, pp. 1145–1148, Copyright (2000) AAAS. Permission from AAAS is required for all other uses).

SST and Mg/Ca (Mitsuguchi et al., 1996), and also SST and U/Ca (Min et al., 1995), although such correlations are rarely constant within an individual coral or different corals from the same location and have not received widespread utility in paleoenvironmental reconstruction. Similar measurements have also been made on bivalve shells and fish otoliths. All may be subject to *vital effects* (less predictable physiological variations associated with the life cycle of an organism) and micro-environmental (habitat) variations.

Measurement techniques

While early work on temperature reconstruction from scleractinian coral Sr/Ca ratios had a precision of just $\pm 3^\circ\text{C}$, close to the seasonal SST range of their tropical habitat, the use of thermal ionization mass spectrometry (TIMS) and subsequently (sector field) inductively coupled plasma atomic emission spectrophotometry (ICP-ES) has led to an order of magnitude improvement in precision. Similarly, advances in combining laser ablation technology with inductively coupled plasma-mass spectrometry (ICP-MS) offer the opportunity to measure multiple elemental ratios simultaneously and rapidly on individual foraminifera or calcitic coccolith platelets.

Molecular source indicators

Organisms can regulate the production of constituent lipids, dependent on variable prevailing environmental conditions such as temperature, light, salinity and nutrient availability. The preservation of such compounds in the molecular sedimentary record provides a sink for potentially reconstructing environmental and climatic variations. Therefore, the molecular composition of sedimentary organic matter can reveal detailed information about its production, transport and preservation. Research since the 1970s has sought to identify and characterize a complex suite of sedimentary organic compounds diagnostic of their biological origins, and to relate these compounds to likely sources of OM (e.g., Brassell et al., 1986; Repeta et al., 1992). *Biological marker compounds*, or simply *biomarkers*, are extractable sedimentary lipids with relatively specific biological origins that can provide equally specific organic matter source information (Eglinton and Calvin, 1967). They are typically less sensitive to degradation than the average for bulk organic matter, and may follow an established pattern of alteration during diagenesis, resulting in predictable lipid end-products (“geolipids”). Several hundred biomarkers have been identified in marine sediments, of which only those most commonly investigated in sedimentary records with potential to reconstruct paleoclimate are discussed here; the long-chain C_{37} alkenones, *n*-alkanes, *n*-alkanols, *n*-alkanoic acids, sterols and pigments.

Several factors are prerequisites for the utility of any specific biomarker. The survival of the biomarker signal during sedimentation is crucial to its use. Unfortunately, some of the most diagnostic biomarkers, such as carotenoids, are frequently the most labile. Alternatively, a biomarker may be ubiquitous or too widespread in the sedimentary record, such as long chain *n*-alkanes, to provide detailed diagnostic information about a specific organism, but may still be informative about a particular environment. Thus, it is important for the utility of a biomarker that it should originate from a specific organism or type of organism, from a restricted environment, with modern analogous organisms. It is preferable that a biomarker occurs widely, thus providing information about a variety of sedimentary regimes, and over an extended period of geological time. Finally, it is also

preferable that the biomarker be generated and buried during a short time period, preserving a time-dependent signal useful in high-resolution environmental reconstructions.

Variable lipid contributions from vascular land plants or algae can be distinguished according to consistent differences in molecular chain-length. For example, there is significant variation in the distribution of *n*-alkanes between organisms: aquatic algae are dominated by the presence of lower (shorter chain) *n*-alkanes, such as C_{15} and C_{17} (e.g., Blumer et al., 1971; Simoneit, 1977; Cranwell et al., 1987), whereas the leaf waxes of higher plants are typically dominated by longer chain C_{27} , C_{29} and C_{31} *n*-alkanes in the sedimentary record (e.g., Eglinton and Hamilton, 1967; Rieley et al., 1991). The distributions of long-chain *n*-alkanols and *n*-alkanoic acids can be similarly related to long-term variations in organic matter supply. The waxy coatings of land-plant leaves, flowers and pollen contain C_{24} , C_{26} and C_{28} long-chain *n*-alkanoic acids, whereas C_{12} , C_{14} and C_{16} *n*-acids are dominant in algae. A ratio of these source indicators has been used to identify changes in the terrigenous versus aquatic organic matter contribution (e.g., Bourbonniere and Meyers, 1996). Those properties of vascular plants that protect them against environmental change, such as desiccation, similarly favor the survival of longer chain *n*-alkanes during microbial degradation, eolian transportation over long distances (e.g., Gagosian and Peltzer, 1986) and sinking in aquatic environments. Conversely, lake and marine sediment trap studies of settling particles indicate that the contribution of short-chain biomarkers from algal material is selectively depleted during sinking, presumably because such material is fresher and more labile (Meyers and Eadie, 1993). Combined with palynological information, the lipid data can provide important paleoclimatic evidence regarding wind strength and direction and changing environmental conditions in source areas such as the Chinese Loess Plateau or Sahara. Studies have shown a correspondence between the flux of higher plant *n*-alkanes and *n*-alkanols in sediments and climatic severity, especially during cold glacial intervals (e.g., Poynter et al., 1989; Pelejero et al., 1999; Figure G9).

Sterol biomarkers

A number of sterols (tetracyclic alcohols) have been exploited as paleoenvironmental proxies, differentiated by the presence/absence of double bonds, positions of methyl groups and length of the C_{17} branched sidechain (Volkman, 1986; de Leeuw and Baas, 1986). Individual sterols have been assigned specific organisms of origin, such as dinosterol (dinoflagellates), brassicasterol (diatoms) and cholesterol (Figure G10a). In addition, algal and vascular plant contributions have been differentiated by the presence or absence of particular sterols, for example on the basis that leaf waxes contain C_{28} and C_{29} , but not C_{27} sterols (Rieley et al., 1991; Figure G10b). However, sedimentary sterols are practically ubiquitous, and many sources in marine and terrestrial environments remain uncharacterized (Volkman, 1986). The distribution of sterol biomarkers appears most informative when there are successive variations in abundance and precursor/product relationship within a single sedimentary sequence (e.g., Higginson and Altabet, 2004).

Alkenones

The most widely applied biomarkers for paleoceanographic reconstruction are temperature-sensitive lipids comprising the series of C_{37} – C_{39} di-, tri- and tetra-unsaturated methyl and

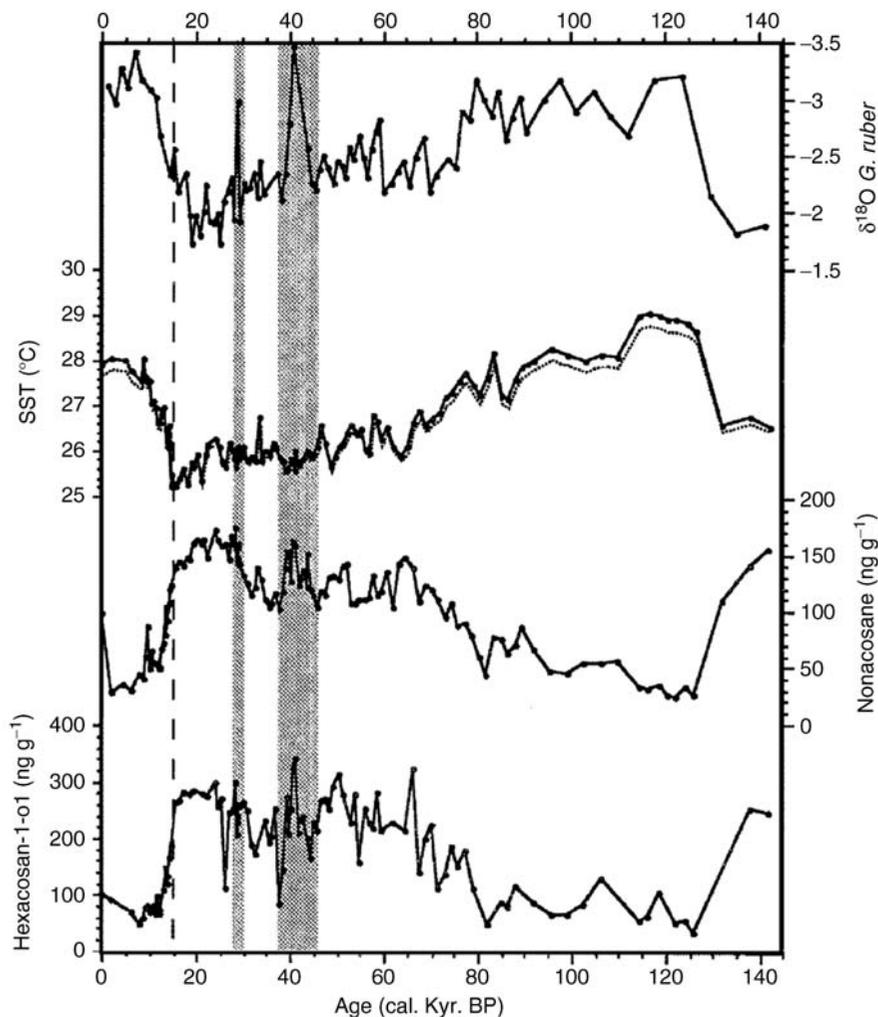

Figure G9 $\delta^{18}\text{O}$ isotopic composition of *G. ruber*, U_{37}^K , sea surface temperature (SST), *n*-nonacosane, and *n*-hexacosan-1-ol abundances in a core from the South China Sea covering the last 140 kyr (after Pelejero et al., 1999; reprinted from Marine Geology, 156, Pelejero C., Grimalt J.O., Sarnthein M., Wang L., and J.-A. Flores, Molecular biomarker record of sea surface temperature and climatic change in the South China Sea during the last 140,000 years, pp. 109–121, Copyright (1999), with permission from Elsevier).

ethyl ketones (“alkenones”; Figure G11a,b). First identified in sediments from Walvis Ridge off southwest Africa during DSDP Leg 40 (Boon et al., 1978), they are now known to occur in marine sediments from all oceans (e.g., Brassell, 1980; Marlowe et al., 1984). Their detection in sediments of Cretaceous age confirmed their production over an extended period of geological time (Farrimond et al., 1986). The compounds were initially traced to the abundant marine unicellular coccolithophorid, *Emiliania huxleyi* (Volkman et al., 1980). However, they have subsequently been identified in other members of the Gephyrocapsaceae algal family (e.g., *Gephyrocapsa oceanica*; Marlowe et al., 1984; Conte et al., 1998). Because alkenones are specific biomarkers of coccolithophorids, quantification of the abundance of the long-chain alkenones in deep-sea sediments is used as a proxy for changing paleoproductivity (e.g., Prahl et al., 1988; Madureira et al., 1997). More significantly, the distribution of marine sedimentary alkenones appears to be related to growth temperature of their source algae, and thus climate (Brassell and Eglinton, 1984). Subsequent

testing of this hypothesis in laboratory cultures grown at different temperatures (e.g., Brassell et al., 1986 and references therein; Conte et al., 1998) has verified the temperature dependence in the biosynthetic production of alkenone unsaturation. This may be related to the ability of such aquatic organisms to change the molecular composition of their lipid bilayer to maintain a constant cell membrane fluidity under a range of thermal conditions, although this remains to be proven.

Values of U_{37}^K , defined as the alkenone unsaturation index, are calculated from the relative concentrations of the $C_{37:2}$, $C_{37:3}$ and $C_{37:4}$ alkenones according to the formula (Brassell et al., 1986; Prahl and Wakeham, 1987):

$$U_{37}^K = [C_{37:2}] - [C_{37:4}] / ([C_{37:2}] + [C_{37:3}] + [C_{37:4}]) \quad (2)$$

These values appear to increase linearly with growth temperature, and may be converted to ambient water temperatures through a calibration equation according to the prevailing oceanic setting (e.g., Prahl and Wakeham, 1987; Prahl et al.,

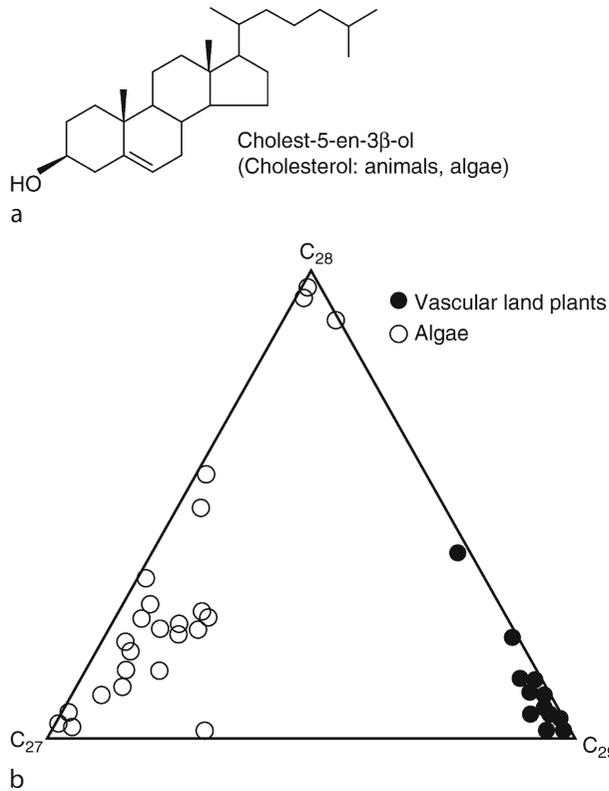

Figure G10 (a) Chemical structure of cholesterol. (b) C₂₇, C₂₈, and C₂₉ sterol source characteristics (compiled from Meyers, 1997; reprinted from *Organic Geochemistry*, 27, Meyers P.A., *Organic geochemical proxies of paleoceanographic, paleolimnologic, and paleoclimatic processes*, pp. 213–250, Copyright (1997), with permission from Elsevier).

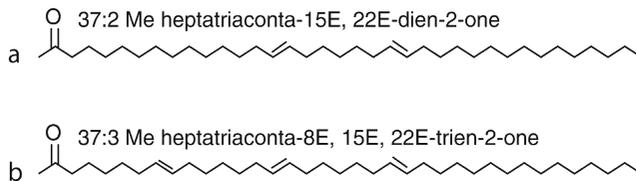

Figure G11 Molecular structures of (a) C_{37:2} alkenone; (b) C_{37:3} alkenone.

1988; Figure G12). Where the C_{37:4} alkenone is absent, such as in warm tropical waters, the U₃₇^{K'} index, which excludes this component, is more commonly used (Müller et al., 1998; cf. Figure G13a–c). The index relates to the general chemical property that the number of carbon-carbon double bonds in related organic molecules varies inversely with their melting points. As a consequence, values of relative abundance of the di- and tri-unsaturated alkenones for bottom sediments in equatorial regions are close to unity. Conversely, the C_{37:3} alkenone dominates in sediments from beneath the much cooler Southern Ocean (Sikes and Volkman, 1993). Since the algae generating the alkenones synthesize their lipid constituents within the photic zone, their rapid response to changes in water temperatures produces relative abundances in bottom sediments that

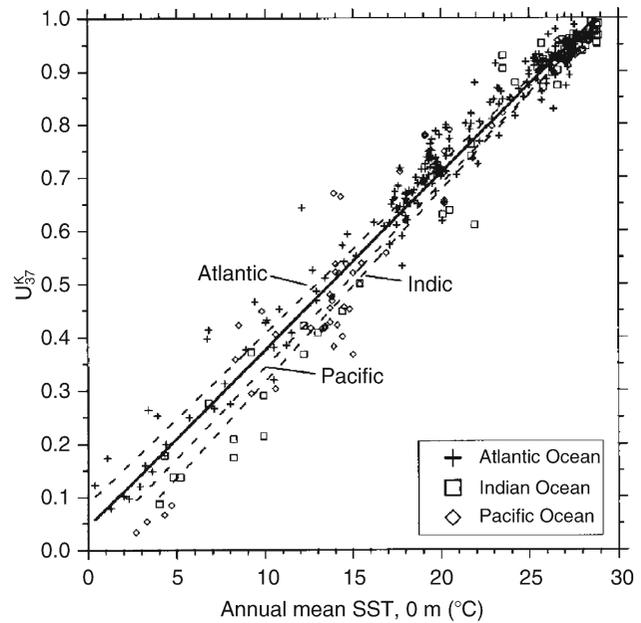

Figure G12 Relationships between U₃₇^{K'} index and annual mean SST (0 m) for surface sediments from the global ocean, 60° S–60° N. The global core-top calibration (U₃₇^{K'} = 0.033SST + 0.044) is equivalent to that obtained from cultures of *E. huxleyi* by Prah and Wakeham (1987) (reprinted from *Geochimica et Cosmochimica Acta*, 62, Müller P.J., Kirst G., Ruhland G., Von Storch I., and A. Rosell-Melé, Calibration of the alkenone paleotemperature index U₃₇^{K'} based on core-tops from the eastern South Atlantic and the global ocean (60° N–60° S), pp. 1757–1772, Copyright (1998) with permission from Elsevier).

approximate near-surface temperatures at the time of maximum biosynthesis during spring blooming (e.g., Herbert et al., 1998). The algal source of alkenones discovered in lacustrine sediments has not been similarly resolved, thereby precluding any specific paleoenvironmental reconstruction from such records.

Reconstruction of sea surface temperature is informative about changing ocean circulation, upwelling intensity (wind strength) and near-surface stratification. The alkenone method conveniently avoids biases inherent to temperature calibrations based upon variable biological groups since production has been shown to be specific to haptophytes (Marlowe et al., 1984), and the production ratio/temperature relationships of the two most common individuals (*Emiliania huxleyi* and *Gephyrocapsa oceanica*) are statistically inseparable (Conte et al., 1998). Although alkenones experience degradation, especially under oxic conditions (Prah et al., 1989), this seems to affect all alkenones roughly comparably, and has little significant effect on U₃₇^{K'} values (Marlowe et al., 1984; Rontani et al., 1997; Hoefs et al., 1998). Site-specific biases in temperature reconstruction have been associated with alkenone incorporation, differential preservation of the chemical species, and region-specific inconsistencies of growth seasonality. Furthermore, alkenones can be produced at various depths (and temperatures) by populations of a single species (Conte et al., 1998) and there may be temperature-independent differences in alkenone unsaturation rates due to regional nutrient variations affecting coccolithophorid growth depth. Nevertheless, in areas and times in which *E. huxleyi* has been dominant (since first occurrence at 268 ka), such as in the North Atlantic, paleotemperature and paleoclimatic reconstructions have

proven valuable (e.g., Weaver et al., 1999) since they are otherwise independent of past changes in sea water salinity and ice volume.

Pigments

Changes in past higher plant and algal populations can be recorded in pigment compositions preserved in sediments since such molecules are essential for photosynthesis. Some organic compounds exhibit specificity to certain types of plants and

have therefore been used as paleoenvironmental biomarkers. The role of pigments is to absorb (light) energy at certain wavelengths, converting it into chemical energy. They are found on the chloroplast membranes and are physically arranged to maximize light absorption. Since each pigment may only be active within a narrow wavelength range, several kinds of pigments are often found together. Photosynthetic pigments can be grouped into three classes: chlorophyll, carotenoid and xanthophyll. Each contains a chemical group capable of selective light absorption (resulting in characteristic coloration) known as a chromophore, which typically involves conjugated C=C double bonds (each separated from the other by a single bond). Combined with oxygen-containing functional groups that are common to many, these sites render pigments susceptible to diagenetic alteration to more stable sedimentary end-products.

Chlorophylls are the principal photosynthetic pigments common to all plants. They contain a central tetrapyrrole ring, and differ according to the nature of the attached alkyl sidechain. The most common, chlorophyll *a*, has an ester-linked diterpenoid alcohol sidechain, phytol. Diagenesis affects the amount and types of pigments preserved in sediments. Specifically, chlorophyll is rare in marine sediments, especially where there is a deep water column and similar pigments are degraded if they are not rapidly incorporated into sediments. Even after incorporation, pigments continue to undergo diagenesis. Sedimentary studies have led to the establishment of predictable conversion routes for chlorophyll pigments, including de-metallization to form pheophytins, ester hydrolysis to form pheophorbides and transesterification to form the more resistant steryl chlorin esters (Keely and Brereton, 1986). These products have been given the collective name "chlorins" (Higginson, 2000).

Chlorophylls absorb solar energy most efficiently at longer wavelengths of the visible spectrum, wavelengths that are also readily absorbed by water. Therefore, aquatic plants have evolved *carotenoid* accessory pigments to expand energy capture to a wider range of wavelengths useful for photosynthesis. Carotenoid pigments such as β -carotene (Figure G14a) are composed of two six-carbon rings separated by a conjugated carbon chain. The *xanthophylls* such as fucoxanthin (Figure G14b) are also classified as secondary pigments, since they do not transfer energy directly from sunlight to the photosynthetic pathway, but involve chlorophyll as an intermediary. These secondary pigments are present in different amounts in different plants/algae and therefore act as discrete source identifiers for sedimentary organic matter.

Combined sedimentary lipid/pigment studies can yield important information regarding the history of regional phytoplankton community structure. For example, pigment and lipid analyses of a core of marine sediments recovered from the northeast Arabian Sea revealed that four biomarker compounds, dinosterol, alkenones, brassicasterol and chlorins, attributed to dinoflagellate, prymnesiophyte, diatom, and chlorophyll production, respectively, exhibited concordant concentration maxima coincidental with total organic carbon peaks over the past 200 kyr (Schubert et al., 1998; Figure G15). The similarity of the individual biomarker distributions and good correlations with total chlorins indicated a stable phytoplankton community structure driven by nutrient upwelling. A lack of correlation with records of long-chain *n*-alkanes and *n*-alcohols illustrates the independence of the terrestrial organic contribution.

Techniques

The analysis of organic geochemical proxies is heavily reliant upon liquid and gas chromatographic techniques. The term chromatography arises from the Greek words for color and writing and accordingly involves the separation of components of a mixture (such as colored pigments) by the differential distribution of those components between a mobile and a stationary phase. Mobile phases can be gas, liquid or supercritical fluids; stationary phases can be solids or liquids adsorbed to a solid. Separation depends on the differential affinities of solutes for a mobile and stationary phase.

Gas chromatography (GC) developed rapidly in the 1960s after the epic pioneering work of James and Martin (1952). For the modern analysis of lipids, sufficient quantities of lipids to quantify terrestrial or aquatic inputs, or to determine $U_{37}^{K'}$ values, are typically extracted from <1 g of freeze-dried, well-homogenized bulk
